The most common (and insufficient because it does not describe the variability) descriptor of data is the average or mean. However, average assumes that the data are normally distributed. Some common data types encountered in mining time studies are rarely normal. Cycle times are often Poisson (distribution), while others, such as yes/no-type (or on/off) data, are typically binomial. Thus, before data are described, their distribution should be confirmed.

After the distribution is confirmed, data should be described in a way that is consistent with its distribution. It should also describe or indicate the spread or variability. Ideally, the description would be intuitive. Thus, while the phrase "time to load is lognormally distributed with a mean and standard deviation of 0.25 and 0.6" is an accurate and probably sufficient description of the time to load, a more intuitive description would be that the "expected value" of time to load is 1.82 minutes, though the expected value alone is insufficient, as it does not indicate the variability. Thus, the expected value, which is always part of a good description, should be accompanied by the variance and, preferably, the deciles or quartiles for an indication of variability. See Table 9.10-1 for more information.

An important reason for describing the data is to obtain a feel for the process. An additional tool for obtaining a good feel for data is in the form of basic plots (NIST/SEMATECH 2006). Indeed, plotting is considered the first step in exploratory data analysis.

Analyzing Non-Normal Data

Some analysis tools, such as Six Sigma (described later), require normality assumptions. Often, non-normal data can be adapted for such tools, as follows (Padnis n.d.):

1. **Converting data to normal distribution:** There are many available transformations for converting non-normal data to normal data. Examples include Box–Cox and Logit (for on/off data) transforms.

   The Box–Cox transformation is as follows (NIST/SEMATECH 2006):

$$x_i(\lambda) = \frac{x_i^{\lambda}-1}{\lambda}$$

   where

   x_i = i^{th} sample in the data set containing the "n" samples; $\mathbf{X} = (x_1, x_2, \ldots x_n)$
   λ = transformation parameter (usually between –2 and 2)
   $x_i(\lambda)$ = transformed i^{th} value

   λ is selected by trial and error and is the one that maximizes the following function:

$$f(x,\lambda) = \frac{-n}{2}\ln\left[\sum_{i=1}^{n}\frac{(x_i(\lambda)-\bar{x}(\lambda))^2}{n}\right] + (\lambda-1)\sum_{i=1}^{n}\ln(x_i)$$

   where $\bar{x}(\lambda) = \frac{1}{n}\sum_{i=1}^{n} x_i(\lambda)$

   After the data are transformed, one could determine confidence intervals as required by Six Sigma or other processes. These intervals or limits can then be back-transformed to raw data, though back-transformation can be complicated, depending on the transformation, because confidence intervals that are directly back-

Table 9.10-2 Box–Cox transformation

Raw Data, x_i	Transform, $\lambda = -0.1$ $x_i(\lambda)$	$\ln(x_i(\lambda))$	$(x_i(\lambda) - \bar{x}(\lambda))^2$	
1	0.0000	0.0000	2.6466	
13	2.2624	2.5649	0.4040	
6	1.6404	1.7918	0.0002	
3	1.0404	1.0986	0.3439	
93	3.6445	4.5326	4.0709	$f(x,\lambda) = -22.5$
2	0.6697	0.6931	0.9162	
1	0.0000	0.0000	2.6466	
19	2.5505	2.9444	0.8532	
45	3.1659	3.8067	2.3688	
4	1.2945	1.3863	0.1105	
	$\bar{x}(\lambda) = 1.6268$			

transformed need not be reflective of the original data. This is certainly true of lognormal transformation, where the confidence interval is computed differently to account for bias arising from back-transformation. Olsson (2005) suggested that for log-transformed data, the confidence intervals should be computed as follows:

$$\text{confidence interval} = \mu + \frac{s^2}{2} \pm t\sqrt{\frac{s^2}{n} + \frac{s^4}{2\times(n-1)}}$$

where

μ = mean of the transformed data
s^2 = variance
n = number of data points
t = appropriate t-statistic (such as 2.23 for 10 samples and 95% confidence)

The obtained interval can then be directly back-transformed to the original form. Because the Box–Cox transform has no bias issues with back-transformation, confidence intervals can be computed the traditional way ($\mu + t \times s$).

2. **Using subgroup averages:** Subgroups or clusters of non-normal data can be normal. Thus, analysis can be done on these groups, though the results of the analysis must be understood in the context of groups. For example, though truck cycle time may not be normally distributed, the average cycle time per hour may be normally distributed.
3. **Subdividing the data set:** In this strategy, data are subdivided into large groups based on some logical reasoning. Often, such subdivision yields normal data. For example, again assume that truck cycle time is not normal. Also assume that for some internal reason in that mine, truck dispatch system works differently in the day shift than in the evening shift. Treating the day shift data and evening shift data as two different data sets may result in two almost-normal subsets.

Example 6. The following data were collected: 1, 13, 6, 3, 93, 2, 1, 19, 45, and 4. The process requires that 97.5% of the samples be less than 80. Based on the samples, does the process meet the specifications?

Solution. The 97.5% (single tail) requirement defines a distance of two standard deviations from the mean.

Wrong analysis. The following is not correct:

1. Assume normality automatically.
2. Therefore, the sample mean = 18.7, and the standard deviation = 29.4.
3. A statistical analysis says that 97.5% of the data are less than 77.5 ($18.7 + 2 \times 29.4 = 77.5$).
4. It is concluded that the process meets specifications.

Correct analysis. Whenever the standard deviation is close to or greater than the mean, one should be concerned with normality assumptions. The correct analysis is as follows:

1. First, determine the distribution or test for normality. If the distribution is not normal or the data fails a normality test, then transform the data. In this case, the samples (that are truly lognormal) fail the Anderson–Darling test (NIST/SEMATECH 2006) for normality. The Anderson–Darling test is not presented here.
2. Next, convert the data to a normal distribution using Box–Cox transformation. Similarly, compute $f(x,\lambda)$ for λ between –2 and 2, in increments of 0.1. However, in this example, only $f(x,\lambda)$ is computed for $\lambda = -0.2, -0.5, 0.1, 0.2$, and 0.5. The highest $f(x,\lambda)$ occurs at –0.1. Thus, the λ chosen to transform the data is –0.1. The Anderson–Darling test for normality confirms that the transformed data (second column in Table 9.10-2) is indeed normal.
3. Next, conduct confidence interval analysis on transformed data. The transformed data have a mean and standard deviation of 1.62 and 1.26. Therefore, 97.5% of the data falls below 4.14 ($1.62 + 2 \times 1.26 = 4.14$).
4. Finally, back-transform the upper limit (4.14); that is, solve the following equation:

$$4.14 = (x^{-0.1} - 1)/-0.1$$

Therefore, $x = 209.4$.

The Box–Cox transformation can be back-transformed directly, unlike the lognormal transformation.

The process fails. The limit (80), when transformed is 3.54, which is 1.52 standard deviations away from the mean (i.e., $(3.54 - 1.62)/1.26 = 1.52$), which implies 6.6% of the samples are greater than 80.

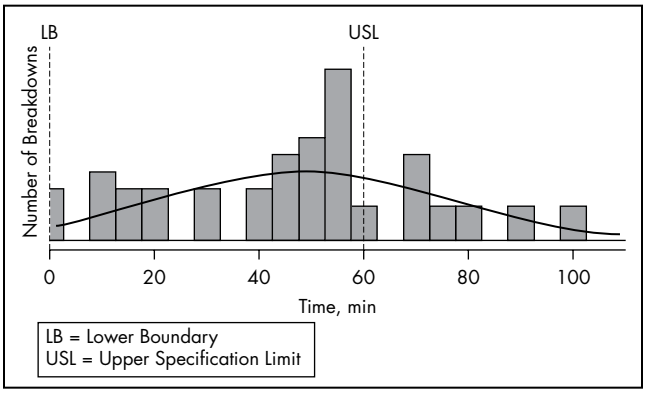

Figure 9.10-2 Histogram of CM breakdowns before implementation of a maintenance program

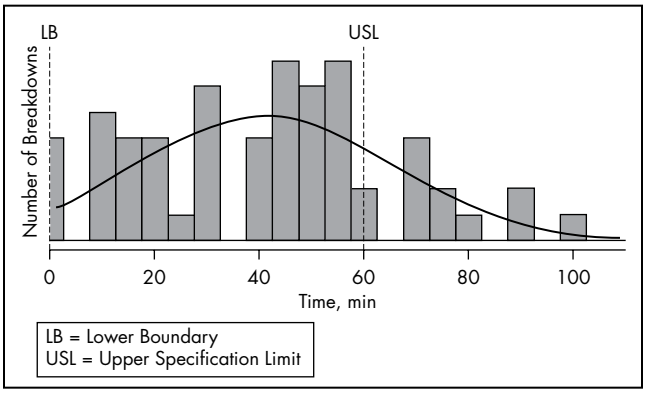

Figure 9.10-3 Histogram of CM breakdowns after implementation of a maintenance program

Six Sigma

Six Sigma is a discipline utilizing strict measuring and data analysis procedures to quantify the quality performance of a process and to then measure and verify changes made in that process. The goal is to achieve a nearly defect-free process in which the rate of defects is at or below 3.4 per million. Using a manufacturing analogy, if the process results follow a normal bell curve (and many do), then 3.4 defects per million or 99.9997% efficiency falls within plus or minus 6 standard deviations (sigmas) of the bell-curve distribution mean. The Six Sigma methodology strives to make the process so well controlled, and hence the distribution curve so tight, that plus or minus 6 standard deviations of the curve fit within the specifications for the product.

Except for mineral processing, applying Six Sigma to mining may not seem straightforward, but with a little adjustment, such as redefining "defects" and "specification limits," it can be quite applicable. Suppose a major change in the preventive maintenance program at an underground coal mine is planned. To see if it has a positive effect on major downtime elements associated with a continuous miner (CM), one can simply define a defect as any downtime in excess of, for example, 1 hour. Assume that the CM downtime data over a time period of 56 shifts is represented by Figure 9.10-2.

In a case such as this, there is no lower specification limit per se. The lower limit is, of course, zero minutes. But it is not a specification; it is a natural boundary to the data. Hence, it is defined as the lower boundary. One should not automatically assume that the collected samples are normally distributed (i.e., Six Sigma only applies when the data are normally distributed). (The previous section gives instructions for handling non-normal data.)

The analysis of the data shown in Figure 9.10-2 shows that the observed data exceeded the upper boundary 250,000 times out of 1 million (or 25% of the time), while the expected performance of the system (the curve) is about 335,000 times out of 1 million exceeding 60 minutes.

Now assume that the data collected in 60 shifts after the implementation of the new maintenance program are shown in Figure 9.10-3. Did the maintenance program make a difference? Figure 9.10-3 "looks" better with a lot more data appearing that is less than the upper specification limit. The observed and expected performance indicators are both improved, and the average downtime of the data shifted from 48.4 to 41.1 minutes. But did the new preventive maintenance program make a verifiable difference in fact?

This is where the second stage of the Six Sigma discipline becomes useful. One must now verify statistically that the shift in the sample mean represents a real change in the population. This is done through the use of various tools, including the hypothesis tests presented earlier. By using these statistical tools, one can determine (within given confidence intervals) whether or not there has been a real shift in the population that the sample represents (which is the goal) or whether the shift in the sample statistics could be due to the natural variation in the data.

After an engineer becomes reasonably familiar with the Six Sigma methodology and the statistical tools (some of which are discussed here), a whole host of applications in any mining scenario become apparent. Six Sigma provides the mining engineer with the knowledge and tools to help him or her virtually eliminate the old style "seat of the pants" decision making. Given some data, or simply the time to gather the data, the mining engineer can give upper management unbiased, objective, and verifiable input into most any decision process.

OPTIMIZATION

The techniques that can provide an optimum solution to the system include linear programming, mixed integer programming, nonlinear programming, and network flow modeling. These are widely published techniques and are covered in detail in standard textbooks (e.g., Fletcher 2000). Additionally, space restrictions do not allow them to be covered here in any detail. Therefore, they will only be introduced here, except for cutoff grade optimization that has a broader impact. Those desiring advanced developments in the optimization field are referred to Optimization Online (2010), an excellent on-line source.

Standard Optimization Techniques: A Brief Introduction

Many constraints in a mine system can be expressed through basic linear equations, with the overall problem being that of balancing these competing constraints to maximize (or minimize) a linear objective function. Mathematically, this can be stated as follows:

$$f(v) = c^T \boldsymbol{v}$$

Table 9.10-3 Grade–tonnage distribution of a hypothetical gold deposit

Grade Category, oz/st	Short tons (in thousands)
0–0.02	70,000
0.02–0.025	7,257
0.025–0.030	6,319
0.030–0.035	5,591
0.035–0.040	4,598
0.040–0.045	4,277
0.045–0.050	3,465
0.050–0.055	2,428
0.055–0.060	2,307
0.060–0.065	1,747
0.065–0.070	1,640
0.070–0.075	1,485
0.075–0.080	1,227
0.080–0.100	3,598
0.100–0.358	9,576

where

$\boldsymbol{v}$ = vector of variables, whose value needs to be determined
c = set of known constants

The constraints on the variables are described as follows:

$$\boldsymbol{Pv} \leq \boldsymbol{q}$$

where

$\boldsymbol{P}$ = matrix of known constants
$\boldsymbol{q}$ = vector of known constants

Linear programming is a set of techniques that provide methods of solving for $\boldsymbol{v}$ that maximize $f(v)$ without violating the constraints. Different linear programming techniques impose different restrictions on $\boldsymbol{v}$. The simplex method requires that the elements of $\boldsymbol{v}$ be all nonnegative, while mixed integer programming requires that they also be whole numbers. Nonlinear programming, on the other hand, allows both $f(v)$ and the constraints to be nonlinear, while quadratic programming allows quadratic terms in $f(v)$. Network flow programming/graph theory involves describing and solving network problems as linear programming problems. Network problems are those that intuitively relate to a network structure, such as a system of pipes (constrained by flow direction and pipe capacity), highway traffic, or conveyor systems. However, they have also been related in abstract to problems with no physical flow at all, such as the famous Lerchs–Grossman algorithm for pit-limit determination. In this problem, the restrictions in how mining can advance can be related to flow. For example, one cannot mine a block of ore unless the blocks above it are mined. The interested reader is directed to Hustrulid and Kuchta (2006) for an elaborate presentation of different pit-optimization techniques.

Cutoff Grade and Scheduling Optimization

Heuristic Cutoff Grade Optimization Algorithms

Cutoff grade is traditionally defined as the grade that is normally used to discriminate between ore and waste within a given ore body. This definition can be extended to mean the grade that is used to differentiate various ore types for different metallurgical processing options. Although the definition of cutoff grade is very precise, the choice of a cutoff grade policy to be used during an exploitation of a deposit is not. Use of simply calculated breakeven cutoff grades during the production would, in most instances, lead to suboptimum exploitation of the resource.

Table 9.10-4 Mine design parameters for the case study

Parameter	Symbol	Value
Price	P	600 $/oz
Sales cost	s	5.00 $/oz
Processing cost	c	19.0 $/st ore
Recovery	y	90%
Mining cost	m	1.20 $/st
Fixed costs	f_s	$10.95 million/yr
Mining capacity	M	Unlimited
Milling capacity	c	1.05 million st
Capital costs	CC	$105
Discount rate	d	15%

Exploitation of a deposit in such a way that the maximum net present value (NPV) is realized at the end of the mine life has been an accepted objective of mining companies. The NPV to be realized from an operation is dependent on interrelated variables such as mining and milling capacities, sequence of extraction, and cutoff grades. These interdependent variables interact in a complex manner in defining the NPV of a project. The sequence of extraction is dependent on the rates of production, the grade distribution of the deposit, and the cutoff grades. Cutoff grades cannot be determined without knowing the extraction sequences and capacities of the mining system. The determination of capacities is directly related to the cutoff grades and extraction sequences.

Mine planning is a process that defines sets of values for each of these variables during life of the project. The biggest challenge during the mine planning is to define the capacities of the mining system that are in perfect harmony with the grade distributions of the deposit through the planned extraction sequence and cutoff grade policy.

For a given set of capacities (the economic costs associated with the capacities within the mining system, the pit extraction sequence, and the prices), there is a unique cutoff grade policy that maximizes the NPV of the project. The determination of these cutoff grades during the life of the mine is the subject of this section.

Traditional Cutoff Grades in Open-Pit Mining

Consider a hypothetical case study where an epithermal gold deposit would be mined by an open pit. Table 9.10-3 gives the grade distribution of the material within the ultimate pit limits of this deposit. Table 9.10-4 gives the assumed capacities and accepted costs to mine this deposit at a 2,720-t/d (3,000-st/d) milling rate.

Traditionally in open-pit mining, a cutoff grade is used to determine if a block of material (free standing, i.e., without any overlying waste) should be mined or not, and another cutoff grade is used to determine whether or not it should be milled or taken to the waste dump.

The first cutoff grade is generally referred to as the ultimate pit cutoff grade, and it is defined as the breakeven grade that equates cost of mining, milling, and refining to the value of the block in terms of recovered metal and the selling price.

ultimate pit cutoff grade

$$= \frac{\text{milling cost} + \text{mining cost}}{(\text{price} - (\text{refining cost} + \text{marketing cost})) \times \text{recovery}}$$

$$= \frac{\$19 + 1.20}{(\$600 - \$5) \times 0.90}$$

The second cutoff grade is referred to as milling cutoff grade and is defined as the breakeven grade that equates cost of milling, refining, and marketing to the value of the block in terms of recovered metal and the selling price.

milling cutoff grade

$$= \frac{\text{milling cost}}{(\text{price} - \text{refining} + \text{marketing cost}) \times \text{recovery}}$$

$$= \frac{\$19}{(\$600 - \$5) \times 0.90} = 0.035 \text{ oz/st}$$

In the calculation of the milling cutoff grade, no mining cost is included because this cutoff is basically applied to those blocks that are already "selected for mining" (by the first cutoff) to get to the higher-grade ore blocks and those blocks that the cost of mining will be incurred regardless of the action to be taken with respect to milling it. Notice that the depreciation costs, the general and administrative (G&A) costs, and the opportunity costs are not included in the cutoff grades given. In the traditional cutoff grades, the basic assumption is that all of these costs, including fixed costs defined as G&A, will be paid by the material whose grade is much higher than the established cutoff grades. The first cutoff grade is used to ensure that no material (unless they are in the way of other high-grade blocks) is taken out of the ground unless all of the direct costs associated with "gaining" the metal can be recovered. This assurance is automatically built into the ultimate pit limit determination algorithms such as Lerchs–Grossmann and the moving cone. The second cutoff grade is used to ensure that any material that provides positive contribution beyond the direct milling, refining, and marketing costs will be milled.

The general characteristics of the traditional cutoff grades

- Are established to satisfy the objective of maximizing the undiscounted profits from a given mining operation,
- Are constant unless the commodity price and the costs change during the life of mine, and
- Do not consider the grade distribution of the deposit.

Heuristic Cutoff Grade Optimization Techniques

Mining the deposit under consideration with a traditional milling cutoff grade of 1.2 g/t (0.035 oz/st) at 95 Mt (1.05 million st) milling capacity results in the exploitation schedule given in Table 9.10-5.

The annual cash flows are given as profits in millions of dollars, and they are determined as follows:

Table 9.10-5 Exploitation schedule for constant cutoff grades

Year	Cutoff Grade, oz/st	Average Grade, oz/st	Q_m*	Q_c†	Q_r‡	Profits, million $/yr
1	0.035	0.102	3.6	1.05	96.3	33.0
2	0.035	0.102	3.6	1.05	96.3	33.0
3	0.035	0.102	3.6	1.05	96.3	33.0
4	0.035	0.102	3.6	1.05	96.3	33.0
5	0.035	0.102	3.6	1.05	96.3	33.0
6	0.035	0.102	3.6	1.05	96.3	33.0
7	0.035	0.102	3.6	1.05	96.3	33.0
8	0.035	0.102	3.6	1.05	96.3	33.0
9	0.035	0.102	3.6	1.05	96.3	33.0
10	0.035	0.102	3.6	1.05	96.3	33.0
11 to 34	0.035	0.102	3.6	1.05	96.3	33.0
35	0.035	0.102	3.4	1.00	91.7	31.4
Total	0.035	0.102	125.8	36.70	3,365.9	1,154.2
NPV = $218.5 million						

*Q_m = amount of total material mined (in millions of short tons) in a given year.
†Q_c = ore tonnage (in millions of short tons) processed by the mill.
‡Q_r = recovered ounces (in thousands) produced in a given year.

$$P_i = (P - s) \times Q_r - Q_c \times c - Q_m \times m$$

where

P_i = annual profits, million $
P = price, $/oz
s = sales cost, $/oz
Q_r = recovered ounces, oz/yr
Q_c = tons processed by mill, million st/yr
c = milling capacity, million st/yr
Q_m = total material mined, million st/yr
m = mining cost, $/st

In the example (Table 9.10-5), a total of 33.3 Mt (36.7 million st) at an average grade of 3.5 g/t (0.102 oz/st) is mined with a stripping ratio of 2.42, and the ore is processed by the mill during the 35 years of mine life. This schedule results in total undiscounted profits of $1,154.2 million and NPV of $218.5 million.

As long as the operator mines and processes the blocks of material with grades greater than or equal to the static cutoff grades without considering deposit characteristics, only the undiscounted profits will be maximized. The maximization of discounted profits versus NPVs are two different things; when the objective is to maximize the NPVs, the maximization of profits without the time value of money amounts to optimization without the capacity constraints of the mining system and thus, when viewed within the framework of constrained NPV optimization, always yields suboptimal NPVs. Realizing the fact that mines that are planned with traditional cutoff grades would not result in maximum NPVs, many approaches have been suggested to modify the traditional cutoff grade policies such that the NPVs from a given operation are improved.

The concept of using cutoff grades higher than breakeven grades during the early years of an operation for a faster recovery of capital investments and using breakeven grades during the later stages of the mine has been practiced in the industry for heuristic NPV optimizations. In this approach,

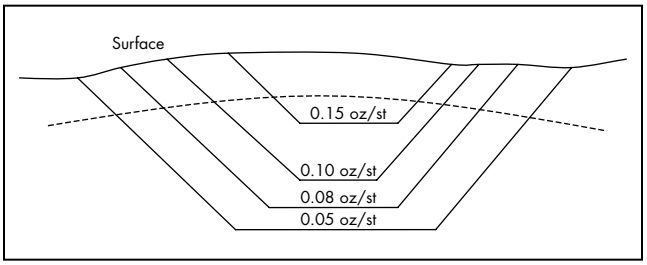

Figure 9.10-4 Idealized cross section of a series of pits for various cutoff grades

the traditional cutoff grade calculation is modified so that they include depreciation, fixed costs, and minimum profit per ton required for a period of time to obtain a much higher cutoff grade during the early years. After the end of the initial period, the minimum profit requirement is removed from the equation to lower the cutoff grades further until the plant is paid off. At that point, the depreciation charges are also dropped where the mine operates with the traditional milling cutoff grades. This concept is demonstrated pictorially in Figure 9.10-4. Analytically, the concept is explained as follows:

- Assume that the $105-million plant capital cost in the case study would be depreciated during the first 10 years by the straight-line method:
  - Depreciation cost per year = $105 million/10 years = $10.5 million/yr
  - Depreciation cost per short ton = $105 million/1.05 st = $10/st of ore
- In addition, assume that a minimum profit of $3.0/st would be imposed to increase the cash flows further during the first 5 years.

Then, the milling cutoff grades, g_{milling}, during the life of mine would be as follows:

Years 1 through 5

$$g_{\text{milling}} = \frac{\text{milling cost + depreciation + minimum prof.}}{(\text{price} - \text{refining} + \text{marketing cost}) \times \text{recovery}}$$

$$g_{\text{milling}} = \frac{\$19 + \$10 + \$3}{(\$600 - \$5) \times 0.9} = 0.060 \text{ oz/st}$$

Years 6 through 10

$$g_{\text{milling}} = \frac{\text{milling cost + depreciation}}{(\text{price} - \text{refining} + \text{marketing cost}) \times \text{recovery}}$$

$$g_{\text{milling}} = \frac{\$19 + \$10}{(\$600 - \$5) \times 0.9} = 0.054 \text{ oz/st}$$

Year 11 through depletion

$$g_{\text{milling}} = \frac{\text{milling cost}}{(\text{price} - \text{refining} + \text{marketing cost}) \times \text{recovery}}$$

$$g_{\text{milling}} = \frac{\$19}{(\$600 - \$5) \times 0.9} = 0.035 \text{ oz/st}$$

The year-by-year tonnage and grade schedule obtained from the modified cutoff grade policy is given in Table 9.10-6. Again, a total 28.44 million st at an average grade of 0.106 oz/st is mined, with an overall stripping ratio of 3.88 and milled during 25 years of mine life. This modified schedule results in total undiscounted profits of $1,112.7 million and an NPV of $355.7 million. The comparison of total undiscounted profits and NPVs in Tables 9.10-3 and 9.10-4 indicate that there was a 3.6% reduction in total undiscounted profits and a 63% increase in the total NPV of the project when the cutoff grade policy was modified from the traditional to the declining approach where cutoff grades were elevated during the initial years.

Table 9.10-6 Yearly tonnage and grade with a declining cutoff grade strategy

Year	Cutoff Grade, oz/st	Average Grade, oz/st	Q_m*	Q_c†	Q_r‡	Profits, million $/yr
1	0.060	0.153	6.9	1.05	144.6	57.8
2	0.060	0.153	6.9	1.05	144.6	57.8
3	0.060	0.153	6.9	1.05	144.6	57.8
4	0.060	0.153	6.9	1.05	144.6	57.8
5	0.060	0.153	6.9	1.05	144.6	57.8
6	0.054	0.141	6.0	1.05	132.8	51.9
7	0.054	0.141	6.0	1.05	132.8	51.9
8	0.054	0.141	6.0	1.05	132.8	51.9
9	0.054	0.141	6.0	1.05	132.8	51.9
10	0.054	0.141	6.0	1.05	132.8	51.9
11 to 27	0.035	0.102	3.6	1.05	96.3	33.0
28	0.035	0.102	0.3	0.09	8.1	2.8
Total	–	–	125.8	28.44	3,032.1	1,112.7
NPV = $355.7 million						

*Q_m = amount of total material mined (in millions of short tons) in a given year.
†Q_c = ore tonnage (in millions of short tons) processed by the mill.
‡Q_r = recovered ounces (in thousands) produced in a given year.

In the previous calculations, the G&A costs were not included in the cutoff grade and profit calculations. The effects of the $10.95 million per year fixed costs on the cutoff grade policy and the resulting total profits and NPVs are computed as follows:

Years 1 through 5

$$g_{\text{milling}} = \frac{\text{milling cost + depreciation + minimum profit + fixed cost}}{(\text{price} - \text{refining} + \text{marketing cost}) \times \text{recovery}}$$

$$g_{\text{milling}} = \frac{\$19 + \$10 + \$3 + \$7.95}{(\$600 - \$5) \times 0.9} = 0.075 \text{ oz/st}$$

Years 6 through 10

$$g_{\text{milling}} = \frac{\text{milling cost + depreciation + fixed cost}}{(\text{price} - \text{refining} + \text{marketing cost}) \times \text{recovery}}$$

$$g_{\text{milling}} = \frac{\$19 + \$10 + \$7.95}{(\$600 - \$5) \times 0.9} = 0.069 \text{ oz/st}$$

Year 11 through to depletion

$$g_{\text{milling}} = \frac{\text{milling cost + fixed cost}}{(\text{price} - \text{refining} + \text{marketing cost}) \times \text{recovery}}$$

$$g_{\text{milling}} = \frac{\$19 + \$7.95}{(\$600 - \$5) \times .9} = 0.050 \text{ oz/st}$$

Table 9.10–7 gives yearly tonnage and grade schedules resulting from the cutoff grade policy that includes fixed costs as part of the cutoff grade and the profit calculation. The policy of declining cutoff grades calculated with depreciation, minimum profit, and the G&A costs further increased the NPV ($357.1 million versus $355.7 million), while overall undiscounted profits were adversely reduced by 20% ($1,112.7 million versus $885.6 million).

Optimizing Cutoff Grades by Lane's Approach

The preceding discussion demonstrated the significant impact of the cutoff grade policy on the NPV of a project. It is generally accepted that the cutoff grade policy that gives higher NPVs is a policy that uses declining cutoff grades throughout the life of the project. The most obvious resulting question is: "How should the cutoff grades for a given mine be determined so that one obtains the highest NPV possible?"

Table 9.10-7 Yearly tonnage and grade schedules with a modified declining cutoff grade strategy (fixed costs included)

Year	Cutoff Grade, oz/st	Average Grade, oz/st	Q_m*	Q_c†	Q_r‡	Profits, million $/yr
1	0.075	0.182	9.2	1.05	171.6	62.8
2	0.075	0.182	9.2	1.05	171.6	62.8
3	0.075	0.182	9.2	1.05	171.6	62.8
4	0.075	0.182	9.2	1.05	171.6	62.8
5	0.075	0.182	9.2	1.05	171.6	62.8
6	0.069	0.169	8.2	1.05	160.0	57.1
7	0.069	0.169	8.2	1.05	160.0	57.1
8	0.069	0.169	8.2	1.05	160.0	57.1
9	0.069	0.169	8.2	1.05	160.0	57.1
10	0.069	0.169	8.2	1.05	160.0	57.1
11 to 17	0.050	0.132	5.4	1.05	124.8	39.5
18	0.050	0.132	1.3	0.26	30.5	9.6
Total	–	–	125.8	18.11	2,562.5	885.6

NPV = $357.1 million

*Q_m = amount of total material mined (in millions of short tons) in a given year.
†Q_c = ore tonnage (in millions of short tons) processed by the mill.
‡Q_r = recovered ounces (in thousands) produced in a given year.

In a paper published in 1964 and in a book published in 1988, K.F. Lane discussed in detail the theoretical background, a general formulation, and a solution algorithm to this problem. In Lane's formulation and theoretical analysis, it was shown that cutoff grade calculations that maximize NPV must include the fixed costs associated with not receiving the future cash flows quicker due to the cutoff grade decision taken now. The cutoff grade equation that maximizes the NPV of the deposit when the system is constrained by the mill capacity is given as follows:

$$g_{\text{milling}}(i) = \frac{c + f + F_i}{(P - s) \times y}$$

where

$g_{\text{milling}}(i)$ = cutoff grade to be used in Year i
i = 1, … N (mine life), years
F_i = opportunity cost per short ton of material milled in Year i (where $F_i = d \times NPV_i/C$)

where

d = discount rate
NPV_i = NPV of the future cash flows of the years (i) to the end of mine life N
C = total processing capacity in Year i

The underlying philosophy in inclusion of the opportunity cost per ton, F_i, in the equation is that every deposit has a given NPV associated with it at a given point in time and that every ton of material processed by the mill during a given year should pay for the cost of not receiving the future cash flows by one year sooner. (In other words, the opportunity cost, F_i, should be viewed as taking the low grade now when higher grades are still available.) The details of this approach are given in the next section.

Table 9.10-8 gives yearly tonnage and grade schedules resulting from Lane's approach. The cutoff grade policy that is determined by this optimizing strategy gives 90% higher NPV and 35% lower profits than the original constant cutoffs determine by the traditional breakeven approach. Even though the total tons mined are the same between the original cutoff policy given in Table 9.10-5 and the optimum policy given in Table 9.10-6, the amount of material milled is lower both in

Table 9.10-8 Annual tonnage and grade schedule using Lane's method

Year	Cutoff Grade, oz/st	Average Grade, oz/st	Q_m*	Q_c†	Q_r‡	Profits, million $/yr	NPV, million $
1	0.161	0.259	18.0	1.05	245.2	95.9	413.8
2	0.152	0.255	17.2	1.05	241.0	94.4	380.0
3	0.142	0.250	16.5	1.05	236.4	92.6	342.6
4	0.131	0.245	15.7	1.05	231.3	90.5	301.4
5	0.120	0.239	14.9	1.05	225.7	88.1	256.1
6	0.107	0.232	14.1	1.05	219.6	85.4	206.4

8	0.079	0.188	9.8	1.05	177.9	65.9	98.1
9	0.065	0.163	7.6	1.05	153.6	53.9	46.9
Total	—	—	125.8	9.45	1931.4	743.4	—

NPV = $413.8 million

*Q_m = amount of total material mined (in millions of short tons) in a given year.
†Q_c = ore tonnage (in millions of short tons) processed by the mill.
‡Q_r = recovered ounces (in thousands) produced in a given year.

tons (i.e., 36.7 million versus 9.45 million st) and in ounces recovered (i.e., 3.37 million versus 1.93 million oz).

The effect of the optimization on the mine life is also significant; shortening of the mine life from 36 years in Table 9.10-5 to 10 years in Table 9.10-8 is the trade-off between the optimum NPV approach versus the traditional breakeven approach. It should be pointed out again that the mining system did not allow for the stockpiling of lower-grade ore for later processing. If stockpiling were allowed, then the stockpiled material has to be worked into the mining schedule given in Table 9.10-8 when it is most appropriate.

Algorithm for Determining Optimum Cutoff Grades for a Single Constraint Problem

The cutoff grades, $g_{\text{milling}}(i)$, given in Lane's equation depend on estimates of NPV_i of the future profits in Year i through the end of mine life from the operation. The NPV_i of the future profits cannot be calculated until the optimum cutoff grades have been decided. The solution to this type of interdependency problem is obtained by an iterative approach, where initial NPV_i values are guessed at first, and at each iteration, they are improved on until the solution converges to a stable optimum answer. This algorithm is as follows:

1. Start with the grade–tonnage curve similar to the one given in Table 9.10-1 for the whole deposit.
2. Assume the most appropriate milling capacity (C) to be used, the selling price (P), refining and marketing cost (s), recovery (y), milling cost (c), mining cost (m), annual fixed costs (f_a), and discount rate (d).
3. Determine the cutoff grade, $g_{\text{milling}}(i)$, to be used in Year i by the following equation:

$$g_{\text{milling}}(i) = \frac{c + f + F_i}{(P - s) \times y}$$

where

$$F_i = (d \times \text{NPV}_i)/C$$
$$f = f_a/C$$

If the initial NPV_i is not known, set NPV_i to zero.

4. From the most current grade–tonnage curve of the deposit, determine the following:
   - ore tonnage, T_c, and grade, g_c, above the cutoff grade, $g_{\text{milling}}(i)$
   - waste tonnage, T_w, that is below the cutoff grade, $g_{\text{milling}}(i)$
   - stripping ratio, $sr = T_w/T_c$
5. If the total reserves calculated in step 4 is greater than the annual milling capacity, set Q_c (the quantity milled in Year i) to $Q_c = C$. Otherwise set it to $Q_c = T_c$. Set Q_m (the quantity mined in Year i) to $Q_m = Q_c\,(1 + sr)$.
6. Determine the annual profit, pi, by using the following equation:

$$P_i = (P - s) \times Q_c \times g_c \times y - Q_c \times (c - f) - Q_m \times m$$

7. Adjust the grade–tonnage curve of the deposit by subtracting ore tons, Q_c, from the grade distribution $(Q_m - Q_c)$ from the cells below the cutoff in proportionate amount such that the shape of the distribution is not changed.
8. If Q_c is less than the milling capacity, C, then set mine life $N = i$ and go to step 9; otherwise set the year indicator to $i = i + 1$ and go to step 3.
9. By using the profits (P_i) estimated in step 6, calculate the incremental NPV_i values for the cash flows to be generated from i to N by using the following equation:

$$NPV_i = \sum_{j=i}^{N} P_j/(1+d)^{j-i+1}$$

For each year $i = 1, N$ (where N is total mine life in years).

10. If the total NPV of future profits for the whole deposit, NPV_i, is not within some tolerance (e.g., ±$500,000) of the total NPV from the previous iteration, go to step 1; otherwise stop; the cutoff grade, g_i, values for Years $i = 1, N$ is the optimum policy that gives maximum NPV of future profits for the operation.

Mine Scheduling and Cutoff Grade Optimization Using Mixed-Integer Linear Programming

A vast amount of work has been done on the development of large-scale production scheduling by using the linear programming and the integer programming models and related solution algorithms since the late 1960s. Johnson (1968), at the University of California at Berkeley, developed one of the most comprehensive mixed-integer linear programming (MILP) models, which is valid even today. This work was followed by Dagdelen's (1985) work in implementing Lagrangian-based solution methodology to MILP models. Application of Lane's cutoff grade optimization algorithm (Lane 1964, 1988) to a gold deposit was described in Dagdelen (1992), and the actual algorithm was given in Dagdelen (1993). The MILP approach as a schedule and cutoff grade optimizer was initially proposed by Dagdelen (1996).

The concept of the MILP approach is demonstrated and discussed in Urbaez and Dagdelen (1999) and was successfully applied to a large-scale gold mine operation with complex process flows at Newmont Mining Corporation's Nevada operations (Hoerger et al. 1999). The use of MILP models for scheduling and cutoff grade optimization on large-scale mining operations involving complex metallurgical process options was further discussed in Dagdelen and Kawahata (2007). Kawahata (2006) worked on improving the solution time for MILP problems by way of the Lagrangian relaxation technique.

The MILP model may be set up do determine optimum schedules and cutoff grades for open-pit and underground mines. For the MILP approach, the mines and stockpiles are treated as the sources to be divided into several "sequences" where sequencing arrangements have to be followed (Figure 9.10-5). To start mining in a given sequence in a period, previous sequences may have to be completely mined out within, or prior to, that period. A given sequence may represent a volume of material as small as a single block, a combination of blocks on a given bench, or a volume as large as a complete phase. Each sequence may consist of a number of "increments." Increments can be based on grade intervals or value intervals if the deposit is a multi-metal deposit (see Figure 9.10-6).

The potential process options and waste dumps are defined as the "destinations" in the MILP model. For a given multiple-mine and multiple-process project, the material flows from each "source" to each "destination."

As the material moves from a given source to a final destination, it is subjected to many operational constraints and associated costs. As the material moves from a given source

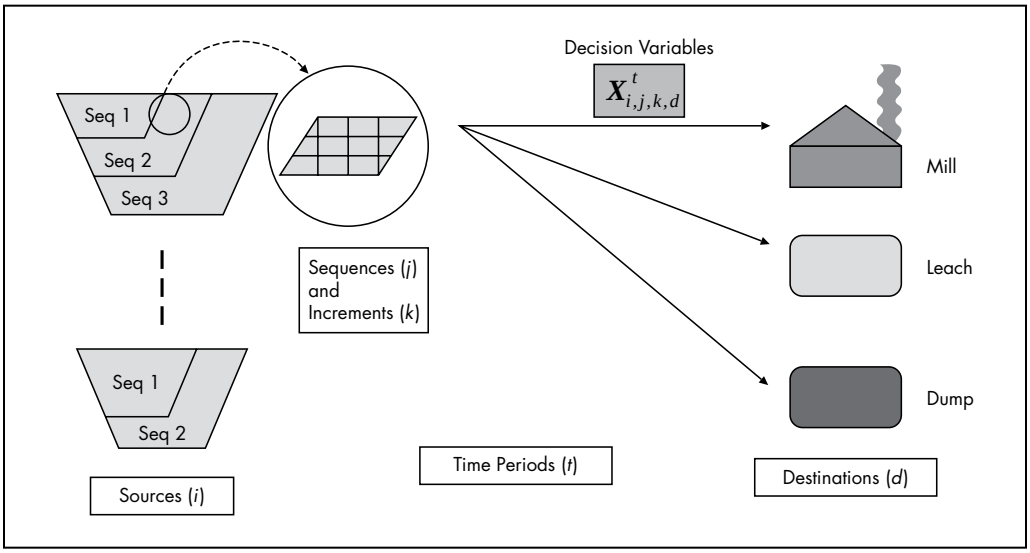

Figure 9.10-5 Production-scheduling decision variables

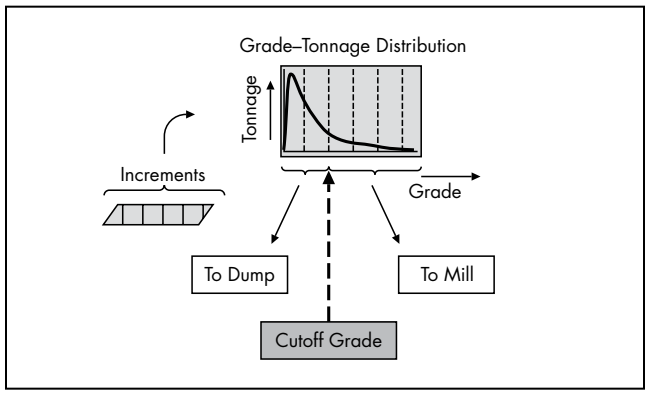

Figure 9.10-6 Cutoff grade determinations in the MILP model

to a given destination, there is an economic value associated with each destination. The objective of the MILP model is to maximize the NPV of the cash flows associated with potentially moving all the material from the sources to destinations such that all of the long-term, operational period requirements and constraints are satisfied.

Objective function. The objective function is defined as follows:

$$MaxZ = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{d=1}^{D}\sum_{t=1}^{T}\left(SR^t_{i,j,k,d} - OC^t_{i,j,k,d}\right)\times X^t_{i,j,k,d}$$

where

i = source ($i = 1,\ldots,I$)
j = sequence ($j = 1,\ldots,J$)
k = increment ($k = 1,\ldots,K$)
d = destination ($d = 1,\ldots,D$)
t = time period an activity is taken ($t = 1,\ldots,T$)
$SR^t_{i,j,k,d}$ = discounted sales revenue per ton of material mined from source i, sequence j, increment k, and sent to destination d in time period t
$OC^t_{i,j,k,d}$ = discounted operating cost per ton of material mined from source i, sequence j, increment k, and sent to destination d in time period t
$X^t_{i,j,k,d}$ = decision variable, tons of material mined from source i, sequence j, increment k and sent to destination d in time period t

Constraints. The objective function is subject to the following constraints:

1. **Reserve constraints:** The material mined is up to what is available in the geologic reserves, $Res_{i,j,k}$.

$$\sum_{d=1}^{D}\sum_{t=1}^{T} X^t_{i,j,k,d} \le Res_{i,j,k} \qquad \text{for } \forall\, i, j, k.$$

2. **Mining capacity constraints:** Mining capacity at each source can be limited in each time period. $Mcap^t_i$ is the upper limit capacity at source i in time period t.

$$\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{d=1}^{D} X^t_{i,j,k,d} \le Mcap^t_i \qquad \text{for } \forall\, i, t.$$

3. **Global mining capacity constraints:** Total mining tons from all the sources can be limited in each time period. $GMcap^t$ is the upper limit capacity in time period t.

$$\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{d=1}^{D} X^t_{i,j,k,d} \le GMcap^t \qquad \text{for } \forall\, t.$$

4. **Process capacity constraints:** Process capacity at each process destination can be limited in each time period. $Pcap^t_d$ is the upper limit capacity at process destination d in time period t.

$$\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} X^t_{i,j,k,d} \le Pcap^t_d \qquad \text{for } \forall\, d \{\text{process}\}, t.$$

5. **Attribute blending constraints:** Attribute blending constraints at each process destination can be limited as lower and upper bound in each time period. $Att^n g_{i,j,k}$ is the grade of n^{th} attribute located in source i, sequence j, increment k; $Att^n L_d$ is the lower bound; and $Att^n U_d$ is the upper bound of blending constraints for n^{th} attribute at process destination d.

$$\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\left(Att^{n}g_{i,j,k}-Att^{n}L_{d}\right)\times X_{i,j,k,d}^{t}\geq 0$$

for $\forall\ n, d \in \{\text{process}\}, t.$

$$\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\left(Att^{n}g_{i,j,k}-Att^{n}U_{d}\right)\times X_{i,j,k,d}^{t}\leq 0$$

for $\forall\ n, d \in \{\text{process}\}, t.$

6. **Attribute cumulative amount constraints:** Attribute cumulative amount constraints at each process destination can be limited as lower and upper bound in each time period. $Att^{n}g_{i,j,k}$ is the grade of n^{th} attribute located in source i, sequence j, increment k; $Att^{n}CL_{d}$ is the lower bound; and $Att^{n}CU_{d}$ is the upper bound of cumulative amount constraints for n^{th} attribute at process destination d.

$$\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}Att^{n}g_{i,j,k}\times X_{i,j,k,d}^{t}\geq Att^{n}CL_{d}$$

for $\forall n, d \in \{\text{process}\}, t.$

$$\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}Att^{n}g_{i,j,k}\times X_{i,j,k,d}^{t}\leq Att^{n}CU_{d}$$

for $\forall n, d \in \{\text{process}\}, t.$

7. **Sequencing constraints:** To control sequencing constraints, binary variables $Y_{i,\text{previous}}^{t}$ are introduced. A sequence j can only be mined after the set of sequences $\forall$ previous $\in \Gamma j$ are mined out. The following set of constraints control these sequencing arrangements.

$$t\sum_{k=1}^{K}\sum_{d=1}^{D}\sum_{\theta=1}^{t}X_{i,\text{previous},k,d}^{t}-Y_{i,\text{previous}}^{t}\sum_{k=1}^{K}Res_{i,\text{previous},k}\geq 0$$

for $\forall i$, previous $\in \Gamma j, t.$

$$\sum_{k=1}^{K}\sum_{d=1}^{D}\sum_{\theta=1}^{t}X_{i,j,k,d}^{t}-Y_{i,\text{previous}}^{t}\sum_{k=1}^{K}Res_{i,j,k}\leq 0$$

for $\forall i, j$, previous $\in \Gamma j, t.$

8. **Non-negativities:** All the decision variables have to be non-negative numbers.

$X_{i,j,k,d}^{t}\geq 0$ for $\forall i, j, k, d, t.$

$Y_{i,j}^{t}\geq 0$ and binary for $\forall i, j, t.$

These are typical constraints that exist in most of the open-pit mine operations. Other sets of constraints and the stockpile option can also be incorporated, as discussed by Hoerger et al. (1999).

PART 10

Surface Extraction

CHAPTER 10.1

Introduction to Open-Pit Mining

Andrew Wetherelt and Klaas Peter van der Wielen

Increasing mining costs, declining average ore grades, environmental considerations, and improved health and safety awareness are some of the main challenges facing the mining industry today (Caccetta and Hill 1999). These challenges emphasize the need for optimization of mining, especially when it concerns large-scale mining associated with open-pit operations.

The underlying message expressed in this chapter is that an open-pit mine is an increasingly complex and interdependent system that can only be optimized by careful coordination, management, and harmonization of its individual elements.

DEFINITION OF OPEN-PIT MINING

Open-pit mining can be defined as the process of excavating any near-surface ore deposit by means of an excavation or cut made at the surface, using one or more horizontal benches to extract the ore while dumping overburden and tailings at a dedicated disposal site outside the final pit boundary. Open-pit mining is used for the extraction of both metallic and nonmetallic ores; application of this mining method in coal is less common. Open-pit mining is considered different from quarrying in that it selectively extracts ore rather than an aggregate or a dimensional stone product. The main difference between strip mining—commonly used in the mining of shallow, bedded deposits—and open-pit mining lies in the overburden disposal. In strip mining, overburden is dumped directly onto mined-out panels rather than outside the final pit boundary, as is typical of open-pit mining.

Production tonnages for open pits range from fewer than 15,000 t (metric tons)/yr in small iron ore operations to more than 360 Mt/yr in large porphyry copper operations such as Escondida in Chile. As of 2008, there are approximately 2,500 industrial-scale open-pit metal mines in the world, which is approximately 52% of all industrial-scale mining operations. Iron ore (44%), copper (38%), and gold (15%) together account for 97% of the total open-pit excavation volume (Raw Materials Group 2008).

TYPICAL DEPOSITS

By definition, ore bodies mined through open-pit mining are located at or near the surface. Although the geometry of ore bodies varies from pit to pit, as a general rule it can be said that open-pit mining favors ore bodies that can be mined on a large scale (e.g., extensive ore bodies with low stripping ratios). Porphyry copper deposits such as Chuquicamata and Escondida in Chile, and Bingham Canyon in the United States, are prime examples of such large low-grade ore bodies. Other common ore-body shapes include stratabound and stratiform deposits such as Western Australia's iron ore deposits and the Zambian copper belt mineralization, diatremes typical of kimberlites (Jwaneng in Botswana) and carbonatites (Palabora in South Africa), and stockworks such as the Kalgoorlie (Western Australia) gold deposits.

OPEN-PIT GEOMETRY

The geometry, or layout, of an open-pit operation is discussed in this section. The main considerations are on those parts of the excavation that have to accommodate the main equipment and their operations, namely the benches, haul roads, and overburden disposal site. Two other subjects related to open-pit geometry—pit expansion and transition to underground mining—are also included in the discussion.

Benches

Benches are possibly the most distinguishing feature of an open pit. They are crucial in an operation as they accommodate the active blasting and excavation areas. Benches can be divided into working benches and inactive benches (Hustrulid and Kuchta 2006). Working benches are in the process of being excavated, whereas inactive benches are the remnants of working benches left in place to maintain pit-slope stability. Between main benches, catch benches are left in place to prevent cascading material from compromising safety in active areas of an operation. Figure 10.1-1 shows a simplified geometry of a typical open pit as well as the layout of some of the crucial elements in more detail.

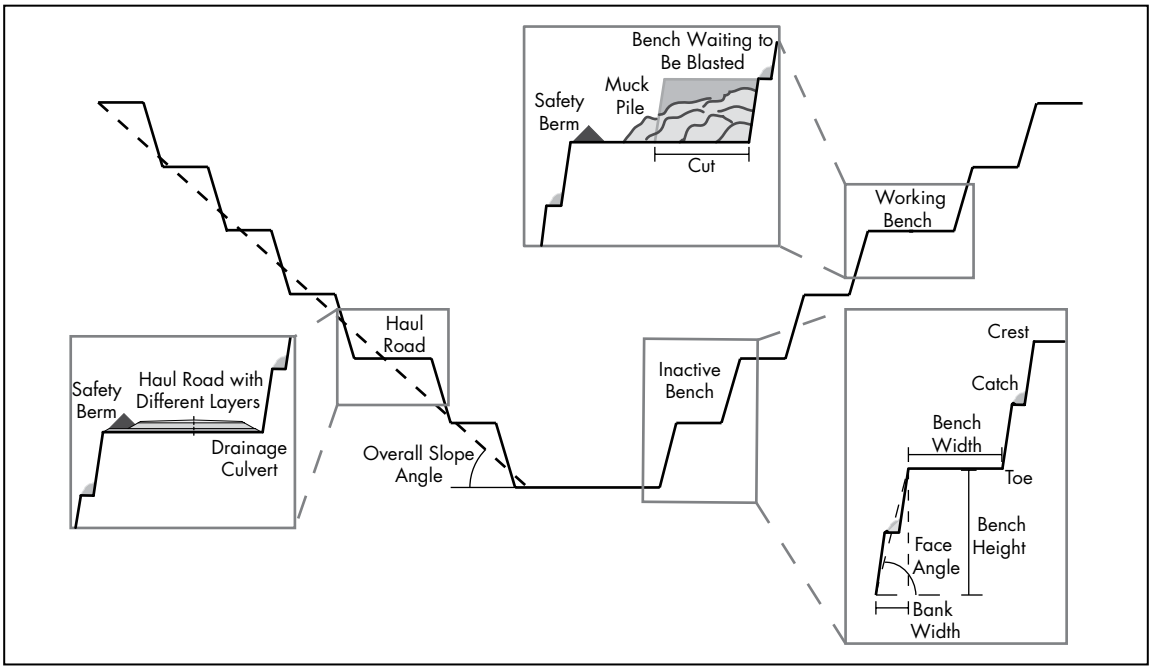

Figure 10.1-1 Typical open-pit geometry

Bench heights typically lie around 15 m. The bench width varies according to equipment size and the type of bench. Working benches should at least be wide enough to accommodate the turning radius of the largest haul truck plus the width of the safety berm (Caterpillar 2006). However, ideally, the bench should at least be wide enough to allow the largest haul trucks to clear the excavator under full acceleration. Depending on the chosen pushback geometry and size of the equipment, the width of a working bench can be anywhere from 30 m to several hundred meters. The width of catch benches is typically between 3 and 5 m but can vary with overall bench height. A small catch berm (~1 to 1.5 m) is usually included at the edge of the catch bench to improve its effectiveness at containing bench-scale rockfalls.

Constituting one of the busiest areas of an open pit, working benches have to accommodate large excavators and dump trucks as well as the muck pile formed after a blast. Therefore, maintaining the quality of a suitable working surface is vital to ensure acceptable safety and productivity levels at an active excavation. As discussed under "Haul Roads," it is important to balance maintenance requirements against the duration and intensity of traffic. This is no less true for benches than it is for haul roads. Floor maintenance resources such as wearing course (also known as road base or road capping), labor, and road maintenance equipment should be allocated according to the added value they have in the operation as a whole. The importance of good floor maintenance on benches is emphasized in research by Ingle (1991), showing that up to 70% of tire damage may occur in active loading and dumping areas. For this purpose, it is important that a well-drained and smooth surface free of rocks is maintained. Dozers or front-end loaders can be used to aid the main excavator in maintaining good floor conditions. Furthermore, they can increase main excavator efficiency by reshaping the muck pile to increase bucket fill factors and possibly aid in the selective mining of ore and barren rock. For health and safety reasons, safety berms (also known as safety benches or windrows) are constructed along crests of benches in a similar manner to those found next to haul roads. The main goal of berms is to stop equipment from backing over the edge of a crest. Generally, a berm with a height equal to the axle height (e.g., at least half of the wheel height) of the largest truck entering an area is not only a safe design but commonly required by mine safety regulations.

Haul Roads

Haul roads constitute a key element of an open-pit mine, providing the main haulage route for ore and overburden from active excavation areas to the pit rim and beyond. Figure 10.1-1 shows the layout of a typical haul road. In light of a trend toward increased gross vehicle mass and haulage distance, detrimental effects of inadequate haul road design, management, and maintenance are becoming increasingly costly (Thompson and Visser 2006). Possible effects are

- Decreased truck and tire life,
- Loss of productivity,
- Poor ride quality, and
- Excessive fugitive dust generation.

All these factors can result in exacerbated vehicle and road maintenance and operating costs. Furthermore, statistics provided by the National Institute for Occupational Safety and Health (NIOSH) show that, in the United States, haul roads are responsible for 20% of lost-time injuries and 42% of fatalities in surface mines (Turin et al. 2001). Lastly, haul roads can significantly impact pit angles and stripping ratios depending on the adopted design and geometry. As such, sound haul road design and management can have a significant positive influence on the safety record, profitability, and environmental impact of a mine.

Thompson and Visser (2006) argue that optimal performance of a haul road network can only be achieved through an integrated approach incorporating (1) geometric, (2) structural,

and (3) functional design as well as (4) the adoption of an optimal management and maintenance strategy. Geometric design covers the basic layout of haul roads based on input criteria such as truck types, traffic intensity, design life of the road, available construction materials, and costs. The next step, structural design, goes into more detail, determining factors such as required materials for road construction material based on the projected design life and traffic intensity. The goal here is to ensure the haul road can accommodate the imposed loads without excessive construction or maintenance costs. Functional design is mainly concerned with providing a safe, vehicle-friendly ride at the best economic performance. Wearing course material selection and performance is crucial during this stage as it is the controlling factor for rolling resistance, fugitive dust generation, ride quality, and surface deterioration rates. The last step, adoption of an optimal management and maintenance strategy, involves developing the most cost-effective approach to maintaining the functionality of the haul road. This subject is covered in more detail later in the "Maintenance and Management" subsection. For a more detailed discussion of design and layout of haul roads, readers are referred to Chapter 10.6 of this handbook.

General Design and Operational Aspects of Haul Roads

Depending on the location and use, haul roads are generally around 3–3.5 and 3.5–4 times wider than the largest truck size on two-way straights and in two-way bends, respectively. Effectively, this places the width of most two-way haul roads between 20 and 35 m, and up to 40 m on bends. For one-way haul roads, a width of 2–2.5 times that of the largest truck size is generally enough. Recommended grades lie between 1 and 8 and 1 and 10 (10%–12.5%), but higher grades are possible when trolley-assist haulage is used. It is important to keep the grade as constant as possible to make truck operation easier and more efficient. Where speeds exceed 15 km/h, corners can be superelevated, although superelevation should not exceed 1 and 10 or 10% (Caterpillar 2006). For better drainage on flat sections, a cross slope of 2% with loaded trucks on the upper part should be considered. On grades, minimum cross slope is required. For safety reasons, angles between roads on intersections should be 90° where possible. Lastly, on two-way sections of haul roads a center berm can be constructed. There is some debate about the effectiveness of such berms—some mines use them; others consider them to be center obstacles without any added value that can cause tire degradation.

Before a shift starts, operators have to perform a basic vehicle check, testing vital systems such as the brakes. Traffic rules on haul roads vary depending on the operation; for example, speed limits for haul roads range from 5 to 40 km/h. Large, loaded trucks in an uphill haul may not be able to achieve the maximum speed. For the rest of a mine site (i.e., workshops, stockyards, crushers, etc.), speed limits generally range from 10 to 20 km/h. In light of safety considerations, trucks traveling in the same direction are normally not allowed to pass, and in most cases passing is also prohibited for light vehicles. In most other aspects, traffic rules on-site closely resemble those of public roads.

Dust

Haul road dust can have a considerable environmental impact, increase maintenance and operations costs, and be a serious safety hazard both in the short term by reducing operator visibility and through long-term exposure, which may cause damage to the respiratory system. The main controlling factors in haul road dust are

- Wind speed at the road surface,
- Traffic volumes and speed on the haul road,
- Particle size distribution of the wearing course material,
- Construction characteristics of the wearing course material, and
- Meteorological conditions at the mine site (Thompson and Visser 2000).

Operator exposure can be decreased significantly by fitting cabs with filtration equipment, airtight seals, and air conditioning as well as increasing the following distance between trucks. Thompson and Visser (2000) state that the most common dust suppression measures include

- The application of a suitable wearing course material,
- Reduction of haulage speeds,
- Regular application of water or chemical suppressants, and
- Sound haul road maintenance.

The selection and application of a suitable wearing course, combined with regular application of water and chemical suppressants, are the most feasible and effective options. Applying a suitable wearing course should be the preferred control measure as it is a preventive rather than mitigating action and it has many beneficial effects in other areas of haul road management and maintenance. The feasibility of watering and chemical suppressants should be evaluated through a cost–benefit analysis. Watering often seems the cheapest alternative, although in light of its short effectiveness and, possibly, limited water supplies, other alternatives may be more feasible (Thompson and Visser 2000). Chemical suppressants are more effective at long-term dust suppression than water. However, as production haul roads are highly dynamic in nature, chemical suppressants generally do not last very long in these environments as continual watering and grading decreases their effectiveness. Furthermore, they do not mitigate effects of material spillages during haulage and are normally more costly. Therefore, continual watering and grading is in many cases the main type of dust suppression for production haul roads, although in some cases a combination of both systems might be the most viable alternative. For auxiliary roads that are more permanent in nature, dust suppressants are a more viable alternative to continual watering and grading.

In addition to the measures discussed previously, avoiding spillages also plays an important role in fugitive dust suppression and, possibly more importantly, prolonging tire life. Chemical suppressants are not effective at suppressing fugitive dust generated from spillages as they are not applied regularly (Thompson and Visser 2000). Watering haul roads will mitigate this problem but suffers from the problems discussed in the previous paragraph. Considering the drawbacks of watering and the effect spillages can have on tire life (as discussed in the "Tire Management" section later in this chapter), avoiding spillages through adequate load placement by the excavator should be preferred over more regular watering.

Maintenance and Management

Rolling resistance is the resistance to motion that a haul truck experiences because of friction. The main contributors are wheel load and road conditions and, to a lesser extent, tire flexing and internal friction. Minimum rolling resistances of

1.5% (radial and dual assemblies) to 2% (cross-ply or single-wheel assemblies) are quoted for rear-dump trucks. Estimates of rolling resistance related to tire penetration indicate an increase in rolling resistance of 0.6%/cm of tire penetration into the haul road (Thompson and Visser 2003). Thompson and Visser also report that similar resistances can arise from road surface deflection or flexing. As haulage is one of the main cost generators in an open-pit mine; rolling resistance reduction can lower capital and operating costs considerably.

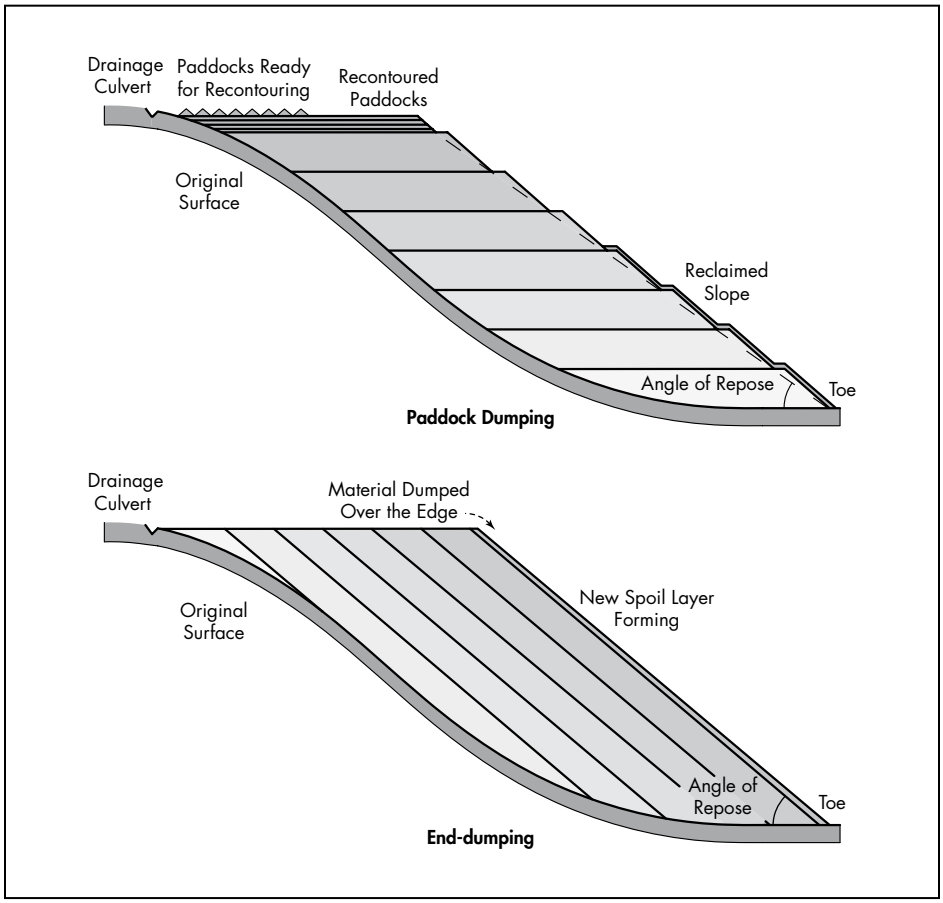
Some of the main contributors to a high rolling resistance and bad haul road performance are inadequate wearing course construction and application as well as haul road defects such as potholing, rutting, loose material (dust and stones), corrugations (commonly referred to as washboards), surface cracking, and insufficient drainage. If these defects are left unattended, they may reduce haul road productivity, impede safe vehicle operations, and damage equipment. Five of the main routine maintenance activities for a haul road are

1. Dust suppression measures,
2. Routine surface maintenance,
3. Clearing material spillages,
4. Replacing the wearing course material, and
5. Drainage culvert and shoulder maintenance (Paige-Green and Heath 1999; Thompson and Visser 2003).

All these measures are aimed at maintaining or improving road quality and will mitigate most haul road defects. However, because of limited resources and complex maintenance requirements, a practical maintenance strategy is more effective at mitigation and prevention of these defects.

Semipermanent and temporary haul roads are commissioned and decommissioned during a mine's life. It is vital that the costs of constructing these haul roads are balanced against their design life (Thompson and Visser 2003). Under-expenditure of resources on permanent, high-volume haul roads or over-expenditure on short-term, low-volume haul roads can have serious detrimental effects related to premature failure, compromised health and safety, high maintenance costs for permanent haul roads, or an excessive drain on resources for haul roads with a short, active life span.

Wearing or surface course material plays a major role in the productivity and maintenance requirements of a haul road and the equipment using it. Therefore, the selection, application, and maintenance of wearing course materials are paramount to the good functional performance of a haul road during its operational life. To determine its influence on overall haul road functionality and road user costs, the performance of wearing course materials should be analyzed and benchmarked (Thompson and Visser 2006). Visual inspection of haul roads has traditionally been the main method of determining the maintenance needs for haul roads. However, recent advances in the use of high-precision Global Positioning Systems (GPSs), communications, and equipment monitoring have led to the development of tools for real-time qualitative assessment of haul roads by haul trucks. The integration of accelerometers in haul truck–mounted road monitoring systems may provide quantitative indicators of haul road quality, and as such add a whole new dimension to haul road management (Thompson and Visser 2006).



During the scheduling of haul road maintenance, it is important to bear in mind traffic intensity (preferably expressed as gross vehicle mass), function, and projected life span of the road, as well as its maintenance requirements. Routine maintenance and grading may seem like best practice, but when traffic intensities and maintenance requirements are not taken into account, it becomes apparent that this practice may incur excessive maintenance costs on sections of the haul road system with low-traffic intensities. Therefore, optimum maintenance intervals should be determined for haul road maintenance activities, based on a cost–benefit analysis of the relationship between maintenance costs and vehicular cost-incurring factors related to road maintenance, according to Thompson and Visser (2003). They conclude that balancing the optimum maintenance intervals for haul road maintenance and dust suppression with available resources, in conjunction with visual inspection or, ideally, real-time monitoring of haul road performance, should form a solid basis for a practical maintenance strategy for all haul roads in a mining complex. When this proactive, holistic approach to haul road management is implemented, significant gains in operating and maintenance costs, as well as road construction costs, can be achieved.

Two other important elements of a haul road that need maintenance are drainage culverts and safety berms. Similar in size and purpose to safety berms on working benches, safety berms are constructed at the side of a haul road. Drainage culverts are constructed where climatic and hydrogeological conditions dictate their usefulness. They can be located at the pit wall side of the haul road (e.g., where there is a high influx of water) or at both sides of the haul road (e.g., for drainage in areas of high precipitation). Sufficient height of the safety berm and maintaining unobstructed flow in the drainage culverts are essential in ensuring safety on haul roads.

Overburden Disposal

Overburden forms, by far, the largest volume of material produced by most open-pit mines. As overburden generally does not generate any revenue, handling is kept to a minimum. Furthermore, it can contain sulfides or other substances that are potentially damaging to the environment. Consequently, selection of the most suitable site for the overburden embankment involves a trade-off between handling costs related to overburden disposal and the environmental impact of the overburden at a particular site. Minimizing costs involves selecting an overburden embankment site in close proximity to the mine where the environmental impact is as small as possible. Preferably, this site is as close as possible to the projected final pit limit, at the same or a lower elevation as the excavation to minimize upslope haulage costs while maintaining the lowest possible cycle time. With these considerations in mind, optimization of overburden management at a mine site can have a considerable positive influence on the environmental impact and economic viability of a mine.

Overburden is deposited either top-down or bottom-up. Both methods are illustrated in Figure 10.1-2. End-dumping (or top-down dumping) of overburden involves dumping the material over an advancing face. During operation of the dump, only limited reworking of material by dozers is required. Recontouring starts after the end of the dump life. In paddock dumping (also known as bottom-up dumping), the layers of overburden are stacked by dumping on top of the dump, followed with spreading by bulldozers to form relatively thin layers. Paddock dumping is favored from a geotechnical point of view because it allows for more control over the angle of repose of the dumped material and provides a better homogeneity of the material and ultimately better stability (Spitz and Trudinger 2008). Furthermore, paddock dumping provides the possibility

Source: Spitz and Trudinger 2008.

Figure 10.1-2 Comparison between paddock dumping and end-dumping

of concurrent rehabilitation of the overburden embankment and more control over the encapsulation of potentially acid-generating overburden. The lack of homogeneity in top-down dumping provides more potential for settlement and creation of zones of different permeability, both of which can cause more pronounced erosion and eventually instability. Moreover, the lack of homogeneity in rock size can also encourage oxidation of sulfides and consequently acid-mine drainage (Department of Resources, Energy and Tourism, Australia 2006). Paddock dumping does not markedly decrease truck cycle times (Turin et al. 2001). The main advantage of end-dumping is that it is significantly cheaper than paddock dumping due to considerably lower rehandling of overburden both during operation and rehabilitation of the dump site. However, most importantly, paddock dumping is far superior in terms of safety because there is less risk of edge failure and a dump truck falling over an edge when backing up. This point is illustrated by Turin et al. (2001) in an analysis of 10 years of lost-time injuries and fatalities at overburden embankments in the United States. They found that "backing up and falling over an edge" accounts for 73% of fatalities at dumps. Three of the main contributing factors to this are edge failure (23%), the lack of a berm or barrier (35%), and driving through a berm or barrier (31%). This not only shows that proper barrier construction is vital, but also that dump site stability is an important factor. Furthermore, these statistics highlight that, from a safety perspective, paddock dumping, with its better geotechnical control, is the preferred option. In order to further increase safety on an overburden embankment, it is good practice for haul trucks to approach the dumping face from left to right so the operator can inspect the dump berm and dump surface for any tension cracks. The next step is stopping and reversing the haul truck to the dump edge, using the berm as a marker rather than a stopping block prior to tipping.

Pit Expansion

Expansion of an open-pit mine is done in a series of phases, often referred to as pushbacks or cutbacks. From a planning standpoint, a pushback should be aimed at maximizing the financial return from a mine. When planning a pushback, this means taking into account not only the grade of a material but also the costs of development, mining, processing, and marketing (Hall 2009).

The exact geometry of a pushback is very site-specific and depends on a range of factors including ore-body geometry, financial goals, geotechnical consideration, mining equipment, production goals, and long-term planning. Pushbacks can be either conventional or sequential (McCarter 1992). Essentially, both methods push back a pit shell the same distance horizontally; however, a sequential pushback does this through a number of smaller, active benches pushed simultaneously at several levels, whereas a conventional pushback mines the whole horizontal extent of a pushback level before progressing to the next level. Different zones of sequential

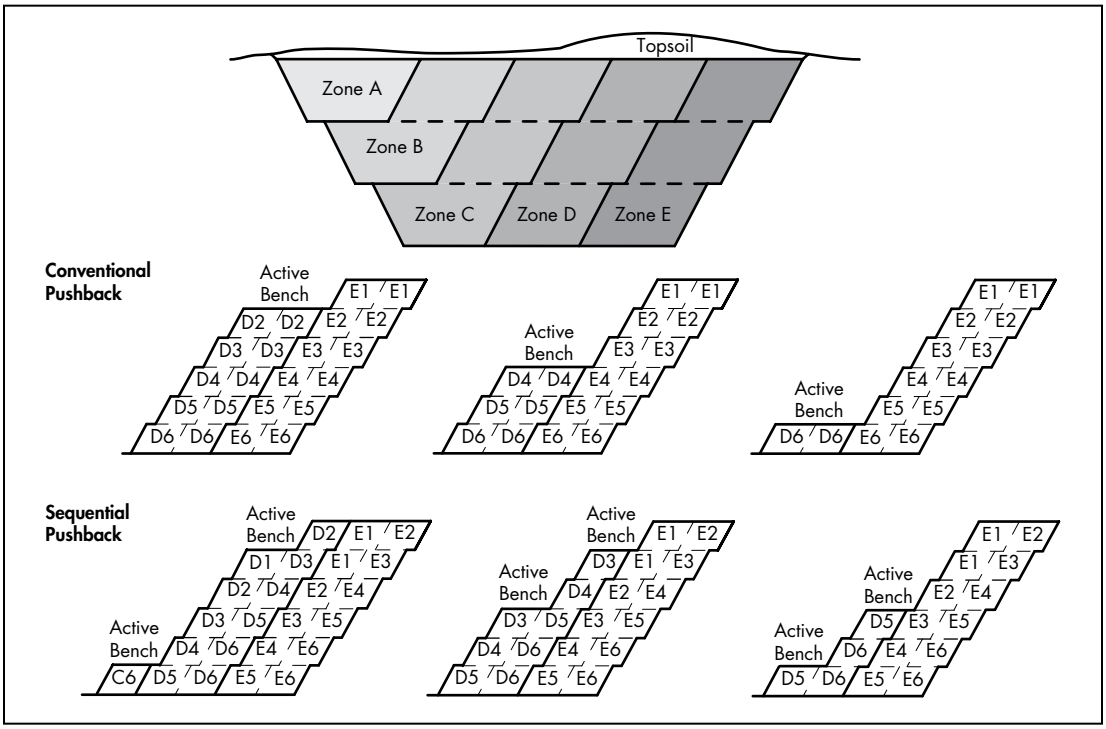


Figure 10.1-3 Conventional and sequential pushbacks

pushbacks are divided by haul roads. Figure 10.1-3 illustrates the differences between sequential and conventional pushbacks. The general pit layout is shown in the top of the figure, divided into different pushback zones (Zone A, Zone B, etc.).

The bottom of the figure illustrates how both methods would mine the same pushback differently. The letter in the blocks denotes the zone, and the number indicates the mining sequence (i.e., mining commences with Block D1, then D2, etc., until the last block is mined).

In a conventional pushback, all activity is concentrated on one level as compared to multiple active levels in a sequential pushback. This means that sequential pushbacks require more complex planning than conventional pushbacks. However, developing several areas simultaneously means there is more flexibility during excavation, allowing superior control over production planning and blending of ore. Furthermore, as sequential pushbacks contain a number of active benches on the pit slope, the working slope angle is lower than the final pit slope angle, which does not have these wider, active benches, resulting in improved slope stability. Conventional pushbacks, on the other hand, are less complex to schedule and the larger active area at a given time allows more working faces within a pushback. Disadvantages include less flexibility in scheduling and blending as well as a greater vulnerability to operational problems.

Presplit blasting is often done at the final reach of a pushback or pit shell. By allowing more control over face angle and back break, this improves long-term stability of the pit face. Sequential pushbacks are more commonly seen in large-scale open pits, whereas conventional pushbacks are more common in shallow and small-scale operations.

Transition to Underground Mining

In some cases, notably with vertically extensive ore bodies, it can be profitable to continue mining by underground methods after the final pit limit has been reached. In recent years several big open pits, such as Palabora, have commenced underground production with others, such as Chuquicamata and Debswana's Jwaneng mine, announcing plans to go underground. The transition from open-pit to underground mining presents a set of unique geotechnical, planning, and management challenges.

With regard to management, the first challenge is deciding on the feasibility of underground mining. Most comparison methods between open-pit and underground mining rely on establishment of a break-even stripping ratio and a comparison of the net present value for the next feasible open-pit pushback to that for an underground mine. After feasibility of underground mining has been proven, timing of underground mining is the next issue to be decided. There are two major considerations in the timing of the transition. First, to maintain continuity of the operation it is important that the underground mine can supplement and eventually take over production from the open pit without major permanent changes in tonnages of ore shipped to the mill. Differences between the open pit and underground ore grade and composition may complicate this issue. A production overlap between open-pit and underground mining is therefore common to allow for a smooth transition from open-pit to underground mining. Second, while a smooth transition requires a production overlap, neither of the two operations should compromise the other's safety. Geotechnical analysis should provide insight into the interaction between the two adjacent operations. Safety in the surface operations could be jeopardized as a result of crown pillar failure or due to mining subsidence-induced slope failure (e.g., when a caving method is used). On the other hand, surface blasting-induced vibrations could compromise safety underground.

Siting of the portal is another major consideration in the transition from open-pit to underground mining. Most

importantly, it is crucial that the stability of the underground mine entrance should not be compromised in any way by surface operations. This is as true for a decline portal within an operating pit as it is for a shaft located near a pit wall. Additionally, when a decline portal is sited within the open-pit walls, surface traffic interactions relating to both excavations should be kept to a minimum. This includes not only keeping haulage routes for both operations separated to the highest extent possible, but also considering the effects of blasting.

UNIT OPERATIONS

In mining, unit operations can be defined as those basic steps necessary for the production of payable material from a deposit, and the auxiliary operations used to support the production (Hartman and Mutmansky 2002). Unit operations in an open-pit production cycle include access, drilling and blasting, excavation practices, and haulage methods. Auxiliary operations and other production-related activities include overburden and topsoil removal, ancillary operations and mine services, and equipment monitoring and maintenance.

Access

The first step in the development of a new mining operation or a pushback is gaining access to the area to be mined. Especially when working in remote areas, an appropriately planned and designed access road with sufficient capacity can make a substantial difference in the initial success of a new operation.

After permanent access to the new mining area has been secured, removal of topsoil and overburden can begin. In mining, overburden refers to all unprofitable material that needs to be excavated to access an ore deposit, including topsoil and overburden. Topsoil refers to the layer of unconsolidated material at the surface that is suitable for sustaining plant growth. Because of the unconsolidated nature of topsoil, it often requires different excavation techniques. Depending on climate, topography, and bedrock geology, topsoil can vary from anywhere between centimeters and tens of meters thick. Overburden refers to the consolidated material underlying the topsoil and generally overlying the ore body. If overburden is encapsulated between two layers of ore, it can be referred to as interburden.

Topsoil Removal

After the initial pit outline has been staked out, vegetation should be removed and any surface water courses should be diverted away from the site. As topsoil is generally free digging, scrapers, bulldozers, front-end loaders, and small hydraulic excavators are the most common equipment used in topsoil stripping. Bulldozers can be used for pushing material onto piles for further excavation by front-end loaders or hydraulic excavators. Alternatively, they can support scraper operation by ripping soil or by pushing scrapers along where they do not have enough traction. Graders are mostly used for precision applications such as haul road construction. Haulage distance is an important consideration in choice of equipment. At short haul distances, scrapers and bulldozers are more economic, whereas a more conventional excavator/truck haulage operation tends to be more economical at longer haul distances.

Before the bedrock is reached, the exposed soil may be a large potential source of dust, and a water bowser or tank truck (a mining truck that has been adapted for the distribution of water) may be required for dust suppression. In many operations, topsoil storage is required for reclamation purposes at the end of mine life. In some cases separate storage of different topsoil and subsoil layers may be necessary to ensure quality of the material. Depending on the duration of topsoil storage, revegetation and erosion control may be required.

In some operations, the excavation may never progress into consolidated material and the practices discussed here may also apply to the excavation techniques used for ore.

Overburden Removal

Removal of overburden is often required before extraction of ore can begin. Regarding materials handling, there are three important differences between ore and overburden:

1. Overburden is not beneficiated and will generally not generate any revenue.
2. Overburden tonnages almost invariably exceed ore tonnages in an open-pit mine.
3. The rock mass characteristics are often different from that of the ore.

The first two points imply that handling of overburden and related costs should be kept to a minimum. To minimize costs related to the handling of overburden, it is often blasted to a coarser fragmentation than ore, and in many cases excavated and hauled by larger-capacity equipment. As a result, in many operations the stripping of overburden is contracted out. Drilling, blasting, excavation, and haulage practices for consolidated material will be discussed in more detail in the following sections.

Drilling and Blasting

Drilling and blasting comprise the first two of the four main stages in the production cycle of an open-pit mine and the most common method of rock breaking. Other rock-breaking methods such as mechanical breaking and surface miners can generally not compete in terms of either production rate or economy and will not be discussed in this chapter.

Blast Design

Blast design is the first and most crucial step in drilling and blasting. First and foremost, blast design is an iterative process, where important factors such as the required fragmentation, production, and muck pile shape are used as a starting point for determining optimal drill-hole diameter, depth and inclination, subdrilling, explosives type, and detonation timing (Hopler 1998). Importantly, operating costs of both the mine and the processing plant are directly related to the fragmentation achieved during blasting (Bhandari 1997). Bench height and subdrilling requirements dictate drill-hole depths. *Subdrilling* is the term used for the length a blasthole extends beyond the excavation level. This is done to reduce the risk of equipment damage as a result of poor floor conditions, which in turn is governed by geological features and the strength of the rock mass. Figure 10.1-4 shows a basic blast and blasthole geometry.

Bench height is generally fixed by ore-body characteristics and geometric and geotechnical considerations and is taken as the starting point for blast design. Selection of a suitable drill-hole diameter is a complex process taking into account a host of factors related to production requirements, rock mass characteristics, environmental considerations, and equipment selection (Hopler 1998). In general, it can be said that larger drill-hole diameters can be operated at larger burdens and spacings. However, this does result in larger

fragments compared to smaller-diameter holes at the same powder factor. Assuming a fixed bench height, a good indication of hole diameter, D, is given by Bhandari (1997) as

$$D = H/120$$

where H is the bench height in meters.

When determining the blasthole diameter, it should be taken into account that there is an inverse relationship between hole diameter and operational costs (Bhandari 1997). Typical values range from 83 to 350 mm depending on the scale of the operation.

Drilling patterns (e.g., burden/spacing ratio) vary substantially in size, and patterns are tailored to specific operations. There are many ways of calculating spacing (S) and burden (B), most of which are based on hole diameter. The following rules are considered a good starting point for the estimation of the spacing and burden (Hustrulid 1999):

$$B = K \times D$$

where K is a constant and D denotes hole diameter in meters, and

$$S = 1.15 \times B$$

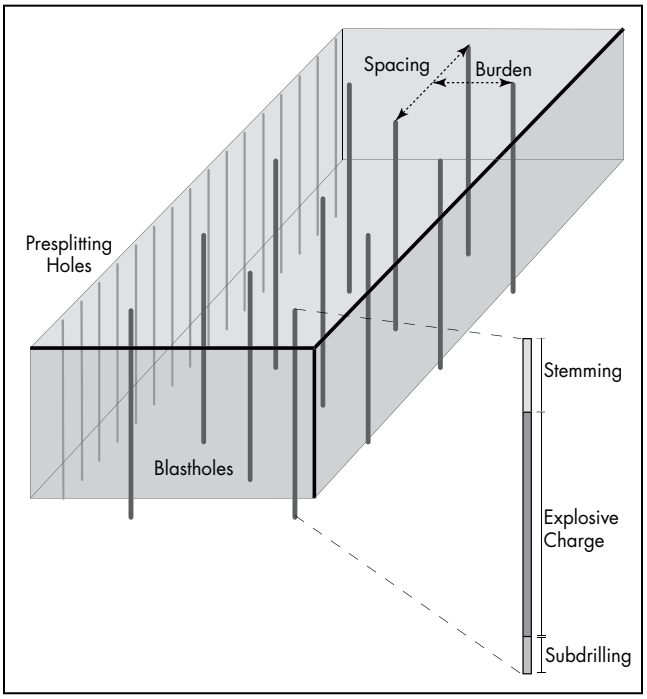
where B denotes burden in meters.

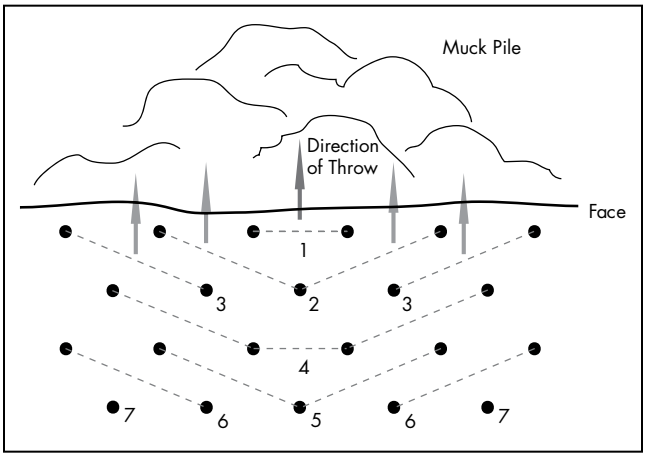
The constant K is dependent on the strength and density of the explosive, as well as rock "blastability." It ranges from 20 in dense rock with light explosives to 40 in light rock with heavy explosives, but typically it lies between 25 and 35 (Hustrulid 1999). In strong or blocky rock and to achieve optimal fragmentation, conservative values should be used when calculating the burden. Typical values for the burden range from 3 m in small-scale operations to 10 m in very large-scale operations.

The relationship between burden and spacing—the burden/spacing ratio—can be varied according to the chosen blasting pattern. Square patterns ($S \sim B$) are easy to lay out but result in poor charge distribution (Bhandari 1997). Elongated patterns ($S > B$) are preferred in hard-breaking rock and when there are problems with back break (Hustrulid 1999). Staggering a pattern further complicates layout but, due to superior blasting energy distribution, results in better fragmentation. If there are problems with back break or when superior face angle control is necessary, presplitting can be done with a smaller drill rig.

Stemming is placed on top of the explosive column to ensure efficient use of the explosive energy and to reduce air overpressure. Drill cuttings are often used for stemming. This is a cheap alternative to inserting specialized stemming material, but it is less efficient at containing blast energy, possibly resulting in unsatisfactory blasting results (e.g., vertical flyrock and oversize blocks). Where possible, angular material is preferred as by nature it tends to lock in place better during the detonation process, further improving confinement of the explosive pressure. Appropriate stemming-chip size lies in the range of 10% of the blasthole diameter. A good approximation of stemming depth is $0.7–1 \times B$, and is commonly between 2 and 7 m.

After a drilling pattern is established, a delay sequence should be fitted to this pattern. The first consideration in determining delay intervals is the availability of free faces. A blast should be initiated at the free face and aim at maximizing the use of the free face throughout the blast. When there are no free faces available (e.g., a box cut or sump blast), a diamond cut is the best option, displacing rock upward. In the case of one free face, a chevron pattern (V-pattern) is recommended, although a row-by-row pattern can also be used (Bhandari 1997). The angle of the V can be varied according to the local geological conditions and the desired blasting result. When there are two free faces, an echelon pattern usually produces the best results. Figures 10.1-5 through 10.1-8 show different standardized blast designs with relative detonation sequencing of the rows. Other cuts exist but are generally used in more specialized applications. After a delay sequence has been established, appropriate delay intervals can be assigned to rows or individual holes. Regarding delay intervals, Bhandari (1997) recommends 3–6 ms/m of effective burden (i.e., at the time it is blasted and not when it is drilled). Apart from the drilling pattern, other important considerations during the selection of suitable delay timings are safety of the blast, geology, prevention of surface cutoffs, vibration reduction, and fragmentation requirements. Delay timings should be customized to prevailing geological conditions, even within the same operation.





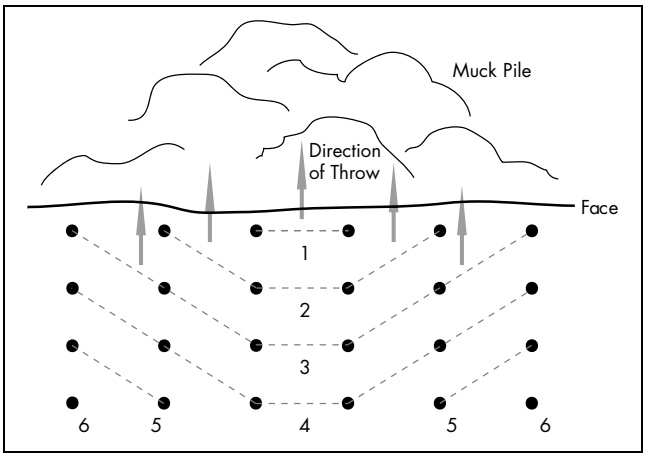


Figure 10.1-4 Blast and blasthole geometry

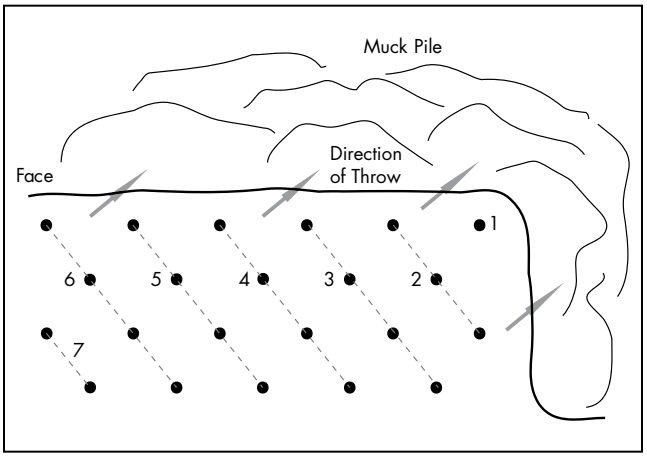
The shape of the muck pile required by the excavator is another consideration during blast design. High, compact muck piles are generally preferable for rope shovels and hydraulic excavators, whereas a low, flat muck pile is better for front-end loaders (Hustrulid 1999). The delay pattern, point of initiation, and number of rows are the main influences on muck pile shape. The higher the number of rows in a blast, the larger the vertical component of rock movement and the higher the resulting muck pile (Bhandari 1997).



The mining industry is becoming increasingly aware of the benefits of achieving a good fragmentation during blasting. Most importantly, drilling and blasting is, comparatively, the cheapest method of comminution. Therefore, achieving good fragmentation at this early stage can have a significant positive

impact on the efficiency and costs of downstream comminution processes (Borquez 2006). Furthermore, better fragmentation allows for better use of the capacity of the excavation and haulage equipment in a mine. On top of that, optimization of blasting at a specific site may suggest that the same results can be obtained by using less explosives, and it may reduce the amount of oversize boulders produced. With these considerations in mind, it becomes clear that determining the optimal fragmentation is a function of not only the effectiveness of the drilling and blasting process but also of excavation, haulage, and the downstream comminution processes.

The first step toward obtaining optimal fragmentation results is adopting a blast design aimed at producing the best fragmentation. Generally, this means implementing a more closely spaced drilling pattern (especially a lower burden) with smaller-diameter blastholes and more accurate timings, but the exact blast design depends on a host of site-specific parameters. Ongoing research is aimed at establishing the most influential factors in fragmentation and how blast design can be geared toward optimized fragmentation using these factors.

Application of high-precision GPSs, accurate drill guidance, and drill monitoring have made it possible to drill blastholes with very little deviation. Together with the use of electronic detonators, these two fairly recent advancements in drilling and blasting have made it possible to consistently produce optimal fragmentation during a blast. These developments are further aided by the introduction of imaging software that can analyze the fragmentation of blasted material, allowing for an iterative approach toward optimal fragmentation.

Drilling

Production drill rigs are usually truck- or crawler-mounted and are powered either by a diesel engine or an electric drive. Pull-down and hoist forces are applied by either hydraulic or chain-hoist systems. A range of systems is available for monitoring machine health and the drilling process.

Production drill rigs are divided into rotary, top hammer, and down-the-hole (DTH) hammer drill rigs. Rotary drill rigs rely on a pull-down force transmitted through a rotating drill string usually with a tricone bit for the cutting action (Australian Drilling Industry Training Committee 1997). Rotary drill rigs are generally most efficient in medium to hard rock and in holes with a diameter larger than approximately 170 mm. Hole depths can extend to more than 80 m in extreme cases. Top hammer drill rigs transmit the hammering force from the drill rig through the drill string down the

hole. They are preferred for hole diameters up to 140 mm, depths down to 20 m, and mostly used in small-scale operations and precision applications such as secondary breaking. Hole straightness and energy loss at drill string joints are the main factors limiting the use of this type of drill rig for deeper and larger-diameter holes. DTH hammer drill rigs rely on compressed air for operating a piston at the end of the drill string to provide the hammering action. Common applications include presplitting, dewatering holes, and other applications where high accuracy is required, although they are also used for blasthole drilling. DTH hammer drill rigs are the most efficient drill rig type in hard to very hard rock. Drill-hole diameters for DTH hammer drill rigs commonly lie between 140 and 170 mm, and depths of up to 40 m are feasible. Selection of the most suitable hole size and drill type for a particular mining operation is a function of balancing projected operating and capital costs with the required rock fragmentation, wall stability, grade control, and production requirements.

Generally, drilling and blasting is the bottleneck in terms of time consumption in the drilling and blasting cycle. It is absolutely essential for the overall productivity of a mine that muck pile volumes are sufficient to keep excavators and the haulage system used to the highest degree at all times (Hopler 1998). Drilling productivity is dependent on rock hardness, drill rig and bit selection, bailing air volume, and engine capacity. Rock hardness is the main determinant in the drillability of a material, and the drill rig and bit should be selected for the prevailing conditions. Engine capacity is the most important factor in fitting a drill rig to the drillability of the material as it determines torque, rotation speed, and pull-down force of the rig. Bailing air, provided by an onboard compressor, is used to clear broken rock from the bottom of the hole. The airflow should be sufficient to clear rock chippings out of the hole but not so high as to cause excessive fugitive dust generation, wear on the drill string, and excessive fuel/electricity consumption.

Blasting

Ammonium nitrate-fuel oil (ANFO) is the most common and cheapest surface blasting agent, followed by emulsions and slurries. The ingredients making up the explosive substance are carried to the blasting location in separate compartments of a specialized truck. For safety reasons the ingredients making up the explosive substance are generally not mixed together by the explosives truck until it is on-site, loading the blastholes. Optimal fragmentation is usually achieved when explosives are distributed so that the lower third of the hole depth contains half of the explosive charge (Hopler 1998). If high drilling costs or problems with fragmentation are experienced, it can be advantageous to use stronger explosives or deck charges, or add additives to increase explosive energy (Bhandari 1997). Shock tube, detonating cord, and trunkline/downhole combinations of these two systems are the most common surface detonation systems. Pyrotechnic millisecond connectors are the most common delay mechanisms, although in recent years electronic detonators have rapidly been gaining ground because of unrivalled delay timing accuracy. In most applications, a detonator is used to set off a primer or booster that will in turn initiate the explosive charge.

Before charging a blasthole, it is good practice to check for water (stagnant or influx) and unexpected voids and to verify drilling was done to the planned pattern, hole depth, and inclination. If water is found, the hole should be dewatered; a polyethylene liner can be inserted and/or a water-resistant explosive can be used.

Secondary blasting may be required to break oversize boulders that are too large for the primary crusher. Mudcapping and blockholing are the two most common secondary blasting methods. Mudcapping involves molding an explosive to a rock surface and covering it with mud. Blockholing requires drilling a hole in the rock and charging it with explosive cartridges. Both processes are expensive and may well produce excessive air overpressure and flyrock. It is essential to be able to see all sides of the boulder in the case of blockholing due to the possible presence of a misfire from the initial blast. Alternatively, mechanical breakers can be used to break oversize boulders, but this technique is often inefficient when dealing with competent rock types.

Excavation

Excavation is the third main stage in the production cycle in a mine. Depending on the size of the operation and the type of haulage system, electric rope shovels, hydraulic excavators, or in some cases large front-end loaders are used in open-pit mining operations.

Equipment

Rope shovel bucket capacities have risen to just over 100 t. The largest bucket capacities for hydraulic excavators currently available are slightly lower than that of rope shovels, topping at 90 t. Front-end loaders normally have capacities of around 36 t, although there are larger models with capacities of up to about 90 t.

Until recently, rope shovels were the sole players in the 60 to 100-t range. However, there are now several hydraulic excavators competing directly with rope shovels in this size range. Rope shovels are still the standard in high-production, low-cost mines because of their reliability and long life. In the intermediate size range (30 to 60 t), the choice of equipment is to a large degree site-dependent, opting either for the flexibility of a hydraulic excavator or the reliability of a rope shovel. In the smaller size range (<30 t bucket capacity), hydraulic excavators account for almost all orders and are slowly replacing rope shovels.

The net digging force in hydraulic excavators is a combination of break-out or curling force (bucket-tilt cylinders), boom force (boom cylinders), and the crowd force (stick cylinders). In rope shovels, the net digging force consists of the crowd force (crowd machinery) and rope pull (hoisting machinery).

For hydraulic excavators, face shovel and backhoe configurations are available. Face shovel configurations are preferred in harder rock and with higher rock faces. Backhoe configurations allow for more selective digging and faster cycle times as swing angles can be reduced when loading a truck on a lower level. Front-end loaders are the preferred choice for specialist jobs where their mobility and flexibility can be used to a maximum extent. Examples include blending operations, road and infrastructure construction, working in the confined space of a drop cut, and as support or backup for larger excavators.

Excavation equipment can be evaluated in terms of productivity (metric tons per hour) and efficiency (cost per metric ton). The bucket fill factor is an important consideration in the overall productivity of an excavator and is dependent on the

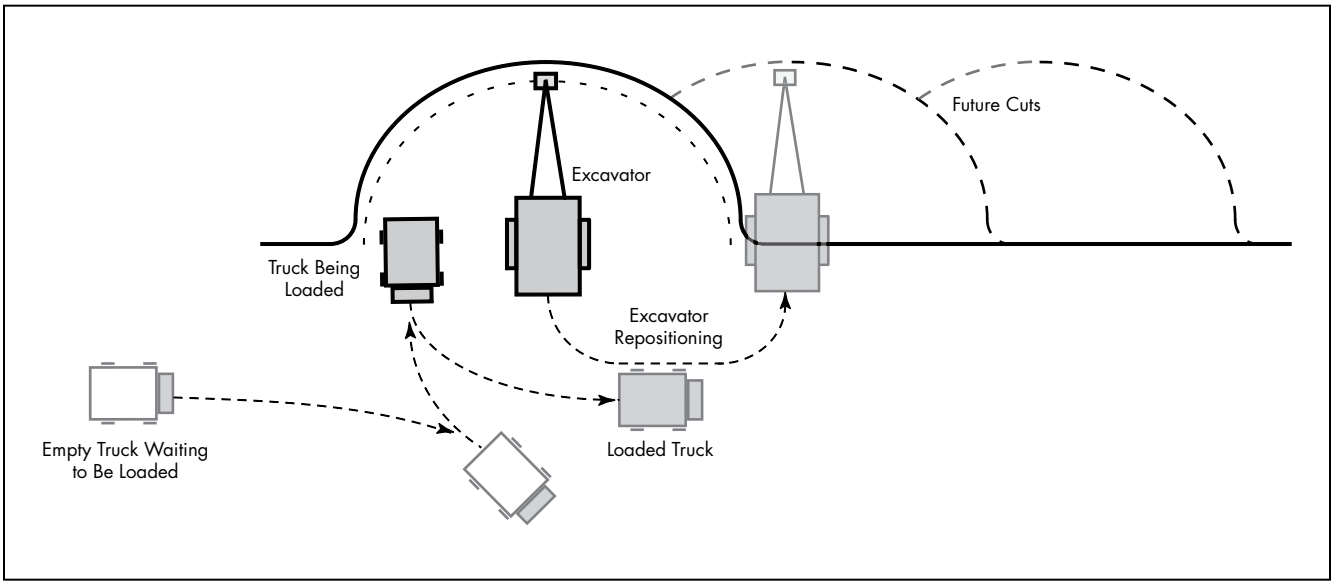
truck coverage, "diggability" of the material, operator skills, and net digging forces from the excavator. Other important factors in achieving acceptable productivity and efficiencies from excavators are matching the trucks to excavator sizes (ideally three or four loading passes), selecting the right excavator for the bench height, and providing enough working space for the excavator and trucks to operate (Hustrulid and Kuchta 2006).

Excavation Practices

Excavation of a new level often begins with a drop cut. Alternatively, when excavations are still above topography (i.e., on a hillside), a new excavation is begun from an access road without the need for a drop cut. The confined working space in a drop cut often requires the use of a backhoe excavator from the top level or a front-end loader driving in and out of the drop cut. Alternatively, a truck can turn and reverse into position next to a small excavator in the drop cut. Lateral extension of the bench is done through frontal or parallel cuts. Frontal cuts involve cutting adjacent niches into the muck pile rather than having an excavator moving with the muck pile parallel to the bench wall as done in parallel cuts (Hustrulid and Kuchta 2006).

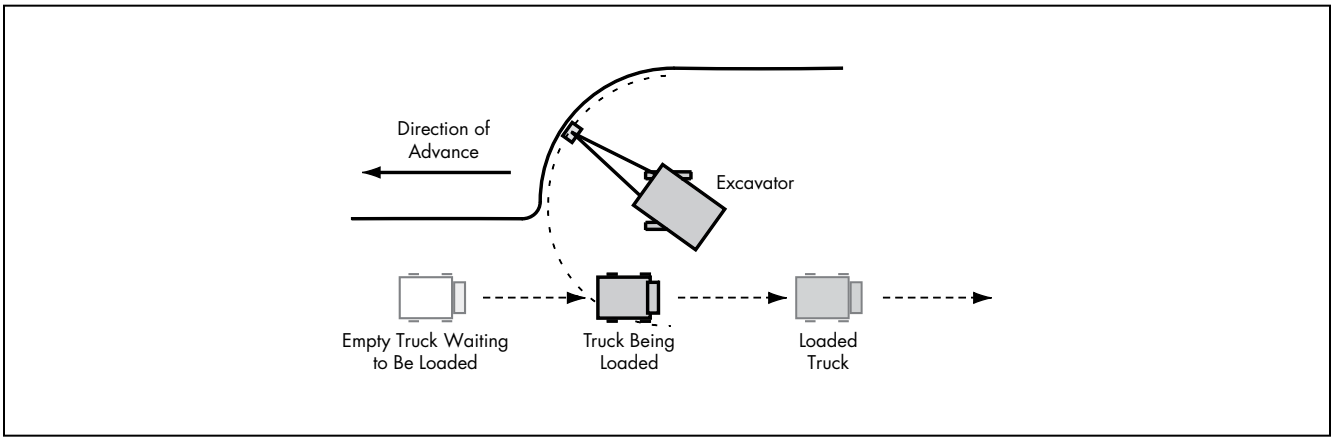
As shown in Figures 10.1-9 through 10.1-11, trucks can drive by or stop and reverse into a position next to the excavator. Hustrulid and Kuchta (2006) have written a comprehensive description of different possible modes of truck–excavator operation. According to them, available working space, the necessary swing angle of the excavator, and truck positioning time are the major considerations in the selection of the type of operation. Drive-by operations are most suitable for parallel cuts, optimizing efficiency by reducing positioning time of the truck. Frontal cuts can require excessive swing angles by the loader, making it inefficient. The disadvantage of drive-by operations is that they require larger working areas and ideally a separate ingress and egress route from the loading area. Stop-and-reverse operations can be employed in combination with both parallel and frontal cuts. They require less operating space and are more efficient from the excavator point of view. When there is sufficient space on the bench, a truck can turn without the need for reversing.

With regard to operating techniques, it is generally considered good practice to excavate the farthest or hardest-to-dig material in the first pass while waiting for the truck to position. The intermediate passes can be positioned where the operator deems fit and the last pass can be used for floor cleanup. This is only necessary when there is no dedicated support equipment for floor cleanup. Correct load placement is crucial in avoiding spillages and excessive truck wear. Ideally, loads are centered on the center line of the body (longitudinally) above the hoist cylinders of the truck (laterally) with no material on the headboard and enough freeboard on the sides and rear (Caterpillar 2006). Considering optimal loading of dump trucks, an original equipment manufacturer (OEM) recommends what they call the 10/10/20 payload policy. This policy states that "no more than 10% of loads may exceed 10% over the target payload and no loads may exceed 20% of the target payload" (Caterpillar 2006). Average cycle times range from 25 to 27 seconds for hydraulic shovels in backhoe and face shovel configuration, respectively, to an average of 35 seconds for rope shovels and 38 seconds for large front-end loaders (Caterpillar 2006). In well-fragmented rock, rope shovels commonly have bucket fill factors around 100% to 105%, for backhoe excavators this lies between 80% and 110%, and large front-end loaders generally can attain bucket fill factors between 90% and 110%. Bucket fill factors of more than 100% are achieved by heaping material in the bucket. Backhoe excavators are most efficient on benches no higher than the length of the stick with short swing angles, loading a truck on a lower level.



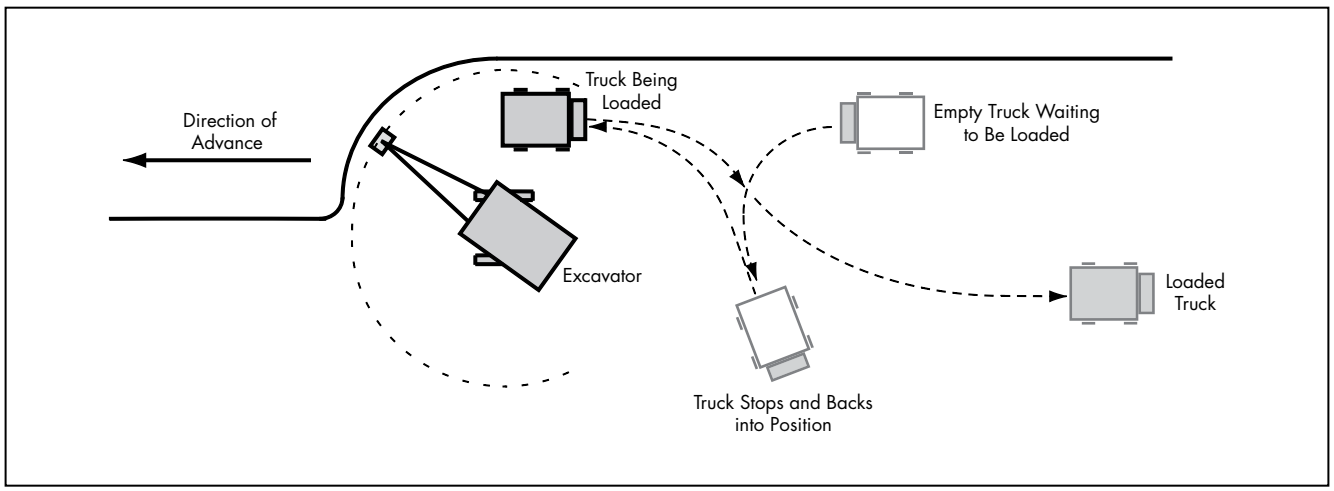
Some of the main productivity losses for excavators are idle time while waiting for trucks, excavator relocation (especially with rope shovels), poor operator skills, bad digging conditions (i.e., poorly fragmented rock, wet material, poor underfoot conditions, incorrect muck pile shape and dimensions), and unplanned downtime. For front-end loaders, there are the additional requirements of good floor condition maintenance and good drainage to prevent excessive tire damage. Careful scheduling can increase productivity by reducing idle time and excavator relocation time. Reduction of excavator cycle times can also improve the productivity of a mining operation markedly. To illustrate this point, in a typical operation, with all other factors unchanged, a reduction of 5% in the excavator cycle time can equate to up to 40 extra truckloads per day. Implementing cycle time improvements suggested by personnel, OEMs, or consultants is crucial in capitalizing on possible cycle time reductions. Among the possible improvements are better floor condition maintenance, adequate operator training, and excavator-optimized blast design to ensure the correct fragmentation and muck pile shape. Furthermore, excavator manufacturers play a pivotal role in providing technological advances such as increased engine performance, monitoring, and automation to reduce possible cycle time.

Grade Control, Reconciliation, and Selective Mining



Open-pit mining has historically been considered a bulk mining method with low selectivity. However, a global trend toward increasingly challenging open-pit mining conditions combined with the need to control costs and optimize mill performance have accentuated the need for optimum fragmentation, selective mining, and improvement in grade control. In line with this need, technological advances make selective mining increasingly feasible by decreasing the selective mining units: the minimum volume of material that can be extracted by an excavator without significant dilution. The ultimate goal of grade control and selective mining is to ensure a constant mill feed, as well as minimizing ore loss and dilution. Depending on the operation, profits from improved grade control, grade reconciliation, and selective mining can be larger than from any other operational improvement and as such they deserve thorough attention (Sinclair and Blackwell 2002).

Grade control requirements and practices are largely dependent on the commodity. First, the commodity price controls the implications of ore loss, and management has to justify the extra expenditures relating to selective extraction. Second, the increased mill performance due to lower dilution must justify any additional actions required during the mining processes. Last, the style of mineralization, often commodity-specific, dictates whether grade control is geared more toward ore/barren rock discrimination or whether it is focused on grade and stockpile control (Davis 1992).



Unbiased sample acquisition, meticulous sample processing, and accurate sample analysis on a short time scale are keys to effective grade control. In hard-rock operations, sampling blasthole cuttings is the most effective option for grade control, although sometimes a drill rig is dedicated solely to grade-control drilling (Annels 1991). In this case, timing of

Figure 10.1-11 Stop-and-reverse parallel operation

sample acquisition is crucial because of the risk of contamination during drilling. Operations mining unconsolidated material often employ a continuous trencher (commonly referred to as a ditch witch) to produce samples. Best results are obtained by trenching at right angles to the predicted ore-body orientation. Sample results should be used to model grade distributions in planning or geostatistical software, while taking into account the minimum selective mining unit of an excavator. On the basis of the produced models, a clear demarcation of ore and barren rock in active operating areas can be provided, often done using colored flags or pegs. Hanging colored ribbons down the face can further aid excavator operators in discerning ore and barren rock.

The next step in grade control is the selective mining of material. A distinction should be made between free-digging material (e.g., laterites) and consolidated material, because drilling and blasting aggravates potential ore losses and dilution (Davis 1992). In free-digging material, excavators often work across the strike of the ore body. *Flitches* refer to the steps or thin "lifts" in which a bench is mined. Depending on ore-body geometry and the minimum selective mining unit of an excavator, they can be as small as 1 m, although 2.5 m is a more common size. Ideally, mineralized portions of the flitch are removed prior to the barren rock. To minimize risk of dilution and ore loss in a drilling and blasting operation, it is important that excessive intermixing and movement of blasted material is inhibited. When a whole blast is located in ore, spacing and burden can be reduced to increase fragmentation and subsequently reduce comminution costs. Alternatively, when a blast only breaks up barren rock, increased spacings and larger burdens reduce fragmentation and decrease production costs. If ore and barren rock are intermixed on a subblast level, they are blasted together before demarcation of both zones. Bulldozers can be used to separate ore and barren rock before excavating, although this can result in "smearing" of the ore or barren rock margin. In any case, supervising excavations closely is important to ensure correct dispatching of trucks and, possibly, to visually discern ore/barren rock contacts during excavation. After the ore is loaded into a truck, it should be dispatched to the dump or the correct stockpile. The use of modern equipment dispatching systems greatly aids in dispatching trucks to the correct destination.

Apart from ore/barren rock discrimination and assigning metallurgical grades to material, grade control also provides a basis for reconciliation of mill production figures, geostatistical models, and pit production tonnages and grades (Davis 1992). Discrepancies between the mine production and mill production can serve as an indication of poor mine or mill performance, a lack of communication between different departments in a mine, sampling error, lab error, or errors in the geostatistical model.

Haulage Systems

The fourth and last main stage of the production cycle in a mine is haulage. Rigid-frame haul trucks have dominated haulage in open-pit mining operations for decades, although in some cases articulated dump trucks (ADTs) have proven a viable alternative, and sometimes rail haulage is still being used. Furthermore, longer haulage distances in many large pits, availability problems with haul trucks, and improvements in technology have revived interest in in-pit crushing and conveying (IPCC).

Rigid-frame trucks, possibly in combination with trolley-assist hauling, are the preferred choice for haulage in most open-pit mines. Compared to ADTs, they are far superior in payload capacity, achieve better speeds in most road conditions, and have lower maintenance requirements. However, in certain cases such as small-scale operations and operations that struggle to maintain adequate surface conditions, the flexibility and versatility of ADTs can pay dividends. IPCC systems are another alternative to conventional truck haulage. Whether IPCC is economically viable is a function of production, duration of the operation, and the distance and vertical lift of the haulage route.

Trucks

Payload capacities for rigid-frame haul trucks currently range from around 25 t to just over 360 t. Depending on the truck size and manufacturer, there is a choice between mechanical-drive and electrical-drive systems. Mechanical-drive systems use a diesel engine in combination with a mechanical power train, whereas diesel–electric systems rely on a diesel-powered alternator to generate electricity for electric motors (mostly AC). Diesel–electric AC systems dominate the larger truck sizes (>150-t payload), while payload capacities for ADTs generally do not exceed 50 t.

Truck cycle times depend on the type of excavator, capacity of the truck, and haulage distance. Assuming good truck–excavator capacity matching and good digging conditions, trucks can be loaded in approximately 100 to 180 seconds, although this can be longer for front-end loaders. Spotting at the excavator typically takes between 40 and 60 seconds.

In the highly interactive system of today's open-pit mine, productivity of the haulage system is largely dependent on the performance of other activities in the mine, notably the haul road and dump maintenance and the excavator efficiency. For that reason, problems with haul truck productivity and reliability can often be traced back to poor performance of other parts of the operation. The operational interdependence of haul trucks and excavators comes to light during synchronization of their use and during loading. Production scheduling can reduce idle times for trucks and excavators. Payload monitoring and good communication between truck and excavator operators is important when trying to achieve optimal loading. Similarly, good operator training as well as a high degree of coordination, communication, and visual confirmation on the part of both the excavator and the truck operator is required for adequate truck spotting. Ideally, excavator operators should communicate the correct position for a truck to the truck operator, rather than relying on the judgment of the latter to get the truck in the right place. Good communication is especially crucial when double-spotting trucks. This method has the potential to reduce excavator and truck idle time but it is more complex than single-spotting or drive-by operations. Lastly, effective dispatching can maximize the use of trucks and excavators by providing a better synchronization between the two.

Other considerations in dump truck productivity are haul road performance, floor conditions in active loading and dumping areas, and retention of material in the truck's bed. Poor haul road performance (e.g., haul road defects and high rolling resistance) can reduce productivity and reliability of dump trucks. Likewise, poor floor conditions in active loading and dumping areas (e.g., benches and dumps) can also affect productivity and reliability of dump trucks and especially their tires. In both cases, management of the floor conditions in a

manner similar to that of haul roads can have a positive impact on haul truck performance. Additionally, retention of material in both the excavator bucket and the truck bed can pose a challenge to operations, especially in arctic conditions or where material has a high clay or moisture content. Adaptation of the truck bed design (e.g., rubber floor mats or circulation of exhaust fumes through the bed to prevent freezing) can alleviate this problem.

Tire Management

Tires are a basic constituent of a dump truck and in recent years tire shortage has been a major challenge for the mining industry. Prolonging tire life can result in big savings, considering that off-the-road tires for large dump trucks can cost more than $50,000 (2009 estimate), while excessive downtime of trucks can result in even higher costs.

More than 80% of tires fail before they wear out. Of all failures, approximately 45% are caused by cuts from spilled material and 30% by impacts with large rock fragments (Caterpillar 2007). Maintaining the correct inflation pressure, maintaining good floor conditions, and ensuring good truck handling and tire awareness by operators throughout the mine are some of the main aspects that can increase tire life. For truck operators, especially when it comes to removing spillages, good communication between truck operators and the road maintenance department is crucial. Analysis of scrap tires and monitoring of tire performance can provide valuable insight into causes of tire failure and possible prevention of premature tire failure. Furthermore, as a response to tire shortages, several major tire manufacturers now offer tire management systems. These systems use software, sensors integrated into tires, and dedicated, handheld tire-monitoring devices to measure and benchmark tire performance.

Trolley-Assist Haulage

Trolley-assist haul trucks are haul trucks that have been adapted from the standard diesel–electric system to a system that relies on pantographs to connect to an electrified overhead line for power supply. Historically, use of this system has been concentrated in southern Africa, but with rising diesel prices, interest in trolley-assist hauling from other parts of the world is increasing. Major infrastructures that need to be installed for the use of trolley-assist haulage include the overhead lines, truck conversion packages, and trolley substations. These conversion packages can be fitted on the majority of diesel–electric trucks.

Increased power supply from the overhead line, compared to a truck-based diesel generator, allows maximum use of the capacity of the electric motor in a truck. As a result, reduced cycle times are possible, and consequently, truck fleets can be reduced. This allows for productivity increases and possibly reduced capital investment costs related to purchasing fewer trucks. Furthermore, as the diesel engine is idling while on trolley assist, fuel consumption and ultimately time between engine overhauls can be reduced significantly. Lastly, energy can be recovered into the trolley supply grid when trucks are moving downgrade.

There is no generic way to determine whether an operation would benefit economically from a trolley-assist system. Savings related to trolley-assist usage are directly proportional to the number of kilometers traveled on the trolley-assist line by the entire truck fleet (Hutnyak Consulting, personal communication). Other important factors to consider in determining the possible savings related to trolley-assist haulage are the truck fleet size, designed life of a ramp, vertical lift of the haulage route, and traffic densities. As such, trolley systems are not suitable for every operation. First, the number of trolley-assist kilometers must be large enough to offset additional investments required for the trolley-assist infrastructure. This is most likely in large mines with a long life and an extensive diesel–electric haul truck fleet. Second, the difference between fuel costs and electricity costs must justify the transition to trolley-assist haulage. Lastly, trolley-assist haulage inherently reduces the flexibility of a haul road system by fixing haul routes. Therefore, trolley-assist hauling is economically most attractive to extensive mines with long, permanent, uphill haul roads and a large truck fleet in regions with high diesel costs relative to electricity costs.

Higher haul truck speeds, more traction, and highly fixed routes increase the chance of rutting and other haul road defects. The main adverse effects of this are reduced productivity and possibly pantograph damage when trucks are rejected from the trolley line. Therefore, haul road maintenance is even more important on trolley-assisted haul roads. The recent adoption of AC drives now allows trucks to connect to and run on trolley assist at variable speeds, negating one of the main disadvantages in the past when they relied on DC drives. Furthermore, sensors can now aid operators in staying underneath the overhead line.

In conclusion, it can be said that trolley-assist hauling can be economically viable, especially now that technological advances have solved some former DC-related disadvantages of trolley systems. However, because of mine-specific circumstances, economic viability of trolley systems should be evaluated on a mine-by-mine basis.

In-Pit Crushing and Conveying Systems

IPCC systems typically rely on gyratory, impact, cone, or jaw crushers to feed an overland conveyor belt that transports material to the mill or overburden embankment. They can be classified into mobile and semimobile systems. Mobile systems are crawler mounted and are often fed directly by an excavator. Having capacities of less than 1,500 t/h, these systems are usually found in small open-pit mines or quarries. Semimobile systems are mostly based on gyratory crushers fed either directly from trucks or from truck-fed apron feeders. They can only be moved with specialized equipment, hence the name semimobile. Having far higher capacities (up to 14,000 t/h) than fully mobile systems, these systems are suitable for mines with very large production tonnages.

The most common conveyor belt configuration is a standard trough-type conveyor. However, this type of conveyor belt suffers from limited curve radii (minimum of ~400 m for large overland conveyor systems) and slope angles (maximum of 16°–18°) it can scale. Pipe conveyors are a relatively recent development used to negotiate tighter curves. They are essentially rubber conveyor belts folded into a pipe shape with idler rollers. As idlers constrain the belt from all sides, far tighter curves can be negotiated. A further advantage is the reduction of spillages and fugitive dust generation. The disadvantage of a pipe conveyor is its limited capacity. To overcome the slope angle limitation, conveyors can be led up switchbacks or a dedicated trench can be excavated for the conveyor belt at the desired angle. Alternatively, one of several high-angle conveyor systems can be used such as the sandwich design or the pocket-lift design. The sandwich design, as the name

suggests, sandwiches materials between two conveyor belts kept in place by idlers. The pocket-lift design relies on material being carried in pockets created by wrinkling the belt. A system similar to the pipe conveyor can also be used for high-angle conveying, provided that material is sufficiently confined.

As mentioned earlier, the economic viability of IPCC depends on production tonnages, duration of the operation, haulage distance, and vertical lift. As a general rule, it can be said that if production exceeds approximately 100,000 t/d, when haulage distances surpass 5 km or when the vertical lift exceeds 250 m and if the installation can be in operation for at least 7–8 years, the benefits of IPCC can offset the higher capital costs of this installation. The economic benefits of IPCC rely on the potential to significantly reduce truck haulage distances and consequently, fuel consumption, haul road and truck maintenance costs, and labor requirements.

Furthermore, operations using IPCC are less prone to tire, equipment, or labor shortages. Other advantages over conventional truck haulage systems include lower carbon emissions and improved safety. The resulting reduction in overall mining costs has led to a revived interest in IPCC. IPCC, especially semimobile systems, reduces the flexibility of a mining operation with respect to pit expansion and pushbacks. Additionally, crusher moves and unplanned downtime of the conveyor belt can have serious impacts on the overall productivity of the system. Careful selection of crusher locations should minimize downtime due to crusher relocation.

Advantages of IPCC systems are best realized in large, high-volume open pits with a long mine life. However, regardless of mine life and size, materializing the potential cost savings still requires a detailed economic feasibility study incorporating site-specific operational, geological, and economical aspects.

Ancillary Equipment and Mine Services

Ancillary equipment and mine services, also referred to as auxiliary operations, are "all activities supporting but not directly contributing to the production of ore" (Hartman and Mutmansky 2002). Among the more prominent and important auxiliary operations in an open-pit mine are power/fuel supply and distribution, haul road construction and maintenance, in-pit water management, and the communications infrastructure. These activities do not generate revenue directly. Nonetheless, it is critical for the overall efficiency of a mining operation that these activities are given adequate attention. Bulldozers, front-end loaders, graders, water bowsers, and fuel/lube trucks are some of the most important pieces of ancillary equipment. Graders and water trucks are absolutely essential to haul road maintenance, which in turn is one of the most important elements of an efficiently operating surface mine. The main role of bulldozers and front-end loaders is maintaining active loading and dumping areas, preventing tire damage, and ensuring effective loading and dumping.

The increasing awareness of health and safety within the mining industry has raised attention for mine rescue service. Many large open-pit mines have one or more ambulances, a fire truck or firefighting equipment, and some have advanced rescue trucks with highly trained crews available 24 hours per day to respond to emergencies. Many operations also have an airstrip or heliport locations for emergency life-flight services if needed.

With many large excavators running on electricity, the power system is undoubtedly the most important mine service. Electricity can be supplied either by a utility company (often more economical) or by an on-site generator (in remote areas). Typically, an open-pit primary distribution system consists of a ring bus or main that partially or completely encloses the pit. The distribution voltage is normally 4.16 kV, but 7.2, 6.9, or 13.8 kV are sometimes used (Morley 1990). Radial ties complete the circuit from the bus to the switchhouses located in the pit. Where necessary, substations are employed where equipment voltages are lower than the main power loop. The power distribution evolves throughout a mine life; substations and other components of the power distribution system are mobile so they can follow mining equipment into a new working area. More details on mine power supplies are found elsewhere in this handbook.

In-pit water management, lighting, and communication infrastructure are three other important mine services. The benefits of efficient in-pit water management are discussed in the "In-Pit Water Management" section in this chapter. Flood lights are important as they enable around-the-clock production, which markedly increases productivity at a modern open-pit mine, especially at high latitudes.

The communication infrastructure in mining operations is rapidly evolving into an essential part of the operation as a response to the ongoing increase in complexity of open-pit mining operations. While initially used mainly for radio communications, the communication infrastructure now also carries information essential for equipment dispatching and monitoring (discussed in more detail in the next section). A well-implemented communications structure in a surface excavation can improve safety, efficiency, and productivity by enabling real-time dispatching and monitoring of mining equipment as well as voice and video communications. Additionally, mine services such as the pumping system can now be monitored and controlled remotely; slope-stability monitoring can be centralized to a large degree; and cameras can be located in critical areas such as the digging face, primary crusher, and other key areas. Several different types of networks are available for surface excavations and the choice of system is site-specific. Open standard wireless local area networks such as IEEE 802.11b/g/n are becoming commonplace as they are cheaper and more versatile than proprietary radio systems, satellite phones, or terrestrial phones. Depending on the application, wireless networks can comprise two or more discrete points (i.e., point-to-multipoint networks) or as a more flexible, all-encompassing mesh network (e.g., Bluetooth, Zigbee, IEEE 802.15.4, or similar standards).

Equipment Dispatching and Monitoring

Advances in GPS positioning, mechanical health monitoring, and production monitoring are contributing to an ever-increasing trend toward automation of open-pit mines. Truck dispatching is now commonplace in most operations, and the benefits and potentials of various other monitoring systems are increasingly being recognized.

All major OEMs include a basic machine management package with their equipment. Their most important function is to monitor the health of vital machine functions such as the power train, suspension, and brakes to detect abnormal conditions or impending failure. By enabling proactive rather

than responsive maintenance, operator safety can be improved while significantly reducing downtime and maintenance costs. The option exists to have OEM engineers analyze the data and make maintenance recommendations remotely. These packages can be expanded with additional features to increase productivity, such as payload monitoring and road analysis in trucks; bucket load monitoring and motion tracking for excavators; and vibration reduction feedback systems, GPS-based drill positioning systems, and drill progress monitoring for drill rigs.

Equipment dispatching systems are offered by most OEMs and several third parties. Originally, these GPS-based systems were geared toward dispatching of dump trucks to the correct areas. However, by applying the same principles to drill rigs, and to ore blending, auxiliary, and other mobile support equipment, modern systems are better described as equipment management systems. Integration of payload monitoring, cycle times, and other production-related variables have further revolutionized equipment management in mines. Tracking these parameters over time allows benchmarking and bottleneck identification in the production cycle. By providing benchmarks and highlighting previously unnoticed bottlenecks in the production cycle, modern equipment management systems can prove a valuable tool in the optimization of an open-pit operation.

Extensive research is being done into the use of autonomous surface mining systems, and the first pilot-scale tests on the use of haul trucks and drill rigs are now under way. However, the use of autonomous surface mining systems is still in its infancy, and the realization of the huge potential of these systems will be an ongoing process in the next few decades. An in-depth discussion of current developments in autonomous mining systems is found in Chapter 9.8 of this handbook.

Production Planning

Adequate production planning is absolutely essential in achieving the highest possible return from a mining operation (Caccetta and Hill 1999). It is a complex process for evaluating a host of variables including ore-body geometry, mill-feed requirements, and equipment fleet-related factors to achieve the required production. Accordingly, in recent years a large amount of research has been dedicated to improving mathematical and financial principles behind production planning. On the basis of these principles, pit optimization and planning software have been developed and included in major mining software packages to aid in production planning. In many cases, production planning is not simply a case of planning the mining sequence for an ore body. Rather, it should be a cost–benefit analysis not only on the extraction of ore but also on the required development and installation of infrastructure required for ore extraction and the interaction between the two in terms of economic performance, safety, availability of labor, and availability of equipment (Hall 2009).

Depending on the type of production planning, a host of factors such as staff and equipment fleet dispatching and availability, pit expansion, processing alternatives, and commodity prices come together in production planning to meet targets set by the management of a mining corporation. It may be contracted out to a consultancy or it can be done in-house by engineers at the operation or sometimes at a dedicated office.

Production planning can be divided into long-term and short-term planning. Long-term (or strategic) planning concentrates on defining a goal and as such is undertaken on a multiple-years to life-of-mine time scale (Kear 2006). Short-term (or tactical) planning, on the other hand, is more geared toward achieving a goal and is done on a time scale ranging from day-to-day planning to multiple-year production plans. Inherently, long-term planning is more concerned with providing frameworks for pit design and expansions (e.g., pushbacks), production schedules, rehabilitation plans, and equipment selection, whereas short-term planning focuses on equipment use, maximization of productivity, and ultimately meeting productions targets. In modern operations, equipment-dispatching systems play an important role in short-term production planning. Short-term production schedules should have a degree of flexibility in them to respond to unanticipated changes in the production environment. These changes range from simple matters such as a haul road defect to complicated issues such as a slope failure. Assessment and, where necessary, adjustment of short-term production schedules as a result of these changes should be implemented in a timely fashion.

OPEN-PIT MINING AND THE ENVIRONMENT

As mentioned in the introduction of this chapter, the influence of mining on the environment is becoming an increasingly important consideration before, during, and after the mining process. As such, discussions of the environmental impacts, as well as mine closure and rehabilitation of open-pit mines, are warranted. Furthermore, to connect several other deliberations within this chapter, a discussion of geotechnical considerations and slope monitoring is included together with a section on in-pit water management.

Geotechnical Considerations and Slope Monitoring

Throughout this chapter, there have been several references to the importance of adequate geotechnical design and slope-stability monitoring of an open-pit mine. Subsequently, a generic discussion of these topics is appropriate. Readers are referred to Chapters 8.3 and 8.5 of this handbook for a thorough discussion of the subjects of geotechnical instrumentation and slope stability.

Rock mass parameters are an important consideration from the feasibility study onward; they not only affect pit layout and geometry, but also blasting practices and, to a lesser extent, mining equipment selection and the layout of the comminution circuit (Wyllie and Mah 2004). Most importantly, rock mass parameters directly determine the steepest possible slope and face angle while maintaining an acceptable factor of safety, thereby having a major influence on the profitability of an operation. Furthermore, they can rule out the use of certain areas of an excavation for important infrastructure such as the main haul road.

In an active excavation, continual slope monitoring is crucial in predicting and preventing slope failures and, when failure is imminent, mitigating the effects of a slope failure. A comprehensive slope-stability monitoring program reduces the risk of major production delays or even sterilization of part of a reserve permanently as a consequence of a slope failure. Moreover, it ensures overall safety of personnel and equipment in an operation. A survey showed oversteepened slopes, failure to appreciate the effects of water, and rockfalls to be the main causes of injuries, fatalities, and damage to equipment (Sullivan 2006). Adequate design and monitoring can largely prevent these situations from occurring. Another situation where pit-slope monitoring is important is when there are

active underground workings in close proximity to an open-pit mine. Crown pillar failure or caving-related subsidence can permanently cease surface excavation activities.

Slope-stability monitoring techniques can be divided into surface and subsurface monitoring techniques (Wyllie and Mah 2004). Surface monitoring techniques include visual survey, direct measurement techniques, prism monitoring, laser systems, and radar systems. Visual survey includes visual inspection of slopes as well as mapping of structural discontinuities (and more recently, photogrammetry). Although the discontinuity mapping and photogrammetry can provide valuable insights into failure mechanisms that cannot be gained using other techniques, they do not provide quantitative data on slope stability and therefore should be supplemented by at least one of the methods discussed in the following paragraphs.

Direct measurement techniques include crack width meters, tilt meters, and other similar devices. These are low-tech methods to provide accurate indications of minor displacements in a possible failure zone. Prism monitoring relies on the use of total stations at permanent, stable reference positions to determine the distance to prisms mounted in areas of instability. From the change in spatial coordinates of targets over time, the displacement velocity and direction can be calculated. It is a very cost-effective method but it is vulnerable to atmospheric conditions such as excessive dust or mist. Laser systems rely on a laser scanner to produce a three-dimensional point cloud model of a slope. The higher density of points compared to prism monitoring makes laser scanning more comprehensive than conventional surveying techniques. A further advantage of laser scanning is that it can aid in photogrammetry and the mapping of discontinuities. Radar systems are similar to laser systems but provide higher accuracy. The drawbacks of radar systems are that they can only monitor one single area at a time compared to a broader picture as gained through laser scanning, and they are generally more costly. However, because of the unrivaled accuracy (submillimeter), they are often used to monitor the highest risk areas, such as working faces or areas of known instability.

Subsurface monitoring techniques include time–domain reflectometry, borehole probes, extensometers, and inclinometers. These techniques rely on measurement of changes of the inclination or other characteristics of a borehole that could indicate deterioration of stability. Additionally, seismic monitoring techniques are used. These rely on geophones registering acoustic emissions associated with failure events.

The most cost-effective approach to slope-stability monitoring is generally a combination of several of these techniques where they are used to complement one another. For instance, laser systems or prism monitoring can be used to determine overall stability of pit slopes and identify possible failure zones. If instability of a slope is detected, extensometers or radar systems can be used for more precise determination of movements in this area.

A last important consideration in slope stability is the presence of groundwater. Phreatic levels in and around a mine are crucial for maintaining pit-wall stability, especially in areas with clayey material or where the rock is heavily affected by structural discontinuities (Wyllie and Mah 2004). If the climate has periods of prolonged frost, the freezing/thawing cycles can further aggravate the negative effects of groundwater on slope stability. Piezometers are the main tool for determining groundwater levels. These, together with rain gauges, can act as an early warning system and serve as a basis for adjustment of the rate of water extraction from dewatering wells to prevent groundwater-induced failures. Apart from the geotechnical implications of groundwater in and around a pit, there are also major production-related considerations associated with in-pit water. These are discussed in the following section.

With mining being a business enterprise, geotechnical design, monitoring, and stabilization of an open-pit mine is ultimately a matter of economics: balancing the benefits and costs of stabilization against the costs and implications of a slope failure (Pine 1992; Wyllie and Mah 2004). This is in sharp contrast to civil engineering where the social and financial consequences of failure can be far more extensive (Pine 1992). A combination of this different approach to risk management together with the bigger scale of potential slope failures means that civil engineering solutions to slope stabilization are generally not feasible in surface excavations. Furthermore, surface excavations can possibly tolerate a degree of slope failure that would be unacceptable in civil engineering applications (Wyllie and Mah 2004). As a result of this, lowering of the water table and decreasing the slope angle are often the only practical options in surface mining, although in some cases applying civil engineering solutions has been economically viable (Wyllie and Mah 2004).

In-Pit Water Management

Responsible water management is essential in minimizing the environmental impact of most mining operations. Furthermore, there are considerable geotechnical, operational, and economical advantages to in-pit water management (i.e., more stable pit walls and a lower stripping ratio). A sound approach to in-pit water management requires the development of drainage strategies for both surface and groundwater and continuous monitoring of the performance of the water management plan (Department of Resources, Energy and Tourism, Australia 2008). For this, a thorough assessment of local geology, rock mass characteristics, hydrogeology, surface hydrology, and local climate are required. When deciding on dewatering methods, it is important to consider not only the above-mentioned factors but also the logistics related to open-pit mine dewatering. This includes the interaction between the chosen dewatering method, dewatering-related infrastructure (i.e., power supply and water transport from the well) and unit operations in a mine (Atkinson 2000).

To maximize the advantages of dewatering, sections of an open-pit mine must be dewatered before mining begins. Ideally, wells, drain holes, pump lines, and other dewatering infrastructure are situated such that they do not require rerouting as mining progresses. Additionally, the destination of water removed from the pit is an important consideration. It can be reinjected elsewhere, used in mineral-processing operations, or it can be treated and discharged into surface water courses.

There are several advantages to a correctly implemented dewatering program. First and foremost, dewatering pit slopes improves and maintains slope stability. This results in safer working conditions and allows for steeper slopes, lowering the stripping ratio. Second, a lower moisture content of blasted material increases diggability and reduces haulage costs as dry material has a lower mass than wet material, and there is less retention of material in the excavator bucket and the truck bed. Detrimental effects of wet haul roads include unsafe traffic conditions, more tire cuts, and increased rolling resistance. Lastly, water influx into blastholes is decreased,

reducing the need for blasthole dewatering or the use of more expensive water-resistant explosives.

Rain can constitute one of the main influxes of water into an open pit. As such, a thorough understanding of the typical local climate and its extremities (e.g., monsoons) is invaluable when formulating the water management plan for an operation. Rain gauges can be a further aid, monitoring rainfall and providing an indication of increased influx and possibly the demand to adjust the pump rate.

Stream diversion and dewatering wells are the main water management activities outside a pit perimeter. Inside the pit perimeter, dewatering wells, sumps, horizontal drain holes, and in some cases drainage adits or grouting are used for water management. Stream diversion, both of permanent and ephemeral streams, is done during the development stage of a mine before or concurrent with topsoil removal. Depending on the hydrogeology, dewatering wells can be situated within pit boundaries or outside of them (Atkinson 2000). Where the direction of flow is mainly lateral, dewatering wells outside the pit perimeter are generally more effective. A further advantage of dewatering wells outside the pit perimeter is that they can be installed before mining commences. However, they are less effective at preventing vertical inflow through the pit floor. To mitigate this, in-pit (vertical) dewatering wells are more effective (Atkinson 2000). This type of well creates more drawdown in the pit than dewatering wells outside the pit perimeter, but they cannot be installed prior to mining, and it generally also requires more complicated logistics. In-pit horizontal drain holes are used for locally depressurizing targeted areas (Atkinson 2000). They are an inexpensive method that can significantly increase slope stability because the small scale of these holes allows them to be installed quickly, targeting specific problem areas. However, they can only be installed after mining begins, they suffer from freezing effects in arctic areas, and water removal usually requires a sump downstream of the drain holes. Sumps are catchment basins at the base of a pit that serve the purpose of collecting in-pit water so it can be pumped back out. Grouting refers to the injection of chemicals that block pores in the rock to provide a barrier that prevents groundwater influx. This is a costly option that is only effective if there is a very well-defined geological feature producing the majority of water influx in a pit. Drainage adits around a pit shell serve the same purpose as drain holes. Because of the labor involved, it is a very costly and inflexible option that is becoming increasingly scarce.

Environmental Issues

In recent years, the pressure on mining companies to minimize the environmental impact of their operations has increased considerably. As a result, prevention and mitigation of detrimental effects to the environment are now high on the agenda of modern operations. Some discussion of environmental considerations related to mining in general is available elsewhere in this handbook, so this chapter focuses on environmental issues specific to open-pit mining.

One of the largest environmental impacts associated with open-pit mining stems from the physical change of the landform as a result of the vast quantities of material moved (Spitz and Trudinger 2008). The physical change of the landscape encompasses both the excavation itself and the disposal sites for overburden and tailings. The excavation will have a large impact on the visual amenity of the landscape, drainage patterns, and groundwater levels. Furthermore, the higher stripping ratios and generally lower ore grades mean that surface mines vastly exceed underground mines in the overburden volume that is generated, both from ore processing and overburden. As a result, a larger surface footprint is taken up by the overburden embankments and tailings impoundment generated by open-pit mining. Associated with the larger volume is not only a larger aesthetic impact on the landscape, but also a higher potential risk of spillage of toxins into the environment. Additionally, the changes in topography make the site more susceptible to erosion. Concurrent or postmining revegetation and placement of geotextiles on erosion-prone surfaces can provide sufficient protection against both wind and water erosion.

Chemical contaminants, increased turbidity, changes in flow patterns, and higher susceptibility to flash floods are the main effects of open-pit mining on the surface water regime (Spitz and Trudinger 2008). Chemical contamination and suspended solids can generally be removed in treatment plants. Channeling or rerouting streams away from vulnerable areas can be done to prevent erosion and mobilization of contaminants. Lowering of the groundwater level in an area due to mining may result in vegetation losses (and consequent changes in fauna), ground settlement, and lower flow rates from spring-fed surface water. Most detrimental effects of groundwater level control can only be effectively mitigated after mine closure.

Effects of blasting include excessive vibration and air overpressure, as well as dust, fumes, and possibly flyrock. The maximum allowed peak particle velocity (PPV) depends on the vicinity of populated areas and national or regional regulations. The U.S. Bureau of Mines found that cosmetic damage to houses can start at a PPV of 12 mm/s at a frequency of 10 Hz. The onset of damage is dependent on both vibration frequency and construction quality of a building, but in general it can be said that a higher frequency needs a higher PPV to be damaging (Siskind et al. 1989). Flyrock should be avoided altogether. Correct blast design should minimize environmental effects from blasting, and good communication with local residents can reduce perception of blasting by the public.

In populated areas, dust, noise, and road traffic effects are more pronounced than at remote mine sites. Noise causes disturbance of wildlife and annoyances both with residents and operators. The emphasis on noise management should be on reducing noise and limiting exposure time (Department of Consumer and Employment Protection of the Government of Western Australia 2005). In this context, hearing protection is regarded as an interim noise-protection measure unless other measures are demonstrably impractical. Cabs on modern equipment are designed to reduce noise exposure and as such play an important role in limiting exposure time. Lower perception of noise by the public can only be achieved by taking noise reduction into account during production planning, control of noise at the source, and noise barriers. Typical exposure limits imposed by legislative bodies range from 80 to 90 dB(A) for average exposure levels and peak exposure levels from 135 to 140 dB(A) (NIOSH 1998).

Depending on the particle size, shape, and chemical composition, dust can cause physical or chemical contamination of equipment and soils as well as respiratory and dermatological problems, reduced visibility, and coating of vegetation

(Department of Resources, Energy and Tourism, Australia 2008). The extent of the impacts of dust is highly dependent on climatic conditions and dust composition. Dust is generated by drilling and blasting, excavation, haulage, dumping, and processing of material, or it can emanate from poorly vegetated or bare areas like tailings impoundments in combination with wind. Dust generated from drilling can be suppressed by adding water to the bailing air from the drill hole, and by employing drill deck shrouds that envelop the drill stem. Haul roads are the most significant contributor of dust in surface mine operations, emitting between 78% and 97% of all dust.

As discussed earlier in the section on haul roads, dust suppression measures include spraying with water or chemical dust suppressants, and compacting or changing wearing course material. If loading, hauling, and dumping causes significant dust release, wetting the material before excavation can be considered, although this has detrimental effects on the efficiency of excavation and haulage. Water sprays around other sources such as stockpiles and the mill can be used to prevent fugitive dust from these areas. In Australia, maximum exposure levels for PM10 (dust with a median diameter <10 μm) lies at 50 $\mu g/m^3$ on a 24-hour average (Department of Resources, Energy and Tourism, Australia 2008). Toxicity of the particulate matter is dependent largely on silica content and exposure levels should be adjusted accordingly.

An increase in mining-related surface traffic on public roads may cause congestion, damaged or polluted roads, dust, noise, and unsafe situations. Where unacceptable situations occur, other forms of haulage, careful route planning, and mitigation of effects can relieve pressure on the road network, but often the problems cannot be solved completely.

Mine Rehabilitation and Closure

The main objective of mine closure is to ensure physical and chemical stability, as well as restoration of the ecosystem in all areas disturbed by the mining operation (Spitz and Trudinger 2008).

Before closure of a mine, ore robbing or scavenging can be done. This practice involves extraction of residual ore tied up in haul roads and other areas that did not allow extraction of the ore for operational reasons. One example of ore scavenging was done at Palabora, South Africa, to supplement underground ore production. It is important to realize that ore scavenging may reduce factors of safety for slopes to dangerous levels and should only be done after careful analysis of the probability, extent, and consequences of slope failure. Furthermore, it may inhibit access into the pit, should this prove necessary in the future.

Mine closure aspects specific to open-pit mining mostly arise from the large surface impact and large volumes moved (Spitz and Trudinger 2008). Careful planning during the development and operational stage and taking into account postmining use of an operation can significantly reduce postmining site disturbances and costs. Generally, it is attempted to put the postmining landscape to an equal or better use compared to the premining landscape. Stabilization and erosion protection of steep slopes and unstable faces are crucial for ensuring physical and chemical stability. This usually involves recontouring to stabilize pit faces and embankments to approximate original contours of the landscape, followed by establishment of vegetation or liner placement for erosion protection. Flooding of the excavation allows it to be more successful at blending in with the landscape and natural ecosystem, it prevents oxidation of sulfides and subsequent potential acid mine drainage, and it aids in the prevention of reestablishment of drainage patterns. Backfilling is another option for rehabilitation of an excavation but may be a very costly option that is generally only considered when there is a depleted open-pit mine nearby, when there is an active excavation or other supply of large volume of material in close proximity to the pit to be backfilled, or when backfilling is explicitly demanded by environmental regulations.

Maintaining chemical stability of overburden and tailings typically involves the prevention of acid mine drainage and subsequent metal leaching, as well as immobilization of any other toxic chemicals left over from the mining process (Spitz and Trudinger 2008). Flooding or sealing any potentially acid-generating material prevents oxidation of sulfides and the resulting acidification of water. If mine drainage is expected to contain any contaminants, a treatment plant should be erected with sufficient capacity to treat all effluent water and possible storm surges.

ACKNOWLEDGMENTS

The authors thank their colleagues at the Camborne School of Mines (University of Exeter), as well as industry contacts and friends at various operations around the world for assisting greatly by sharing their knowledge and thoughts on various topics discussed in this chapter. Additionally, the authors are very grateful to both the Raw Materials Group, Stockholm, Sweden, for providing the production statistics on open-pit mining operations and Hutnyak Consulting for providing information on economic aspects of trolley-assist haulage. They also thank mining consultancy Wardell–Armstrong LLC for being very helpful in sharing their knowledge on many of the topics discussed in this chapter.

CHAPTER 10.2

Open-Pit Planning and Design

David Whittle

INTRODUCTION

Open-pit planning and design is a decision-making process that leads to a realistic and actionable plan to profitably harvest mineral resources. Planning can be carried out for a wide range of time frames from the very short (e.g., the next shift of mining activities) to the very long (e.g., the profitable extraction over the complete life of the mine). This chapter is focused on the long term and on the creation of long-term value. It is about maximizing the value of the mine to the company.

Excellence in long-term mine planning involves making good decisions in pit design, mine sequencing, production rate, process method, ore selection, and mining method. All these decisions need to be made simultaneously and in conditions of great uncertainty, such as the following:

- Are the geotechnical conditions well understood? Will the pit walls survive future seismic and weather events?
- What is the resource under the ground really like? How much ore is available and how will it respond to the planned processing methods?
- What will commodity price and costs be next year? In 30 years?

Welcome to the very exciting (and the very uncertain) world of open-pit mine planning and design. To excel in this field, the planning team will need to know something about mathematics and engineering, business and economics, and risk and uncertainty. It is impossible to cover all of these subjects completely in one chapter. Therefore, this chapter has been written to equip the reader with a basic framework and a good set of analytical tools to allow one to have a fair degree of competence in open-pit mine planning. The chapter is organized as follows:

- **Planning process:** This section describes an overall planning process for open-pit mine planning and design.
- **Principles:** This section outlines guiding principles for the open-pit mine planning process. Adoption of these principles is a major assumption for the rest of the chapter. For example, net present value (NPV) maximization is established as the primary objective, and this is treated as an assumption in the rest of the chapter.
- **Open-pit planning techniques:** This section provides information on basic techniques used in open-pit mine planning. Techniques are presented in their approximate order of application.
- **Models and tools:** This section provides information about model structures, optimization, and workshop techniques.

PLANNING PROCESS

The process described is generic and can be adapted for many types of projects, including open-pit mine planning. The process is summarized in Table 10.2-1, and the details are provided in the following discussion. The process is described as a sequence of steps for clarity. In practice, however, it is not uncommon to cycle back to earlier steps. For example, when new information becomes available in Step 2 (preparation of inputs), it may give rise to a change in the purpose and scope of the study (Step 1).

The whole process may be applied once, or iteratively to cover the range from a broad study of resource potential, to a narrow optimization study intended to generate a detailed actionable plan. The difference between the broad and narrow application is reflected in the study's purpose and scope.

General Preparation

Any open-pit mine planning process requires leadership, management, and resources, with responsibilities shared by a number of people. Example responsibilities and role assignments are shown in Table 10.2-2.

Stakeholder analysis is conducted to determine the purpose and scope of the process, to generate inputs to the study, and to define the structure of the outputs. Engagement should be considered with all stakeholders, including internal stakeholders (e.g., senior management, planning team members, users of the plans, and resource providers) and external stakeholders (e.g., investors, customers, government agencies, and local communities).

David Whittle, Global Manager, Planning Leadership Program, BHP Billiton, Melbourne, Victoria, Australia

The Steering Committee defines the purpose and scope of the study, subject to the outcomes of the stakeholder analysis. Examples of purposes and scopes are provided for different study types in Tables 10.2-3 and 10.2-4.

Preparation of Inputs

The next five subsections provide guidance on the main categories of information that should be prepared for the open-pit planning process. Much of the information will be uncertain, and one of the principles, described later, is to treat uncertainty explicitly. One of the ways to deal with uncertain data is to employ the method described in the "Workshop for Building a Model of Highly Uncertain Data" section near the end of this chapter.

Resource Information

Information concerning exploration and mining rights in and near the area of interest must be prepared. If the scope of the mine planning project extends to possible acquisitions, then information should be gathered about the mineral rights held by others at nearby properties. The rights held by others for alternate resources on the property should also be considered. For example, it is not uncommon for coal rights and coal-bed methane rights to be issued separately. Although these rights apply to different resources, it is very difficult to harvest one resource without impacting operations designed to harvest the other. Separately held rights can lead to very significant operational constraints and should be considered early in the planning process.

Block models should be prepared for the areas of interest. The reader is referred to the "Resource Models" subsection later in this chapter for information about block models.

Current Operations

The following information about the current state of the operation needs to be obtained or prepared:

- A process flow sheet encompassing mining, operations, and shipping operations (if applicable)
- Bottlenecks in the business:
  - The current bottleneck (the component in the flow sheet that determines overall system output) with information about reliability and throughput variance
  - Growth bottlenecks (what is standing in the way of mine expansion?)
- Significant drivers of recovery, dilution, loss, time in process, and cost
- A cost model detailing fixed and variable costs for each part of the process flow sheet

Project Alternatives

Information about potential technology alternatives for the expansion of an existing mine or the development of a new mine must be prepared. It may helpful to conduct a brainstorming session to generate a broad range of alternatives for consideration. The reader is referred to the "Workshop for Framing" section near the end of this chapter for further information.

For each alternative, information must be prepared that includes performance expectations (expected throughput rates and variances, etc.) and cost data (capital, fixed, variable, and terminal costs).

Table 10.2-1 Steps in the process

Step	Action	Details
1	General preparation	Assign roles (Table 10.2-2). Perform stakeholder analysis. Determine purpose and scope.
2	Preparation of inputs for the study	Prepare the following: • Information about exploration and mining rights in the area of interest • Resource information, including reports, maps, drill-hole data, and block models for the area of interest • For existing mines, information about the mining operations and equipment, processing facilities, and infrastructure (Include data for operational performance, variability, capacity, and costs.) • Information about alternate mining and processing methods that may be considered in the study • Information about applicable mining and environmental laws and details of exploration and mining rights • Forecasts of future commodity demand and price • Forecasts of future costs
3	Framing	Determine the set of decisions and alternatives to be tested as part of the study.
4	Assessment	Conduct the modeling, optimization, and economic evaluation of alternatives. Conduct risk assessment on main candidates for selection.
5	Selection	Select the best alternative plan(s). Select the actions to preserve future options.

Table 10.2-2 Planning project roles

Typical Role	Responsibilities	Typical Composition
Steering Committee	• Conducts the stakeholder analysis • Sets purpose and scope for the study • Provides resources (including personnel) • Monitors progress	Heads of departments who provide input or people to the planning process
Planning project manager	• Manages the process. • Ensures study objectives are met within budget and on time	A person with project management and mine planning skills
Planning team	• Conducts the work	Full- and part-time members with appropriate skills for the work to be completed

Whenever the term *expected* is used in this chapter, it should be understood to mean "qualitatively," that is, "the most likely." If a mathematical definition is preferred, then it should be defined as "the probability-weighted mean of all possible values."

For legal, environment, and community issues, information should be prepared about mining and environmental laws, applicable to the area of interest, that will potentially limit the approach to mining or processing, or affect costs.

In relation to local communities, information should be prepared to address the following:

- The potential for the community to provide people, services, or infrastructure
- The expectations of the community to share in the benefits of the mine proceeding

Table 10.2-3 Example purposes and scopes for different types of studies for an existing mine

Study Type and Frequency	Purpose	Scope
Resource potential study Frequency: Every 3 to 4 years or whenever key information (price forecasts, resource estimates) changes significantly	Explore a wide range of expansion and development options in pursuit of maximum value	• No constraints on capital or on major changes to the operation • Short- and medium-term (<3 years) optimization decisions are not considered • Long-term price forecasts are considered
Life-of-mine plan Frequency: Updated annually	Determine the actionable life-of-mine plan that will maximize value, provide the basis for reserve reporting, and set the scene for medium-term production planning	• Major operational changes are subject to permitting and capital approvals • Focus on value-maximizing optimization decisions • Long-term and short-term price forecasts are considered

Table 10.2-4 Example purposes and scopes for different types of studies for a potential mine or a mine expansion

Type	Purpose	Scope
Concept study	Seek to identify a concept for development or expansion that has a reasonable prospect of creating value	• No constraints on capital or on major changes to the operation • Short- and medium-term (less than 3 years) optimization decisions are not considered • Long-term price forecasts are considered
Prefeasibility study	Examine a wide range of strategic alternatives for development or expansion, and select the single plan that would create the greatest value at an acceptable risk	• Major operational changes are subject to permitting and capital approvals • Focus on value-maximizing optimization decisions • Long- and short-term price forecasts are considered
Feasibility study	Optimize the single plan (output from prefeasibility study) to create an actionable plan that meets company requirements for investment approval	

- The community's concerns regarding safety, noise, dust, and impacts on the environment
- Any other factors that may lead to the community being negatively or positively impacted by the mine

In evaluating matters relating to legal, environment, and community, it may be relatively easy to determine the minimum requirement for compliance, and a desire to minimize costs may be the motivation to pursue that outcome. However, planning only for minimum compliance may not be the most effective way to progress a project. The government and community are significant stakeholders, and their support for the project will be strongly influenced by the mine's ability to meet their needs and expectations. Accordingly, it is important to evaluate other alternatives that seek to actively garner the support of government and communities. Not only the costs associated with different alternatives should be considered but also their potential to avoid or cause delays and impacts on social license.

Prices

Commodity price is the single most important variable impacting critical mine-planning decisions. It has a direct bearing on the optimal rate of production, the final pit size, and the desired degree of operational flexibility that is built into the operation. If it were possible to know future prices with certainty and precision, that knowledge could be applied as follows:

- Near-term prices up to about 10 years into the future have the greatest impact on the determination of the optimal production rate for the mine.
- The price at the end of the mine's life has the greatest impact on the size of the final pit.
- The variable nature of the price (measured over 3 to 36 months) has the greatest impact on the degree of flexibility designed into the operation.

Commodity price is, however, the most difficult variable to predict. Many different forecasts can rationally be made for future prices, and they all have one thing in common—they are all almost certainly wrong. Because of this, a mine should not rely on only one price forecast. It should use at least the following three:

1. Mid-price forecast: The expected price
2. High-price forecast: A somewhat optimistic forecast
3. Low-price forecast: A somewhat pessimistic forecast

Price forecasts are generally sourced from either the mining company's economist or an external consultant or research company. Whatever the source, it is important to recognize that forecasts do not normally model all aspects of future price behavior. This fact becomes apparent when a comparison is made between a chart showing historic prices and a corresponding price forecast chart (e.g., see Figure 10.2-1). They are characteristically different. A historic price chart will show the price as it happened—subject to the effects of market discontinuities, changes in economic conditions, investment cycles, balances and imbalances between supply and demand, and the influence of market speculators. None of these price drivers can be predicted with certainty, and some cannot be predicted at all. Forecasts can only be made based on scenarios. The following are some example coal price scenarios:

- Declining coal resources will constrain supply, leading to a price increase.
- Ongoing mining technology improvements will reduce coal industry costs, thereby reducing the coal price.
- Coal supply currently exceeds demand, and when marginal producers close down, prices will rise.
- Emerging clean energy technology will reduce the demand for coal, leading to price decline.
- Economic growth in developing nations will increase the demand for coal, thereby increasing price.

Consequently, most price forecasts are, in effect, straight-line assumptions modified by a scenario. Examples of simple forecasts are provided in Figure 10.2-1.

In addition to the simple models for price forecasts, planners are increasingly using stochastic models for price in an effort to better plan for the random nature of prices. Methods include *random walks* and *mean reverting random walks*. The

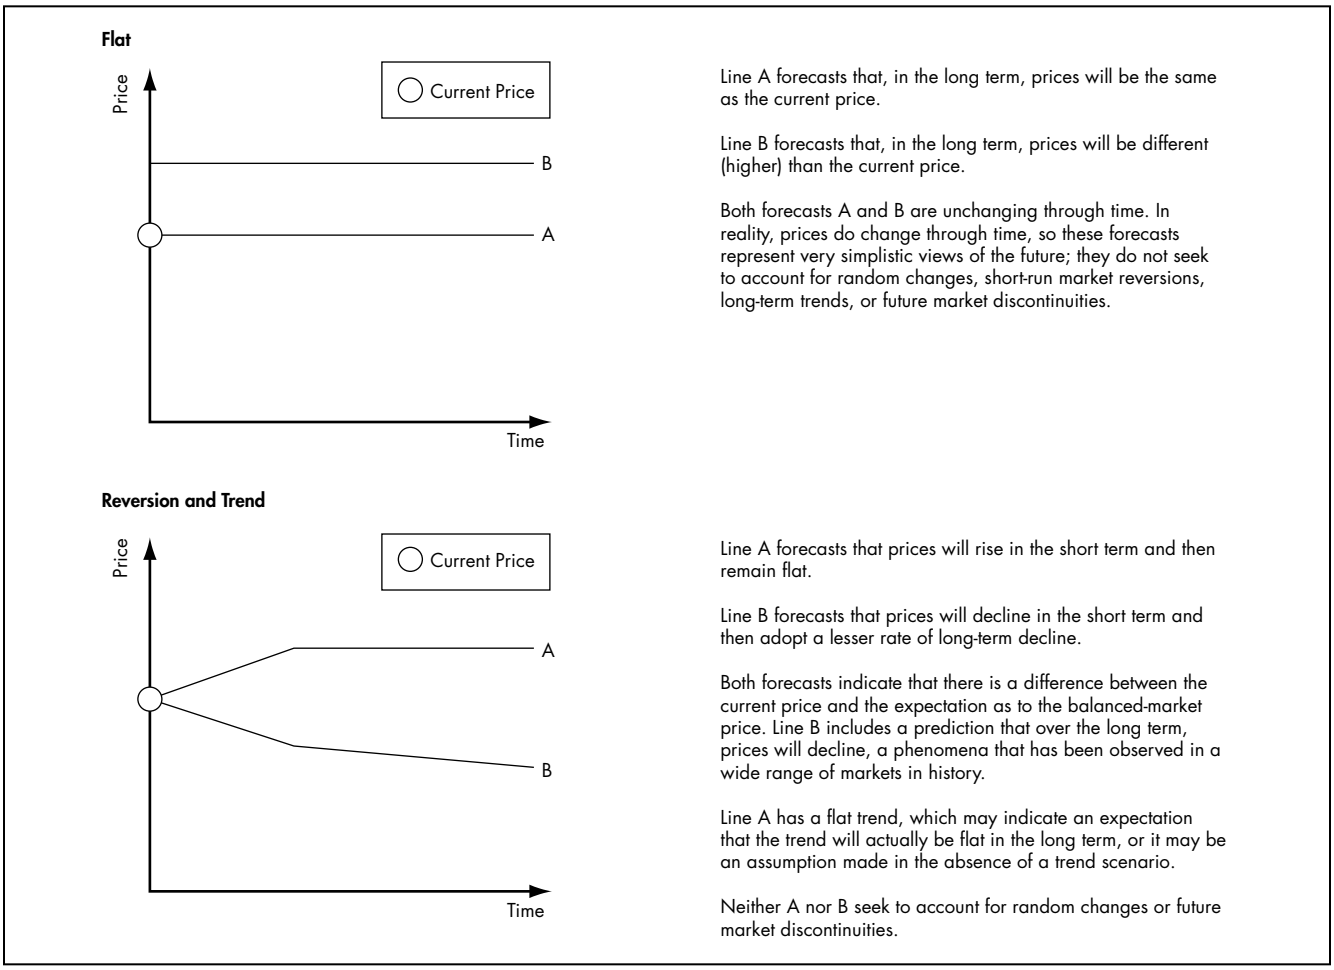

Figure 10.2-1 Simple price forecasts

use of these approaches can lead to better decisions as to the degree of flexibility in an operation; however, the detailed discussion of these methods is beyond the scope of this chapter.

When obtaining price forecasts, one should inquire as to the following:

- What aspects of future price behavior (long-run stable price, long-run trend, near-term reversion, short-run random) are modeled in the forecast?
- Is the forecast in real or nominal currency?
- Are there intentional biases (i.e., intentionally conservative or optimistic) in the forecast?

Most planning should proceed with the mid-price forecast, but the high- and low-price forecasts can be used to test sensitivities and to develop options.

Most planners are familiar with sensitivity analysis. The idea is to determine how much a project value changes with a change in a major input variable. Sensitivity analysis often proceeds by varying the input variable by an arbitrary amount (e.g., ±10%). However, the results of the sensitivity analysis would be a lot more useful if the cases tested were more representative of the uncertainty in the input variable. The high- and low-price forecasts should serve this purpose. Apart from their use in sensitivity analysis, high-price and low-price forecasts can also be used to develop options, discussed later in this chapter.

Costs

All costs need to be rendered in a structure suitable for cash flow modeling in one or more optimization systems. Planners should not rely on only one set of cost forecasts but instead should use at least the following three:

1. Mid-cost forecast: The expected costs
2. Low-cost forecast: A somewhat optimistic forecast
3. High-cost forecast: A somewhat pessimistic forecast

Some costs are market based, and the concepts and models described for forecasting prices may equally be applied to the forecasting of market-based costs. Examples of market-based costs include oil, shipping, equipment, and construction services.

Assumption Sets

To facilitate the assessment of alternatives, it is very useful to define and document a number of assumption sets. Each assumption set consists of price, cost, and geological and operational settings. The first assumption set should be the reference assumptions set and should include price forecasts at expected values (the mid-price forecast) and cost, recovery, throughput rates, geological and geotechnical models (including pit slopes) at expected values.

Secondary assumption sets may be built to represent different scenarios for future conditions or resource quality/volumes. The following are examples:

- **High-price assumption set:** This is the same as the reference assumptions set except that the high-price forecast is used (along with any associated impacts on costs).
- **Low-price assumption set:** This is the same as the reference assumptions set except that the low-price forecast is used (along with any associated impacts on costs).
- **High-resource assumption set:** This is the same as the reference assumptions set except that the high-price case from the resource range is used.
- **Low-resource assumption set:** This is the same as the reference assumptions set except that the low-price case from the resource range is used.

Each of the above-mentioned assumption sets should have a reasonable (>10%) probability of being the most representative of current or future facts. As analysis continues, more assumption sets may be created. For example, in testing a broad range of production rates, the impact of rate on mining width, dilution, and other factors should be carefully considered, and appropriate assumptions should be determined and documented.

In some cases, market-based cost movements are correlated to commodity price movements. If that is the case, then the correlation should be reflected in the high- and low-price assumption sets by including corresponding changes to the correlated costs.

Framing

The framing process leads to a set of high-order decisions and alternatives to be tested as part of the study. The result of the framing exercise is a strategy table, an example of which is shown in Table 10.2-5.

Table 10.2-5 Example of a strategy table showing key decisions (column headings) and alternatives*

Mining	Processing	Water	Power	Transportation
Current plan (sublevel stope mining)	4.5 Mt (current)	3,000 ML artesian (current)	Gas-fired (current)	0.75 Mt truck and rail (current)
Open pit in northern zone; continue sublevel stope mining in southern zone	6.0 Mt (brownfield)	6,400 ML artesian	Expand gas-fired to pipe capacity	**Concentrate slurry pipeline**
Open pit in northern zone with new decline from base of pit	10 Mt (brownfield)	**3,000 ML artesian plus desalination to meet demand**	**Grid connection**	1.5 Mt truck and rail
Open-pit everything	**11.5 Mt (7-Mt greenfield)**			

*A hypothesis is represented by the choice of one alternative from each column. A "big capital" hypothesis is indicated in bold type.

Assessment

The framing exercise gives rise to a set of hypotheses (possible best planning decisions) to be tested. Each hypothesis should be subject to simulation and optimization to determine its economic value. The initial assessment should be conducted using the reference assumptions set. This assessment will reveal which set of decisions yields the highest value. The structure of the conclusion is as follows: *If* the reference assumptions set is true, *then* the [defined set of] decisions are optimal.

Example 1. Using the reference assumptions, a pit of 60 Mt ore feeding a 5-Mt processing plant is optimal.

Assessment should continue with the application of other assumption sets to determine the optimal set of decisions for each. The generalized structure of the conclusions is as follows: *If* the [named] assumptions set is true, *then* the [defined set of] decisions are optimal.

Example 2. If the high-price assumptions are true, then a pit of 75 Mt ore feeding an 8-Mt processing plant is optimal.

The final stage of assessment involves identifying a list of candidate decisions to carry forward and subjecting these decisions to risk assessment.

Selection

The plan is selected based on the assessment results. The following is a recommended structure.

- **Best-case plan:** A theoretical best-case plan with few constraints and no secondary objectives applied. This is generated using the reference assumptions set. For further information, the reader is referred to the "Establishing a Theoretical Best-Case Plan" section later in this chapter.
- **Optimized plan:** The plan based on decisions that are optimal for the reference assumption set, with all constraints and secondary objectives applied. The NPV change associated with the application of constraints and secondary objectives should be documented.
- **Risk management actions:** These are modifications to the optimized plan designed to manage risks identified in the risk management process. The cost to NPV resulting from the application of risk management actions should be documented. For further information, the reader is referred to the "Identifying and Managing Risk" section later in this chapter.
- **Option preservation actions:** These are modifications to the plan designed to respond to alternate assumption sets. A simple model for the preservation of options can be applied.
- **Final plan:** This is the optimized plan as modified by the risk management and option preservation actions.

PRINCIPLES

The following principles are posited as a foundation for open-pit mine planning:

- Employ evidence-based decision-making methods.
- The primary objective is the maximization of NPV.
- Treat secondary objectives as constraints.
- Do not apply public reporting rules to the input of the planning process.
- Deal with uncertainty and risk explicitly rather than by practicing conservatism.

Details of each principle are discussed in the following four sections.

Evidence-Based Decision Making

Evidence-based decision-making methods should be employed as follows:

- Seek to avoid bias in data gathering and in decision making.
- Assess information for its probability of being correct or predictive.
- Account for gaps in information and understand how those gaps contribute to uncertainty.
- Avoid using rules of thumb. Rules of thumb are simple approximations or rough methods for estimating or measuring something. They are usually handed around from person to person without sufficient explanation of the limitations and hidden assumptions underpinning them. Such approximations are only useful if all their limitations and hidden assumptions are understood.
- Apply defined decision-making processes and analysis methods. For example, applying the processes and methods described in this chapter will help to avoid making poor decisions.
- Learn to recognize and avoid logical fallacies. An example of a logical fallacy is: "The mine must be either open pit or underground." This example is called a false dichotomy because in reality there are other possible choices (e.g., a combination of open-pit and underground mining and in-situ leaching). Interested readers can find information about logical fallacies on the Internet.

Primary and Secondary Objectives

The primary objective is the maximization of NPV. This is the one goal that must be achieved, subject only to the constraints of the secondary objectives. The pursuit of the primary objective is one of optimization, and only the maximum possible value will be satisfactory.

The primary objective is a matter of choice for a company engaged in the planning activity, and a company is free to choose any primary objective it likes. However, in mining, NPV maximization is a very common primary objective, and with a desire to elevate its readability, this chapter has been framed with the assumption that NPV maximization is the primary objective.

Secondary objectives should be treated as constraints. In the mathematical framework for optimization, it is only possible to have one objective (to be minimized or maximized). However, in business, it is not uncommon to nominate multiple objectives. To profitably employ the mathematical frameworks for optimization in open-pit mine planning, one of the objectives must be nominated as the primary (e.g., maximize NPV) and all other objectives treated as constraints. Constraints are specified by minima or maxima (or both) and act to limit or modify the pursuit of the primary objective. Examples of secondary objectives are shown in Table 10.2-6.

Secondary objectives applied as constraints cannot enhance the pursuit of the primary objective; they can only inhibit it. A sacrifice is made on the primary objective (i.e., NPV is reduced) when a secondary objective is applied. Secondary objectives should only be applied sparingly, and the resultant sacrifice of NPV should always be reported.

Separation of Public Reporting from Planning

Public reporting rules should not be applied to the inputs of the planning process. This principle is particularly important when considering publicly reported mineral resources and ore reserves. Rules for public reporting are framed to provide a basis for consistency in reporting across all reporting entities and act as a filter on available information. For example, the Joint Ore Reserves Committee (JORC) Code requires the competent person to make a preliminary judgment as to the technical and economic factors likely to influence the prospect of economic extraction and to apply those factors to ensure that the reported mineral resources have a "reasonable prospect of economic extraction" (JORC 2004). (The JORC Code applies in Australia, but provisions are similar in many other jurisdictions.)

The competent person's preliminary judgment as to economic factors acts as a filter to the full range of data regarding in-situ mineralization. It is much better for mine planners to be exposed to the full range of data regarding in-situ mineralization, including inferred resources and potential mineralization beyond inferred resources. The planner can then apply more comprehensive economic criteria and analysis to determine the subset of in-situ mineralization that is economically extractable.

When the planning process is complete, the rules and conventions of public reporting should be applied to generate accurate public reports.

Explicit Treatment of Uncertainty and Risk

Uncertainty and risk should be dealt with explicitly rather than through the practice of conservatism. It is common for mine planners to practice conservatism as a means of dealing with uncertainty or reducing risk. Two examples are (1) deliberately overestimating costs to compensate for the potential for costs to be accidentally underestimated, and (2) deliberately underestimating the grades to compensate the potential for accidentally overestimating them.

- Acknowledge that there is uncertainty associated with most inputs to the mine planning process.
- Understand the inadequacy of single estimates of uncertain inputs. Even when a single estimate is an expected value, its exclusive use can lead to poor planning decisions because it does not represent the probabilistic range. An uncertain input is best represented as a continuous or discrete probability distribution, and the full range of potential consequences of that distribution must be understood.
- Risk management should be applied when the full range of consequences of input uncertainty is understood.

OPEN-PIT PLANNING TECHNIQUES

Basic Technique for Generating Life-of-Mine Plans

Table 10.2-7 shows a recommended series of steps to achieve the technical design of an open-pit mine and its long-term schedule. The steps are iterative, and at various points it is necessary to cycle through the steps in the pursuit of a good overall plan.

Pit Parameterization Methods

Applying pit optimization to a single resource model and a set of assumptions will produce one pit outline—the outline that maximizes the net cash flows (undiscounted) for a mine and often called the "cash pit." However, it is useful to have a number of pit outlines available for analysis—to be used as candidates for final pit designs and pushback designs. A technique pioneered by Matheron (1975), referred to as pit

Table 10.2-6 Examples of secondary objectives

Secondary Objective (Constraint)	Rationale
Maintain a favorable position on the industry cost curve. *Example:* Do not exceed a cash cost of $0.80/kg.	Reducing costs is always a sub-objective to maximize profit. However, for strategic reasons, low costs may override the objective to maximize profit. This is the case if a company has a relative cost objective—for example, to only produce copper if it can be produced at a marginal cost in the bottom half or quartile of the marginal costs for the industry.
Declare a large reserve. *Example*: Plan a mine that will allow the reporting of a minimum reserve of 5 Mt.	A major nonfinancial measure used in the valuation of shares is the reserve. Appleyard (1997) writes: "The reserve is probably the major input in a company's ability to raise debt or equity finance and, if listed, in its rating on the share market." In seeking to maximize their share price, some companies may be prepared to sacrifice NPV to quote a higher reserve.
Conserve capital. *Example:* Do not exceed $100 million in capital spending.	It is sometimes not possible to access the capital required to achieve the optimal rate of production.
Stretch the mine life so that it spans at least two price cycles. *Example:* Reduce the production rate to ensure a mine life of at least 10 years.	Many commodity prices are thought to have cyclical behavior. For example, every 3 to 7 years, the price will move from high to low and return to high again. The risk of having too much of the mine life occurring in low-price times is reduced if the mine life is extended.
Avoid risk. *Example:* Invest in the $50 million processing plant that can be funded from free cash flow, even though the $100-million processing plant promises a higher NPV.	Walls and Eggert (1996) performed some research on the decision-making behavior of mining CEOs and found that they do not generally make highest NPV decisions—their decisions being tempered by risk-averse behavior. Walls found that CEOs of smaller mining companies tend to be more risk-averse and suggested that this is because for small companies, the higher risk projects carried with them a greater risk of company failure. Smith (1997) suggested that, rather than choose the maximum NPV production rate, this rate should be seen as the maximum rate and that the actual rate should be less. Part of the reasoning behind the attenuation is that a maximum NPV production rate tends to lead to an unreasonably short mine life, leaving minimum time to recover from early difficulties.

parameterization, harnesses the pit-optimization process to deliver a set of nesting pit shells that serve the purpose well. Several pit parameterization techniques are now in use, each with varying advantages and disadvantages. The following techniques are described in this section: revenue factor, cost factor, vertical bounding, and mining direction.

Revenue Factor

In the revenue-factor technique, a range of factors is applied to the block revenue to alter its value in consecutive optimization runs. The application of a lower revenue factor leads to ore becoming less valuable or being reclassified as waste, and this in turn leads to a smaller pit. A typical range of revenue factors is 0.10 through 1.00 in steps of 0.01. By running pit optimization repeatedly with incrementally different revenue factors, a range of pits from large to small is obtained. The pits so produced are often referred to as shells and are numbered 1-*n* from smallest to largest. The shells do not overlap and are good candidates from which to choose pushback designs.

Cost Factor

Similar effects can be obtained by applying factors to either mining or processing costs or by direct manipulation of cutoffs. A typical range of cost factors is 1.00 through 20.00 in 100 equal steps, with higher cost factors yielding smaller pits.

The main advantage of this class of pit parameterization is that it usually gives rise to a large range of shells that, if used as the basis of pushback designs, can lead to high NPV. The main disadvantage is that the shells for vertically oriented ore bodies are often impractical, with shells forming as concentric rings, sharing no common wall.

Vertical Bounding

The vertical-bounding technique starts with all benches in the model being sterilized, with the exception of the highest bench.

Table 10.2-7 Typical steps in creating an open-pit plan

Step	Details	Reference Sections in This Chapter
1	Choose a hypothesis from the strategy table (Table 10.2-5) to test. Prepare an assumption set and a resource model for analysis.	Workshop for Framing Assumption Sets Resource Information
2	Apply a pit optimization tool to generate a set of pit shells.	Pit Parameterization Methods Mine Planning Optimization
3	Determine a theoretical best-case plan and choose the final pit.	Establishing a Theoretical Best-Case Plan
4	Choose the production rate.	Determining the Optimal Production Rate
5	Choose a plan for a final pit.	A Plan for a Final Pit Allowing for Topographical Features Allowing for Blending
6	Choose the number of pushbacks and their basic design.	Pushbacks Allowing for Mining Width
7	Optimize the schedule and processing cutoffs.	Determining Processing Cutoffs Mine Planning Optimization

The pit optimizer is run only on the top bench, and this may or may not lead to the creation of a pit (depending on whether there is any ore in the top bench). The process proceeds by progressively unsterilizing benches in the model and rerunning the pit optimizer. The result is a set of nested pits, and the advantage of this approach is that the shells that it produces can often have a better mining width at the base of pushbacks compared to the revenue-factor or cost-factor approaches. The main disadvantage is that this approach may provide too little or too much working space, depending on the nature of the ore body, and there is not much that can be done to make the optimizer produce a better outcome.

Mining Direction

The mining-direction technique is similar to the vertical-bounding technique, but the progressive unsterilization is done in a direction chosen by the planner. In many circumstances, the nested pit shells produced by the technique are more practical than those produced by other techniques, as there is a propensity for shells to have a common wall. The technique is implemented though user-defined formulas in the pit optimization software, acting to progressively unsterilize blocks according to their distance from a defined point or plane in the model. The process is normally run several times using different origin points or planes. The results can then be compared and evaluated based on their NPV and practicality.

The main advantage of this technique is that it can quickly generate a range of alternative sets of pushbacks that are more practical to mine.

Establishing a Theoretical Best-Case Plan

When applying optimization tools to open-pit mine planning, it is useful to start by generating plans that have as few constraints as possible. This theoretical best-case plan can be prepared as follows:

1. Generate multiple pit shells using the revenue-factor method and use all of them as pushbacks. This may lead to an unusually high number of pushbacks, but that is of no concern when creating this theoretical best-case plan.
2. Apply a simple schedule that limits prestripping (e.g., one that mines out each pushback in turn) or apply schedule optimization.
3. Only apply one production constraint at a time (i.e., only one of mining, process, or selling limits) and experiment with that limit over a wide range until NPV is maximized.
4. Do not apply sinking rate limits or mining-width constraints.
5. Ignore all secondary objectives.

The plan will almost certainly be impractical, but it provides a very useful internal benchmark for the project. The benchmark can be used to evaluate the NPV impact of imposing secondary objectives and of the constraints applied to make the plan more practical. When a practical plan can be created with an NPV close to the theoretical best-case plan, then it is known to be a good plan (practical and with a high value), and there is little to be gained by further refining the pit designs and schedules.

Determining the Optimal Production Rate

The optimal production rate is the rate at which NPV for the project is maximized. The simplest method to determine the optimal production rate is to calculate the NPV for a range of different alternatives. The testing is done by scheduling the mine for a range of different assumption sets, with each assumption set representing a different production rate alternative with its associated capital; variable costs; fixed costs; and selectivity, pit geometry, and infrastructure requirements. As the rate increases, there are several impacts on operations and efficiencies in the pit, and these should be reflected appropriately in the assumption sets. The following are examples:

- Congestion will increase, leading to longer cycle times unless additional mining width is provided.
- Larger equipment may be required, leading to an increase in the size of the selective mining unit and an increase in dilution and/or mining loss.
- Demands on ramps will increase, leading to a need for wider or additional ramps.

The expenditure of capital unlocks productive capacity. If the level of capital spending is increased, it causes some upward and some downward impacts on value, as follows:

- The capital spending reduces the NPV directly.
- The capital spending increases production throughput, which in turn increases net positive cash flows in each period and increases the NPV.
- The mine life is reduced, thereby reducing the number of periods in which positive NPV can occur and bringing forward terminal costs.
- The fixed costs per period associated with maintaining the level of production may go up.
- The variable costs associated with processing each unit of production may go down.

The results, once graphed, should be a convex curve, such as the one shown in Figure 10.2-2.

The overall production rates for metals mines are ordinarily set by the comminution (crushing and grinding) function, whereas for other types of mines, the pace may be set by a different part of the value chain. For example, in an iron ore operation, the pace is likely to be set by the capacity of the rail network or the port.

Why are they different? In each case, the pace is set at the economic design bottleneck, that is, that part of the process chain that *should* be designed as the bottleneck of the operation. The choice is based on examination of the capital costs and fixed costs of different parts of the process chain. Considering only capital costs for a moment, the economic design bottleneck is that part of the process chain with the highest ratio of capital to product-unit throughput. For example, if it costs $50 million to establish mining equipment and $100 million to establish process equipment to achieve a given level of product output, then processing, rather than mining, is the design bottleneck. In a metals mine, the capital intensity of the comminution circuit normally outweighs the capital intensity of the mining operation or finished goods shipping. Therefore, it is common for the pace in metals mines to be set in comminution. In contrast, the cost to install matching mining or finished goods shipping is relatively low, so it is uncommon for these functions to constitute the economic design bottleneck for a metal mine. In an iron ore operation, the design bottleneck is likely to be in the rail or the port. This is because the capital intensity for these parts of the value chain is relatively high. Fixed costs associated with maintaining a certain level of production also contribute to the determination of the design bottleneck, but it is beyond the scope of this chapter to discuss this in detail.

When the economic design bottleneck has been determined, it should be used as the primary lever for testing increased or decreased production rates for the whole mine. The design bottleneck constraint should only be applied in early stages of the analysis; a wide range of production rates must be tested. Secondary constraints should only be introduced in later stages of the analysis, and their impact on value and overall throughput should be carefully examined.

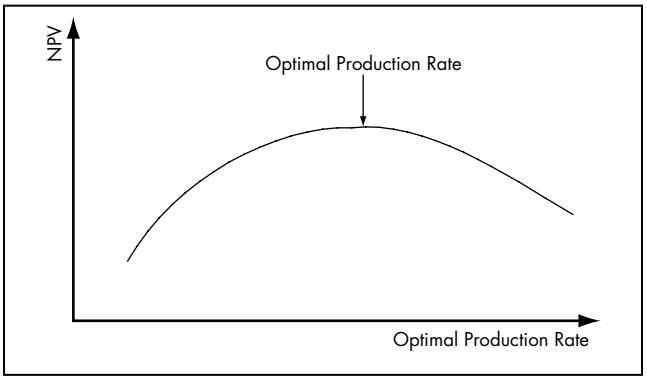

Figure 10.2-2 Relationship between production rate and NPV

Throughout the planning process, focus should be maintained on the economic design bottleneck. If a schedule emerges for consideration in which this constraint is underutilized in some periods, then this is a strong indication that the schedule or plans are not as good as they should be.

Determining Processing Cutoffs

In practice, mine planners rely on software to calculate or optimize the setting of processing cutoffs. However, it is important to understand the basic concepts and not merely place blind faith in the software. To that end, a simple explanation of some of the concepts is provided, including the calculation of marginal cutoffs for simple situations and descriptions of some of the issues encountered when seeking to effect ore/waste discrimination in more complex situations.

As part of the open-pit planning process it is necessary to determine the treatment of run-of-mine material. The alternatives typically include the following:

- Treat as ore and allocate to one of the available processing pathways.
- Treat as ore but defer processing by allocating the material to a grade stockpile (the material would later be reclaimed for processing).
- Treat as waste and allocate to a waste dump.

The traditional method is to differentiate material by its product grade and the application of cutoffs. In a simple case, material with a grade above a defined product grade cutoff will be processed and material below the cutoff grade will be treated as waste.

The cutoff grade is calculated such that material will be processed only if processing will lead to a net increase in value. If the objective is to maximize net cash flows, the cutoff is calculated as the grade at which the net cash flow from processing is the same as the net cash flow from treating the material as waste. The mathematics for this is shown in Equations 10.2-1 through 10.2-6. The conventional term for this type of cutoff is *marginal cutoff*.

The simplest way to think about this is to consider material as it emerges from the pit, at the pit rim, with all mining costs paid. The marginal cutoff is set at the grade at which the cost of processing exactly equals the revenue generated by the recovered product.

The cash flows associated with treating the material as waste, C_{mw}, can be calculated with the following equation:

$$C_{mw} = -M \times C_m \qquad (10.2\text{-}1)$$

where

M = mass of the material
C_m = cost to mine a ton of material

The cash flows associated with treating the material as ore, C_{mo}, can be calculated with the following equation:

$$C_{mo} = P \times R \times M \times G - M \times C_p - M \times C_m \qquad (10.2\text{-}2)$$

where

P = price obtained for a unit of product
R = metallurgical recovery in the process
G = grade of the material
C_p = cost to sell a ton of material

The cutoff grade is calculated as the grade (G) at which the net cash flow from processing (C_{mo}) is the same as the net cash flow from treating the material as waste (C_{mw}):

$$C_{mo} = C_{mw} \qquad (10.2\text{-}3)$$

or

$$P \times R \times M \times G - M \times C_p - M \times C_m = -M \times C_m \qquad (10.2\text{-}4)$$

$$P \times R \times M \times G = Cp \times M \qquad (10.2\text{-}5)$$

$$G = Cp/(P \times R) \qquad (10.2\text{-}6)$$

The following are some important observations as to the marginal cutoff shown in Equation 10.2-6:

- The cutoff is independent of the mining cost.
- The cutoff is independent of the grade distribution in the ore body.

The derivation of Equation 10.2-6 is easy to understand, and this method can be applied in very simple cases if the simple objective (maximization of net cash flows) is acceptable. However, the mathematics becomes more complicated when multiple products or multiple processes are available. This is because of the following:

- Multiple-product mines require the application of multiple-product grade cutoffs—one cutoff per product. Figure 10.2-3 shows graphically how two product grade cutoffs are applied.
- Multiple-process mines require the application of cutoffs for each process—one cutoff per product per period per process. Figure 10.2-4 shows how multiple process cutoffs are applied.

When the objective is changed from maximization of net cash flows to the maximization of NPV, the calculations become intractable without the use of optimization software. This is because decisions made in one period affect the discounted value of material processed in subsequent periods. Instead of calculating just one grade cutoff per product and per process, a separate set is required for each time period. If, for example, a mine has two products, three processing methods, and operates for 20 years, then 120 cutoffs must be calculated, and the setting of cutoffs in each period affects the optimal setting of all others.

When one further complexity is added, the whole concept of discriminating based on product grades alone becomes problematic. When the processing recovery for one product

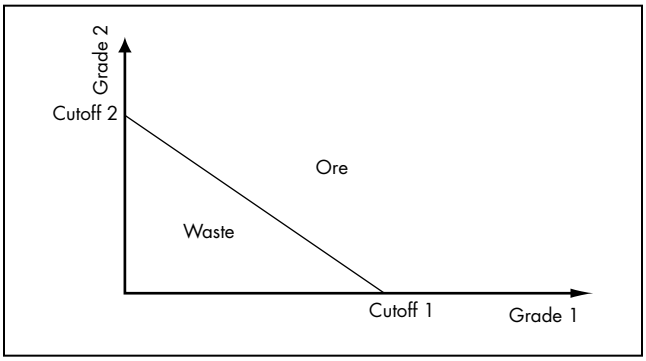

Figure 10.2-3 Application of multiple-product grade cutoffs

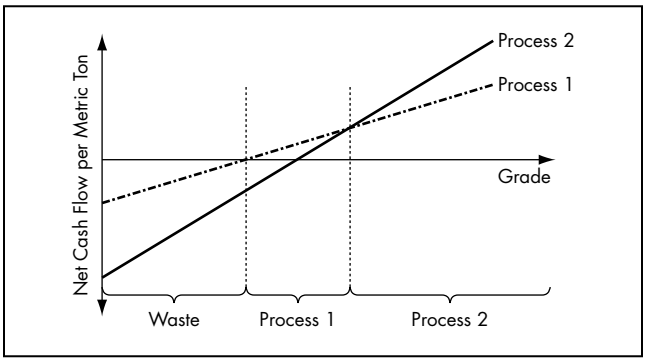

Figure 10.2-4 Application of cutoffs for multiple processes

(e.g., gold) is affected by the grade of another product (e.g., copper), the application of product grade cutoffs, as shown in Figure 10.2-3, becomes inaccurate—it can lead to the misclassification of some ore as waste and some waste as ore. The solution is to use a cutoff method based on cash flows rather than product grades. This allows for the avoidance of the misclassification described above, and it also significantly reduces the number of decision variables. In optimization software, this is usually referred to as the cash-flow method, and it is very easy to apply when the objective is to maximize undiscounted net cash flows. Each parcel of material is assigned to the processing path that will maximize the profit (or minimize the loss) for the parcel.

If the objective is to maximize NPV, then a related approach called the DC method can be used. The DC method extends the cash-flow method used for marginal cutoff calculation and allows for its application to NPV maximization problems.

Figures 10.2-5 and 10.2-6 illustrate the application of the DC method to two processes: "mill" and "heap," respectively. The illustrations are for two processes only, but the approach is applicable to any number of processes.

Allowing for Topographical Features

Mine planners often need to deal with topographical features such as existing infrastructure, roads, and rivers that are difficult or expensive to move. Two methods are described here to deal with such features. The first method is forcing the pit optimizer to avoid undermining them, and the second method is allowing the pit optimizevr to undermine them only if there is economic justification to do so.

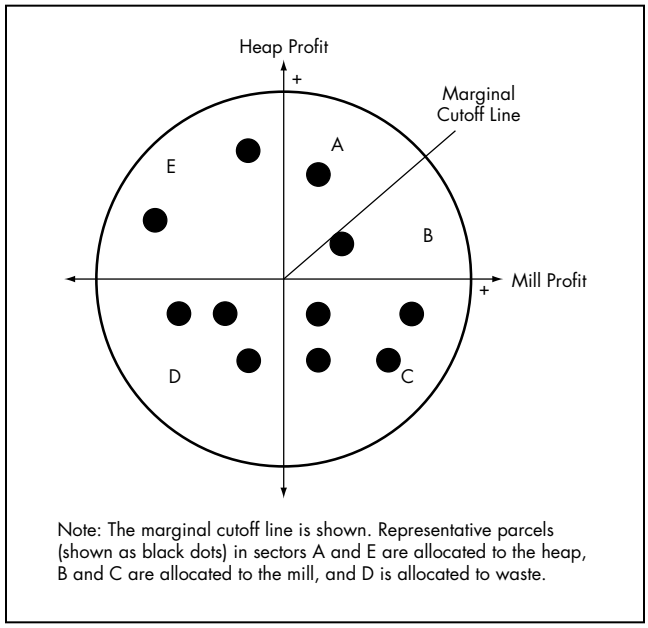

Figure 10.2-5 DC diagram indicating the domain for parcels in a given increment

The first technique involves the application of extremely high mining costs to certain blocks in the model and is effective at stopping a pit optimizer undermining defined topographical features. Figure 10.2-7 shows the surface-level blocks in a model. The shaded blocks represent the area that cannot be mined because of the presence of a river (black line). Assigning extremely high mining costs (e.g., $10 million per metric ton) to these blocks will make them uneconomic to mine, no matter how much ore is under them.

The second technique involves the definition of a set of arcs to model a topographical feature and to associate with this set the cost of relocating the feature. Arcs are normally used to model the pit slope constraints in pit optimization, but their application can be extended to modeling other things, including topographical features that are either expensive or impossible to mine through. Figure 10.2-8 shows how arcs can be used to represent such a constraint. The dotted line shows the approximate southern boundary of the river. The river may be relocated further to the north at a cost, but without relocation, the dotted-line boundary is the furthest north that a pit can extend. The arcs, shown as arrows in the diagram, trace a path along the boundary, and then one final arc completes the loop. The effect of this loop of arcs is that if a pit outline were to include any one of the linked blocks, then all blocks must be mined. The cost of relocating the river is built into the cost of mining one of the blocks; in this example, the shaded block. It does not matter which block carries the cost, provided that the cost is only carried once. The effect of this arrangement is that the pit optimizer will mine through the boundary only if doing so will maximize the value of the pit (i.e., only if relocating the river is economically justified).

Allowing for Safety Berms and Ramps

Pit optimizers cannot model safety berms and ramps directly. Instead an average pit slope angle must be calculated for the purpose of pit optimization, which takes into account the

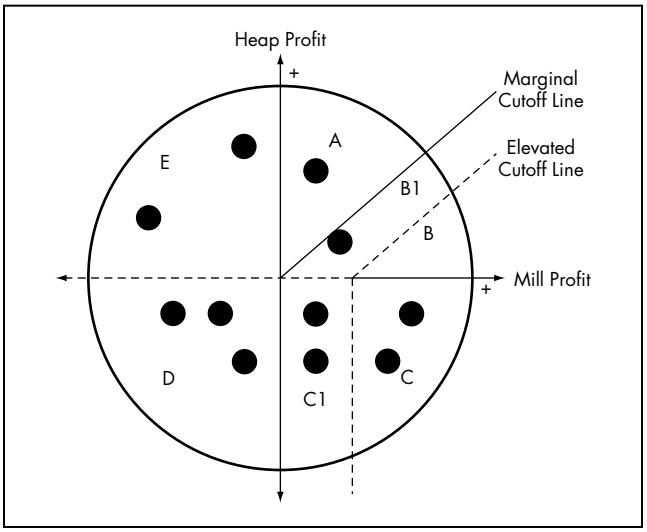

Figure 10.2-6 DC diagram indicating the application of an elevated cutoff on the material leading to the reallocation of parcel in sector B1 to heap and C1 to waste

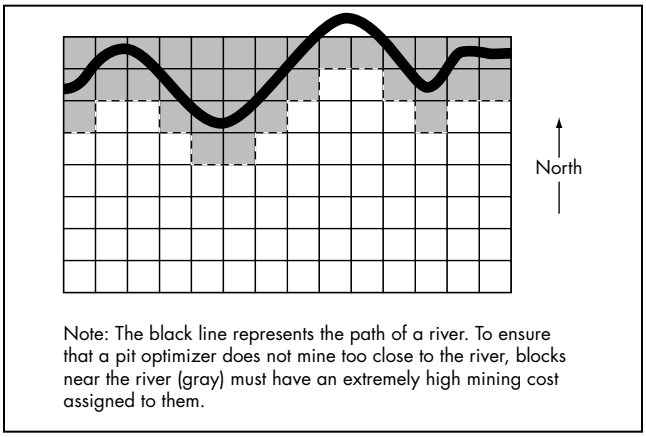
safety berms and the width and number of times a ramp is expected to intersect a pit wall. When the pit optimization work is complete, the safety berms and ramps should be inserted into the design.

A geotechnical engineer prescribes the inter-ramp angle. It is the maximum slope that can be safely sustained between ramps and the base or the rim of the pit. The geotechnical engineer will prescribe the vertical frequency and width of safety berms, which must be taken into account in the calculation of the inter-ramp angle.

The average pit slope for a given sector of pit wall is based on the inter-ramp angle but adds an allowance for ramps. To calculate the average pit slope for a given section of pit wall, the following information must be known:

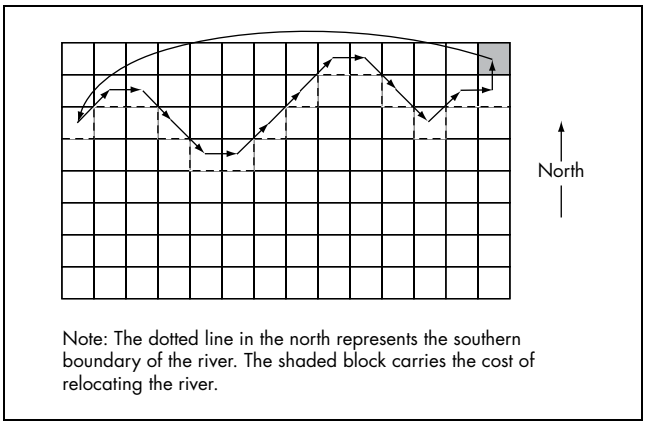
- The design width of the ramps—the width must take into account the types of equipment that must use it, the corresponding height and position of the safety windrow, the need for drainage and utilities, and the requirements for geotechnical stability
- The number of times the ramp is expected to cross this section of wall
- The height of the wall from the base of the pit to the pit rim



In the early stages of study, these things may be unknown or poorly understood. The solution is to work iteratively to a solution throughout the planning process, adjusting the average pit slopes (Equation 10.2-8) for use in pit optimization as better information becomes known.

Referring to Figure 10.2-9, the horizontal distance from toe to crest without ramps (B) is calculated using Equation 10.2-7:

$$B = (C/\tan(x°)) \tag{10.2-7}$$



where

C = depth of the pit
$x°$ = inter-ramp slope angle

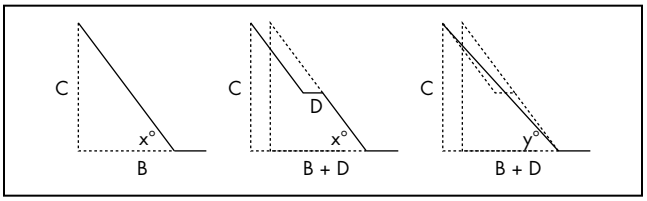
Note: The black line represents the path of a river. To ensure that a pit optimizer does not mine too close to the river, blocks near the river (gray) must have an extremely high mining cost assigned to them.

Figure 10.2-7 Plan showing the surface level of blocks

Note: The dotted line in the north represents the southern boundary of the river. The shaded block carries the cost of relocating the river.

Figure 10.2-8 Plan showing how the path of a river is defined using arcs

The average pit slope $y°$ is calculated using the following equation:



$$y° = \text{atan}(C/((C/\tan(x°)) + D)) \tag{10.2-8}$$

where D is the width of the ramp.

A Plan for a Final Pit

In the life of a mine, the plan for the final pit may change many times. The changes occur as new information becomes available, for example, new drill results that extend the resource, revised price and cost forecasts, or improved technology. Information constantly changes, and to the greatest extent possible, plans should be refined and improved over time to take advantage of the new information. The final pit only comes into existence when mining stops, and up until that time, its final form is uncertain. Consequently, the use of the term *final pit plan* is discouraged. It implies that both the pit and the plan are final. The plan is rarely final, so the term *plan for a final pit* is preferred.

Having established the plan for the final pit as a changeable thing, for practical purposes it must manifest at any given time as something concrete—something that can be tested with various economic assumptions, schedules, and

Figure 10.2-9 Allowing for ramps and safety berms in the average slope *y°*

mining rates and adjusted for different mining widths and ramp designs. At the beginning of a planning project, a reasonable proxy for the final pit can be found in the optimum pit outlines determined in the pit optimization process. The pits corresponding to revenue factors 0.75 through 1.5 provide a good spectrum of pit sizes for consideration in the early part of the planning process. In examining this range of pits, the existence of common walls or floors must be determined. Common walls and floors indicate aspects of the pit shape that are stable for a range of economic assumptions. These stable areas can be useful in mine planning, but before relying on them as design features, one must try to understand why they are stable. It could be that the geological model includes a boundary that limits the ore zone and leads to a common wall in a range of pits, or that the geological model shows ore extending only to a certain depth, thereby limiting the depth of the pit. In these situations, the reliability of the geological information should be tested as follows:

- Could it be that the boundary indicated in the geological model is not exactly where it is shown? Could there be unexpected folds or faults?
- Is the vertical limit of the modeled ore based on positive information (e.g., drilling penetrated barren rock below the ore) or the absence of it (e.g., drilling has not been extended below this level)?

This sort of examination may prompt further data gathering or reinterpretation of the geology. In the meantime, planning should proceed as follows:

1. Use the largest pit in the range to establish a reasonable maximum footprint. This footprint will help in the positioning of infrastructure, waste dumps, and leach pads. Positioning these things outside the maximum footprint will reduce the risk of incurring the capital outlay to relocate them in the future. However, this risk reduction comes at a cost: the cost of hauling waste and ore over greater distances. The final decision as to distancing should be made on the balance of costs of longer haulage and the benefit of reducing the risk of future relocation.
2. Use the revenue factor 1.0 pit as a proxy for the final pit, for the purposes of determining the mining schedule and production rate.
3. As testing of the mining schedule and production rate proceeds, retest pits in the range of revenue factors 0.9 through 1.0, and adopt the one with the highest NPV as the new proxy final pit.
4. Refine the pit shapes based on ramp designs and mining widths. Produce a range of pit sizes and test them to determine the pit that yields the highest NPV.

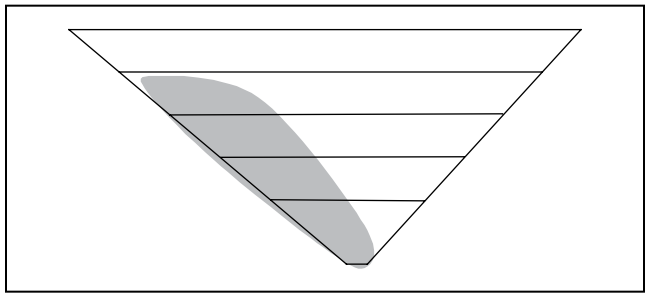

Figure 10.2-10 A worst-case mining sequence. The stripping ratio in the early part of the mine life is extremely high, requiring a significant amount of waste mining to access the ore.

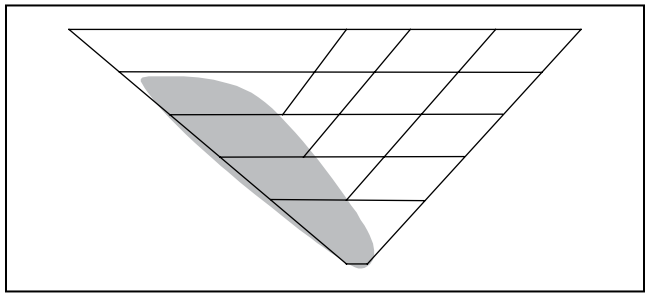

Figure 10.2-11 Mining sequence with four pushbacks. By mining each pushback in turn, the amount of prestripping required to access early ore is significantly reduced.

Pushbacks

Two mine sequences are illustrated in Figures 10.2-10 and 10.2-11. The first is simple to achieve, with excellent mining access and low complexity. However, the stripping ratio in the early part of the mine life is very high and then decreases over time. In this sequence, much of the cost of stripping is incurred early in the mine life, and access to ore is delayed. This sequence leads to poor NPV and for that reason is often referred to as a worst-case sequence (worst for NPV). In Figure 10.2-11, a mining sequence with four pushbacks is shown. By mining each pushback in turn, the prestripping is deferred and ore access is achieved earlier. The stripping ratio starts out low and ends up high. This sequence is more complicated than the first, but it will yield a higher NPV.

The sequence shown in Figure 10.2-11 is similar to the best-case schedule described previously. It has a many pushbacks and a high NPV. The trade-off is practicality. Specifically, too many pushbacks can lead to excessive expense to maintain multiple working slopes, vertical advance rates that are difficult or impossible to achieve, operational problems associated with moving equipment around multiple working faces, lack of adequate mining width, and extra cost associated with reworking ramps.

If these problems are experienced with a design that has many pushbacks, it is likely that the NPV calculated for that particular case is unachievable. On the other hand, if all pushbacks were eliminated, practicality could be assured, but for many ore bodies there will be a significant loss in NPV. How should the need for pushbacks be determined? If pushbacks are needed, how many should be employed? The simplest way to determine the need for pushbacks is to experiment with different numbers of them. The two extremes have already been

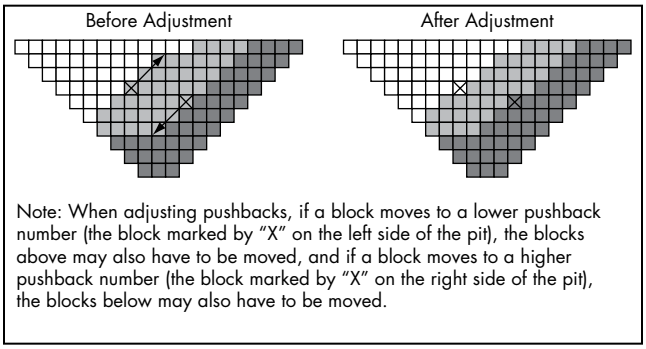

Figure 10.2-12 Pushback adjustments

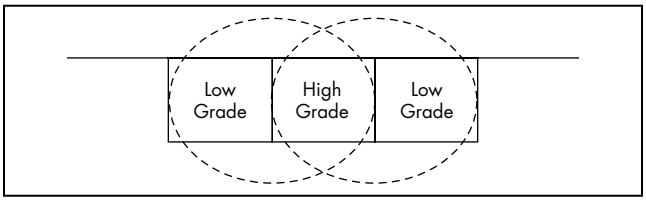

Figure 10.2-13 In this example, low-grade ore can be blended with high-grade ore in a 1:1 ratio to make salable product

discussed—no pushbacks and many pushbacks. The value difference between these two schedules will provide an indication as to the value-adding potential of pushbacks. If the value difference between a best-case and worst-case schedule is small, then there is little or no advantage in employing pushbacks. However, if the value difference between a best-case and worst-case schedule is great, employing some number of pushbacks will add significant value.

In a best-case schedule, many pushbacks are used, often in the range of 50 to 100. This is not a practical number, but it is easy to generate this many, and it provides a useful benchmark. In practice it is possible to achieve very nearly the same value as a best-case schedule merely by sizing each pushback to contain about a year's production. However, the success of this approach is to some extent illusory. If NPV is being calculated on annual rests, which is usually the case for long-term planning, then the calculation of NPV will be no different, for example, for 12 annual pushbacks compared to 48 quarterly pushbacks. The NPV calculation is insensitive to anything that happens on a timescale shorter than 1 year. Annual pushbacks are a good starting point but may still be more than is required to achieve a good NPV. Therefore, the recommended approach is as follows:

1. Compare the value of a best-case schedule and a worst-case schedule. If the values are similar, then there is little advantage in employing pushbacks. Focus instead on practicality and operational efficiency.
2. If the value difference between best case (many pushbacks) and worst case (no pushbacks) is great, then an examination of pushback alternatives is warranted. Start to simplify the best-case schedule by choosing pushbacks that each represent about a year of production. Also estimate the maximum number of pushbacks that can fit given the mining-width constraint. This is where practical requirements and theoretical best-case NPV collide. If pushbacks are too small to be mined, then the reported NPV is theoretical. Proceed with no more pushbacks than can be practically achieved.
3. Experiment with reduced numbers of pushbacks, adjusting their size to achieve the most favorable schedule. If a stripping hurdle occurs in a schedule, it will often be associated with the conclusion of one pushback and the commencement of another. Try to increase slightly the size of the concluding pushback, or try decreasing the size of the commencing pushback to overcome the stripping hurdle. Test the NPV of each alternative and settle on the smallest number of pushbacks that will achieve NPV that is close to the best-case benchmark.

Allowing for Mining Width

When a pit optimizer generates a set of pit shells, it takes no account of mining width. As a result, there is no guarantee that any pair of shells will obey mining-width constraints to the extent that good mine planning requires. A mine planner can take care to choose pit shells that exhibit most of the attributes required, but inevitably some intervention will be required to adjust the shape of the pits. Some software packages have options to apply mining-width constraints subject to a user-defined set of parameters. Without access to such systems, manual design techniques should be applied to adjust for mining width.

Whenever an adjustment is made to a pushback in one bench, it can affect the shape of the pushback in benches below or above it (refer to Figure 10.2-12). Any such changes to pushbacks will almost certainly lead to a loss of NPV.

Allowing for Blending

In the field of open-pit mine planning, few would doubt the enormous impact that the Lerchs–Grossman pit optimization method has had. The method is highly efficient, and it can be guaranteed to produce an optimal solution. However, it can only produce an optimal solution if each block in the model is assigned an independent value, and it is not always possible to do that. This can certainly be the case when run-of-mine material is blended to make a salable product. A simple three-block model is shown in Figure 10.2-13. In this example, low-grade ore can be blended with high-grade ore in a 1:1 ratio to make salable product. Assuming all blocks contain identical tonnages of material, the high-grade block should be mined, but which of the two low-grade blocks should be mined? Either one or the other of the low-grade blocks should be mined, but not both. There are two optimal solutions to this problem, and no matter how the economic model is built, it is unlikely that the Lerchs–Grossman method will be able to find either solution.

So, how does one define the pit shape for blended products? Lerchs–Grossman pit optimization can still be used to contribute to the solution, but it cannot be relied on to the same extent as for nonblended products. The Lerchs–Grossman method must be supplemented by a technique to prepare models for optimization and test for the optimality of solutions. These will be discussed in reverse order.

To describe the test for optimality, it is necessary to first establish a typical pricing model for blended products. Figure 10.2-14 shows a typical pricing arrangement based on the product grade. There is a target grade and a price applicable for blended product with that grade. Above the target, a premium is paid, and below the target, a penalty is applied.

If the grade gets too low, the product is rejected altogether. In addition to being affected by product grade, blended product price may also be affected by the grade of deleterious elements. Figure 10.2-15 shows a typical structure for the premium or penalty for a deleterious element. If the grade is too high, the product is rejected altogether.

In most cases, the best value for a mine will be achieved when it can consistently produce blended product that just meets or slightly exceeds the target grade requirements. This is because the gradient on the price curve changes at the target grade—the rate at which a premium is paid is less than the rate at which penalties are applied if the product is worse than the target grade. The implication for pit design is that the average grades (product grade and deleterious element grades) of all ore mined must equal the grades of the on-specification product. That sets an important condition for optimality of the pit—that the average grades of all material flagged as ore and included in the pit must be equal to or slightly better than the target grades.

This condition can be considered as it might be applied to the simple example in Figure 10.2-13, but to ensure that there is just one optimal solution, the data can be perturbed by assigning slightly different tonnages to the two low-grade blocks. The left-hand low-grade block contains 10,000 t—the same tonnage as the high-grade block. The right-hand low-grade block contains 11,000 t. There is now just one optimal solution: Mine the left low-grade block and the high-grade block. This is because if the right-hand block was substituted for the left, then an extra 1,000 t of low-grade material would be mined adding to cost, but not increasing the amount of on-target blended product that can be produced.

With this perturbation, one is a little closer to applying the Lerchs–Grossman optimization method. But a method is still needed to prepare the model for optimization, that is, one that will bias the optimizer to choose a pit containing the desired average grade characteristics without biasing the outcome in any other way. The most flexible method involves the use of parametric pricing with price attenuators to increase or decrease the pit optimizer's propensity to include different material in the pit outline. The calculation of the attenuated price, P_a, is shown in Equation 10.2-9 for one product grade and one deleterious element grade, but it can be extended to include two or more deleterious element grades.

$$P_a = P_b\left(\frac{A_p(G_p - T_p)}{T_p} + \frac{A_d(G_d - T_d)}{T_d} + 1\right) \qquad (10.2\text{-}9)$$

where

P_b = price paid for 1 t of on-specification blend
A_p = attenuator for product
G_p = product grade for a block
T_p = target product grade
A_d = attenuator for the deleterious element
G_d = deleterious element grade for a block
T_d = target deleterious element grade

The attenuated price, P_a, is a function of price attenuators A_p and A_d as well as the target grades and prices and the block grades. With the attenuators A_p and A_d set to zero, the attenuated price is equal to the target price, no matter what the block grades are. If an attenuator is set to a positive value, the attenuated price increases for higher grades and decreases for lower grades. If an attenuator is set to a negative value, then the effect is reversed—the attenuated price decreases for higher grades and increases for lower grades. By manipulating the attenuators, relative block values are changed to increase or decrease their propensity to be included in a pit outline by the pit optimizer.

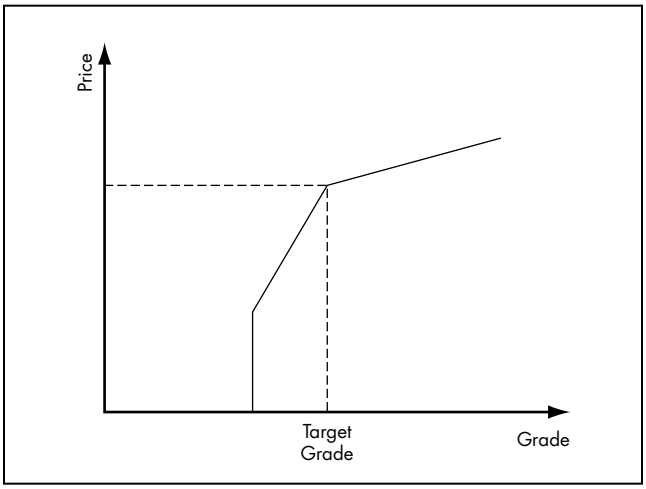

Figure 10.2-14 Typical structure for a sales contract for a blended product. There is a target grade and a price applicable for blended product with that grade. Above the target a premium is paid and below the target a penalty is applied. If the grade gets too low, the product is rejected altogether.

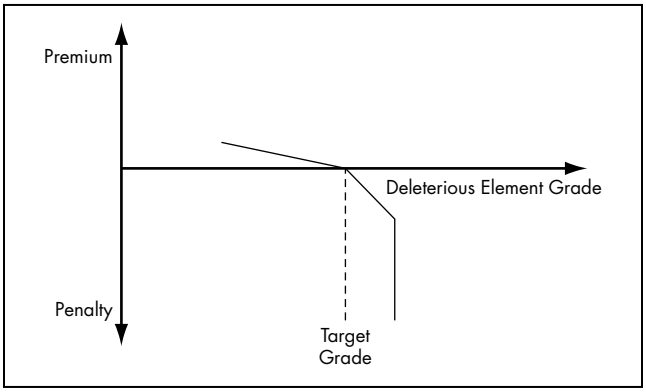

Figure 10.2-15 Typical structure for the premium or penalty for a deleterious element. If the grade of the deleterious element gets too high, the product is rejected altogether.

Two additional tools are now required to conduct pit optimization: a technique to prepare models for optimization and a test for the optimality of solutions. The application of pit optimization with these tools is as follows:

1. Prepare the model for optimization, calculating block values using Equation 10.2-9 with attenuators set to zero.
2. Run the pit optimizer.
3. Evaluate the mined ore in the pit by calculating the average grades for product and deleterious element. Compare these average grades with the target grades. If the average grades are equal to or slightly better than the target grades, then the result is acceptable and you can stop. If not, go to Step 4.

4. Adjust the price attenuators. If, for example, a decrease in the average grade is desired, reduce the value of the corresponding attenuator and go to Step 2.

This is an iterative process with an indeterminate number of steps. It is possible that the approach will not be able to achieve a solution, and here are the following two reasons that it might fail:

1. There may be more than one optimal solution, as was the case shown in Figure 10.2-13. One may experience this problem by being unable to find a satisfactory setting for an attenuator, with a tiny change in the attenuator leading to an extreme change in the average grade mined. In the Figure 10.2-13 case, tiny changes in the attenuator would lead to either both or none of the low-grade blocks being mined. A possible workaround to this problem is to perturb the data, for example, by changing the cost of mining by depth or distance from facilities.
2. There may be an abundance of certain material types that must be mined, with only some of it being useable as product. This is illustrated in Figure 10.2-16. One may experience this problem by being unable to find a satisfactory setting for an attenuator, with a tiny change in the attenuator leading to an extreme change in the average grade mined. This is similar to the case illustrated in Figure 10.2-13, except that, provided that the high-grade block is worth mining, there is no choice but to mine both low-grade blocks overlaying it. In this case, one should settle on the most conservative set of price attenuators that yields a pit with better than target grades. After the pit optimization process, additional material can be added to the blend to bring the actual grades down to the target grades.

Analyzing the Case for Flexibility

The beginning of this chapter has focused on the long-term trends for prices, not the short-term fluctuations. However, short-term fluctuations will surely occur, and mines need to test the impact and assess the case for building flexibility into an operation to allow it to respond to fluctuations. An example of flexibility in a metals mine is the ability to change the processing cutoff grade. When prices are high, it may be advantageous to increase the processing cutoff. This increases the output of product, allowing the mine to take full advantage of the high price. To be able to make this change, the mine must have the ability to move quickly to a higher mining rate because raising the processing cutoff will lead to a higher strip ratio, and to keep the rate of ore constant, the mining rate must be increased. The benefit of flexibility in this case is the ability to take advantage of the higher prices; the cost is the additional cost of having mining flexibility.

Price is the most important economic driver for all mines, and it is also quite variable. Other important economic drivers may exist that are just as uncertain as price, and it is important to analyze the case for flexibility. The following are other examples:

- Providing excess capacity on ramps allows mining rates to be increased quickly.
- Allowing some flexibility in the comminution functions allows short-term recovery and throughput changes to be made in response to unexpected ore characteristics.

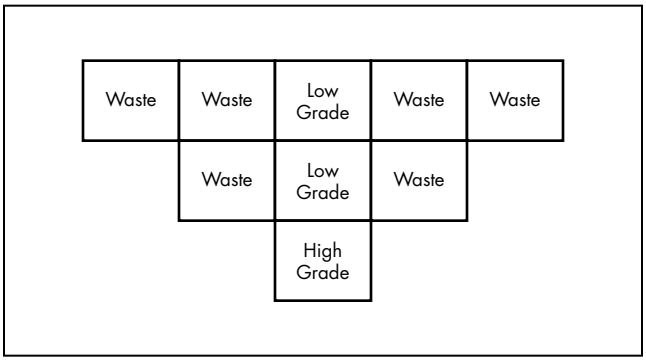

Figure 10.2-16 In this example, abundant low-grade material overlays the high-grade material, and there is no way to mine the material in the desired 1:1 ratio. Provided that the stripping can be supported, the best solution would be to mine both low-grade blocks and the high-grade block and treat half of the low-grade material as waste.

- Maintaining spare mining capacity and an inventory of exposed ore provides more short-term options to manage head grade and throughput.

Identifying and Managing Risks

The inputs to mine planning have varying levels of uncertainty, and uncertainty can translate to risk. Steps must be taken to reduce risks to an acceptable level. To achieve a successful outcome it is necessary to manage all risk aspects closely, including the potential for risk/reward—that is, the acceptance of additional risk (within an approved tolerability limit) resulting in increased rewards.

Each mining company needs to develop an organizational risk management process and culture that provides its management and shareholders with certainty and confidence in its planning process. Organizational management processes are dealt with in detail in other literature. Whichever approach is adopted, it is important that this process accomplish the following:

- Identifies, assesses, and manages both strategic risks associated with the mine plan as well as tactical and other risks that the plan must manage
- Supports the planning process through the objective analysis of the contributing/influencing uncertainties and their consequences
- Designs, implements, and monitors effective risk controls that either reduce the probability of the risk occurring or the consequence/impact of an event when it occurs
- Applies risk management equally to risk reduction/avoidance and to opportunity/upside potential

The result of the analysis will be changes to the mine plan that impact risk and NPV.

Determining Options for Preservation

An option in finance is the right, but not the obligation, to execute a transaction at a later time. An option can be bought and has a value because it exposes the owner to the possibility of the later transaction. In mine planning there are many decisions that are conceptually comparable to an option in finance.

Table 10.2-8 Example of a preserved option

Description of Option	Low-Grade Ore To Be Processed Rather Than Wasted
Trigger for option	Success hypothesis (low-grade ore processing method) is true
Probability, P_o	The study team estimates 70% probability of success, P_e, in achieving a solution with \$2/t lower processing cost and 84% recovery
Success value, V_{oe}	\$150 million
Actions and costs to preserve	Reschedule to avoid moving the low-grade ore until the success of the low-grade processing method is known. Cost of reschedule ~ \$20 million (NPV)
Option value, V_o	\$85 million

Table 10.2-9 Minimum requirements for an underground mine plan—for the purposes of calculating the underground value *Y* of blocks in a model

Information Requirement	Description
Stope envelopes	The shapes that contain mined ore, defined as a set of blocks (stope blocks)
Aboveground value	The value of a stope block after it reaches the surface. The value can be calculated as grade × recovery × price – processing cost × tons
Mining and haulage costs	The costs to mine a stope block and bring it to the surface for processing

For example, maintaining flexibility in a mining fleet has a cost, but it provides the ability in the future to quickly increase mining rate, allowing the processing cutoff to be increased, thereby increasing monthly product output. If this option is available, it is one that could be exercised during periods of very high commodity prices. Without having an option such as this, the product output could not be changed in response to changes in the market. An option must be exercisable in the following situations:

- A credible future price regime
- Response to positive exploration results
- Response to a positive research-and-development outcome
- Other circumstances that are credible and that have non-zero probabilities of occurring

If it is possible to estimate the probability that the future option will become available, the value of the exercisable option, V_o, is calculated using Equation 10.2-10:

$$V_o = P_e \times V_{oe} - C_{po} \quad (10.2\text{-}10)$$

where

P_e = probability that a trigger event will occur (triggers the option)
V_{oe} = value (discounted cash flows) of the option if it were exercised
C_{po} = cost (discounted cash flows) incurred in preserving the option

If it is not possible to estimate the probability of a trigger occurring, then an alternative is to calculate the minimum probability, $P_e\ min$, that is required for the option value to be positive ($V_o > 0$). If $P_e\ min$ is sufficiently low, then it is reasonable to conclude that the option value will be positive. Table 10.2-8 shows an example of a preserved option.

Determining the Open-Pit/Underground Interface

For some ore bodies, mining is possible by either open-pit or underground methods. If the choice is between applying one method and the other, then a decision as to which method to choose can be made by comparing the best open-pit plan with the best underground plan.

In the case that a combination of the two methods may be employed, then a decision must be made as to where one method ends and the other begins. When both open-pit and underground mining methods are used, a great many problems can arise. These include the complexity of sequencing the commissioning and operation of the mines and the costs and risks of managing the geotechnical and safety consequences of digging a pit near an underground mine. The detailed analysis of these issues is beyond the scope of this chapter. What follows is a description of a simple method to determine an interface between the two methods, with some parts of the ore body being taken by the pit while others are left for underground mining.

The interface between the two methods will occur at a depth or location at which the open-pit method becomes less economic that the underground method. The determination of this interface can be achieved by applying a pit optimizer to a specially modified block model. The modifications enable the calculation of the value of each block as the difference between its open-pit value and its underground value. This difference represents the net benefit of mining a block by open-pit method instead of by underground method. The following is an important logical assumption that underpins this analysis: If a block could be mined by underground method and it is not mined by open-pit method, then it will be mined by underground method.

A block can be considered that has value X if mined by open-pit method and a value Y if mined by underground method. The value Y will be achieved if the block is not included in the pit, because it will instead be mined by underground method. The value X will be achieved if the block is included in the pit outline, but the improvement in value is not X, it is only $X – Y$. This is the value that should be used for the purposes of pit optimization—the difference in value between open pit and underground.

The calculation of the underground value Y relies on the application of an underground planning process (beyond the scope of this chapter to describe). Instead, here are some guidelines as to how the underground value of blocks should be considered in the open-pit mine planning process. The calculation is described in principle only as the application details of this method depend on the modeling tools included with the pit optimization software being used. The minimum requirements are described in Table 10.2-9. The underground value Y is equal to the aboveground value, less the mining and haulage costs.

Now that the underground value of each block is known, it should be deducted from the value of each block in the model prior to pit optimization. Pit optimization proceeds with block values equal to the open-pit value, less the underground value ($X – Y$). The result will, in most cases, be a pit that is smaller than it would have been if the block values had not been adjusted. It is possible for the pit to stay the same, but it is not common. That part of the underground mine plan

Table 10.2-10 Treatment of rehabilitation and closure costs

Type of Cash Flow	Description	Treatment
Rehabilitation bond	A bond paid to the government against mine rehabilitation. In the event that rehabilitation is carried out effectively by the mining company, the bond is returned.	The bond can be treated like working capital. There is an opportunity cost (interest foregone) associated with the bond, and it is incurred for as long as mining continues and until rehabilitation is complete. This interest cost should be treated as a fixed cost during the life of the mine.
Waste-related continuous rehabilitation cost	Waste dumps may be continuously rehabilitated to their final form and cover.	These costs are incurred roughly in the same period as mining occurs and are proportional to the tons of waste (assuming a certain waste dump format and rehabilitation plan). The costs should be modeled as a variable cost per ton of waste.
Ore-related continuous rehabilitation cost	Tailings may be treated and stabilized on a continuous basis.	This cost is incurred roughly in the same period as processing occurs and is proportional to the tons of ore (for a given treatment and stabilization process). The sum of the costs should be modeled, a variable cost per ton of ore.
Terminal ore- and waste-related rehabilitation cost	Recontouring a pit, replacing the topsoil, and revegetating at the end of a mine life is required.	Treated as a terminal cost. This terminal cost will vary with the size of the final pit.
Terminal ore-related rehabilitation cost	This includes stabilizing and covering tailings dams.	This cost is treated as a terminal cost. This terminal cost will be different for different totals of ore tons.
Terminal facilities cost	The removal of buildings and equipment and preparing the land for its future use is required.	This should be treated as a terminal cost.

that was not mined out by the open-pit mine remains as an underground mine.

Development costs are not included in the calculation of the underground block value. These costs are important, but there is no satisfactory method for apportioning the development costs to stope blocks in the model. The alternative is to deal with the development costs outside the pit-optimization process. If some blocks are mined in the open pit that could have been mined by underground method, then the initial underground mine plan assumptions are no longer valid. This is particularly true for development that is justified by its ability to gain access to several stope blocks. If some of those stope blocks are removed from the underground mine plan, then the justification for the underground development must be reassessed. This reassessment may lead to further changes to the underground mine plan, specifically the removal of any development that can no longer be justified and, consequently, the removal of any remaining stope blocks that rely on that development. If this is the case, then the whole process of determining the open-pit/underground interface should be repeated, but now based on the new (smaller) underground mine plan.

Another consideration is that the pit optimizer will take no account of the separation between open-pit and underground mining. Without proper separation, either the open pit or the underground or both mines will become unstable and unsafe. A geotechnical engineer should be consulted and adjustments made to the plans to ensure that both plans can be safely executed.

Anticipating and Allowing for Mine Closure

Mine rehabilitation and closure are described in detail in other chapters of this handbook. In this chapter, the treatment of closure is limited to the cash-flow effects and their impact on mine planning decisions. Table 10.2-10 shows different types of rehabilitation costs and their recommended treatment.

The treatment of costs shown in Table 10.2-10 must be simplified for the purposes of pit optimization because in that process, only variable costs can be modeled.

- Fixed costs (e.g., interest associated with a rehabilitation bond) should be treated as implicit fixed costs.
- Terminal costs should be treated in the same way as capital.

MODELS AND TOOLS

Introduction to Optimization

Optimization is a term that can be used in a general sense to mean a process through which an outcome is made as good as it possibly can be through the adjustment of inputs, structures, or methods. The term also has a more precise mathematical definition—which means to "find the optimal value of a function, often subject to constraints."

Optimal (value) in mathematical terms means one of the following:

- **Minimal value:** The lowest possible value (to optimize total cost is to minimize it)
- **Maximal value:** The highest possible value (to optimize total profit is to maximize it)

A model for optimization includes the following:

- **Objective:** This is the item to be optimized.
- **Objective function:** The objective function is a mathematical expression, or some other kind of mathematical model that calculates the thing that is to be optimized subject to the variables described next.
- **Input data:** Costs, prices, and efficiencies are all examples of input data on which the calculation of the objective value depends.
- **Decision variables:** To optimize the objective, an optimization process must find the appropriate settings for one or more decision variables. An optimization problem may have one or many decision variables.
- **Constraints:** The settings of the decision variables are subject to constraints, both on the decision variables themselves and on functions of the decision variables.
- **Optimization method:** This is a method for determining the appropriate settings for the decision variable such that the objective is optimized.

Mine Planning Optimization

Tables 10.2-11 through 10.2-13 show basic descriptions of the most commonly applied optimization processes in open-pit mine planning. These optimization methods are available in a variety of commercial software packages.

Table 10.2-11 Typical formulation for pit optimization

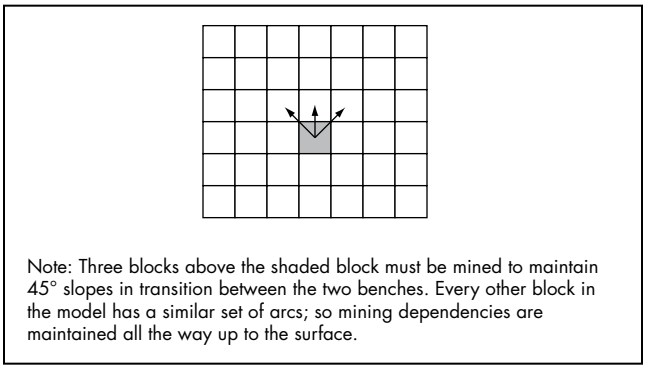
Objective	Maximize the value of the pit (undiscounted).
Input data	A dollar value must be provided for each block in the block model framework. The block values are calculated based on the expected cash flows if the block is mined and (optionally) processed. Blocks can have negative values (e.g., waste) or positive values (e.g., ore). Terminal costs and capital costs are not included in the model except in special cases.
Objective function	The total value of the pit is the sum of the values of all blocks selected for inclusion in the pit.
Decision variables	There is one decision variable for each block in the model with two possible settings: *include* or *do not include* in the pit. The solution is presented as the set of blocks that constitutes the pit.
Constraints	Blocks may only be included in the pit if the blocks above it are also included in the pit. "Blocks above" includes any blocks on higher benches that need to be mined to satisfy pit slope requirements. These block dependencies are defined by arcs. An arc points from one block to another, indicating that if the first block is included in the pit outline, then the other must also be included. Figure 10.2-17 shows a two-dimensional illustration of the use of arcs to define block dependencies. If the shaded block is to be included in the pit outline, then the three blocks above it must be mined to maintain 45° pit slopes. Every other block in the model has a similar set of arcs, so mining dependencies are maintained all the way up to the surface. If the shaded block is mined, then all blocks in a cone (defined by the pit slopes) above the shaded block must also be mined. Figure 10.2-18 shows an example for 31° slopes. The accuracy with which slopes can be modeled is determined by the number of arcs. Most pit-optimization software allows the user to control how arcs are generated. If more arcs are generated, pit slope accuracy is improved, at the expense of processing speed. Arcs can also be used to model constraints other than pit slopes.
Optimization method	The most common optimization method is the one described by Lerchs and Grossmann (1965). This method is framed in graph theory and follows a repeating set of steps until a specific test for optimality is met. The result is a subset of blocks that obeys all block dependencies defined by the arcs and has the highest positive value.

Table 10.2-12 Typical formulation for schedule optimization

Objective	Maximize NPV.
Input data	A dollar value must be provided for each block in the model framework (similar to the requirements for pit optimization). In addition, the ore, process stream allocation, and waste tonnage information for each block is required. Blocks are often aggregated into logical mining units with a defined set of precedences. The aggregation is done to reduce the complexity of the optimization problem.
Objective function	Determine the schedule of blocks (or logical mining units) that will maximize the NPV of the mine.
Decision variables	The period in which each block or logical mining unit is mined
Constraints	Constraints always include maximum rates for mining and processing through each processing stream and product sales. Many software systems also allow additional constraints such as a maximum vertical rate of advance.
Optimization method	Schedule optimization is often formulated as a linear or mixed-integer programming problem in mine schedule optimization software.

Table 10.2-13 Typical formulation for cutoff and stockpile optimization

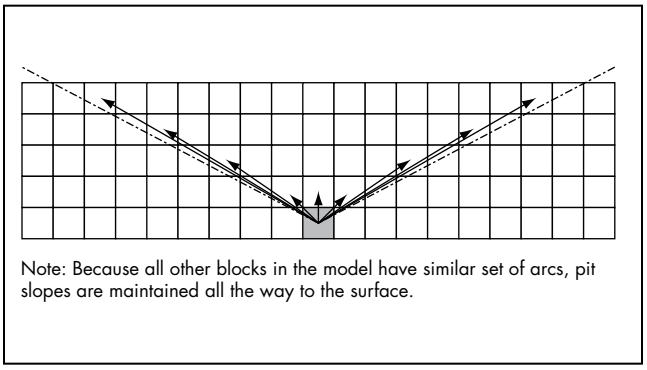
Objective	Maximize NPV.
Input data	A sequence of material made up of discrete increments. Each increment represents a set of parcels, each with information as to tons, grade, and other attributes. Other input information includes capital; fixed, variable, and terminal costs; prices; and metallurgical recoveries.
Objective function	Determine the allocation of material in the sequence of increments to stockpiles, waste dumps, or available processing streams on a period-by-period basis. Determine also the reclaiming of material from the stockpiles to feed to the available processing streams on a period-by-period basis.
Decision variables	The period in which each parcel is mined and the allocation of that parcel to a defined waste, process, or stockpile. The decision may be implemented by way of one or more cutoffs.
Constraints	Constraints always include maximum rates for mining and processing through each processing stream and product sales. Often, additional constraints are available.
Optimization method	Cutoff and stockpile optimization may be achieved as a separate process applying dynamic programming methods. Alternatively, it may be combined with schedule optimization and solved using linear programming or mixed-integer programming methods.



Resource Models

Most open-pit mine planning is conducted with a regular block model. A *block model* is one in which the area of interest is represented in a set of discrete rectangular blocks, each of which accounts for a subset of the total three-dimensional space. Together, these blocks represent the whole area of interest. A *regular block model* is one in which all blocks in the framework have identical dimensions.

A block model should include all mineralized material in the area of interest plus the topography and the surrounding barren ground such that the most optimistic pit could be contained within the model framework. An example of the extent of the model's framework is shown in Figure 10.2-19.



A set of attributes is assigned to each block in the model during the resource modeling process. These attributes include tonnages, grades, and other information about the material in the block. Ideally the set of attributes will include all characteristics that vary with position in the model and all characteristics that are expected to be significant drivers for one or more of the following:

- Units of product produced
- Price achieved per unit of product

Note: Three blocks above the shaded block must be mined to maintain 45° slopes in transition between the two benches. Every other block in the model has a similar set of arcs; so mining dependencies are maintained all the way up to the surface.

Figure 10.2-17 Two-dimensional illustration of the use of arcs (arrows) to define block dependencies

Note: Because all other blocks in the model have similar set of arcs, pit slopes are maintained all the way to the surface.

Figure 10.2-18 Two-dimensional illustration of the use of arcs (arrows) to define block dependencies for a slope of 31° (dotted lines)

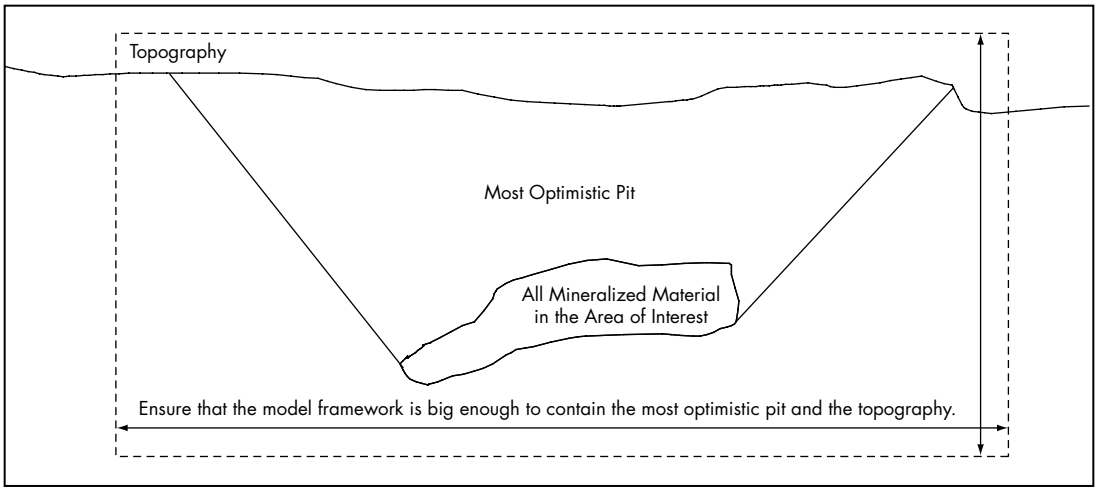


Figure 10.2-19 Extent of the model framework

- Costs (mining, processing, transportation)
- Time in a bottleneck process
- Assignment to an ore or waste stream
- Pit slopes

Examples of significant drivers are provided in Table 10.2-14.

In practice, the data available for inclusion in the block model will be less than ideal, with data collection and modeling constrained by budget, time, or technology. The gap between the information that is desired and the reality of available data should be examined at each phase of planning and recommendations made for exploration and geology so that sufficient modeling data is available for subsequent planning phases.

For planning purposes, blocks are treated as selective mining units (see Table 10.2-15) and also represent the smallest unit used to model pit slopes (smaller blocks lead to more precise modeling of pit slopes). If the original model received does not already have appropriate block dimensions, it may be necessary to split or combine blocks in it to achieve a block shape and size that is suitable for planning. Guidelines for a suitable planning block size are as follows: Set the block height to the likely bench height for mining. Set the block length and width in ratio to block height according to the likely pit slopes. For pit slopes in the range of 45° to 55°, block widths and heights should be approximately equal to the block height. For pit slopes outside that range, apply Equation 10.2-11. (Although the equation will yield a precise answer, it is only intended as an approximate guide.)

The ideal width (W) or length of a block can be calculated using the following equation:

$$W = \frac{1.2H}{\tan\theta} \qquad (10.2\text{-}11)$$

where

H = block height
θ = average pit slope

The selective mining unit is equal to the block dimensions, but the selective processing unit may be smaller.

Individual blocks in a model may include many sub-blocks or parcels, each representing a fraction of a block. A sub-block is a subset of a block with its own grade and tonnage attributes and with a defined position and volume in the parent block. In the modeling process, sub-blocks are produced to more closely follow geological boundaries. Figure 10.2-20 illustrates block models with and without sub-blocks.

Table 10.2-14 Example drivers to consider for inclusion in the block model

Key Parameter	Example Drivers (Various Commodities)
Product produced	• Zinc grade determines maximum zinc available for recovery. • Copper in gold ore may reduce gold recovery. • Ore texture can affect liberation, which in turn impacts separation and recovery.
Price per unit	• Diamond size affects price per carat. • Sulfur in coal reduces the price achieved per ton.
Processing costs	• Clays affect consumption of reagents. • The Bond work index affects comminution costs.
Mining cost (including rehabilitation)	• Geotechnical characteristics affect the need for blasting. • Acid-producing pyrites affect waste management and reclamation costs. • Broken rock texture affects erosion and slope characteristics of dumps.
Time in the bottleneck process	• The Bond work index affects resident time in the mill. • Ore texture affects best screen sizes to achieve target liberation.
Stream assignment	• Any or all of the above-mentioned drivers will contribute to the assignment of the material to an ore or waste stream.
Pit slopes	• Geotechnical characteristics affect the maximum pit slope angles. • The water table affects ground conditions and maximum pit slope angles.

Table 10.2-15 Definitions for selectivity

Term	Definition
Selective mining unit	The smallest unit that can be added to or removed from a pit outline
Selective processing unit	The units of material that, once mined, can be selectively assigned to a process or waste dump

Like a sub-block, a *parcel* is also a subset of a block with its own grade and tonnage attributes. However, unlike a sub-block, a parcel does not have a defined position within the block. In the modeling process, a set of parcels is produced for each mineralized block to represent a grade distribution. Figure 10.2-21 provides an illustration of parcels in a block. In planning, sub-blocks and parcels represent selective processing units (see Table 10.2-15).

The person who created the model and the person who will use the model in the planning process should discuss the use of these artifacts to represent processing selectivity and satisfy each other that the modeling is sufficiently accurate. The previously described methods are general guidelines only. Success in the preparation of a model for use in mine planning is indicated by satisfactory answers to the following questions:

- Is there enough information in the model (block attributes) to allow for sufficiently accurate simulation of cash flows, recoveries, and throughputs?
- Do the block dimensions allow for effective modeling of mining selectivity and pit slopes?
- Are the parcels or sub-blocks sufficiently representative of processing selectivity?

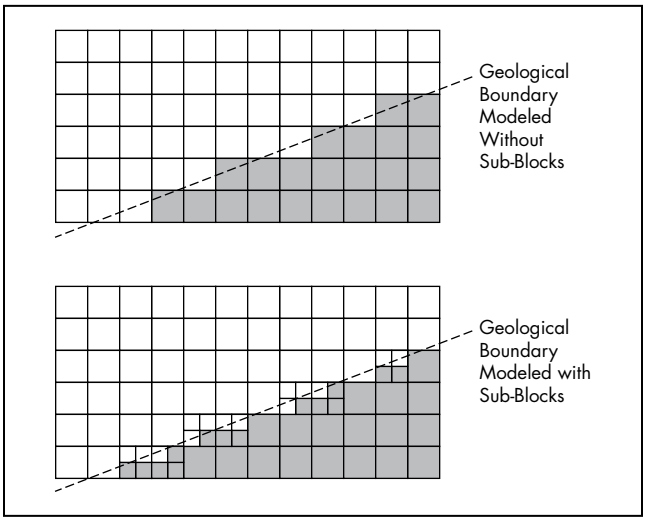

Figure 10.2-20 Sub-blocks may be used to more accurately model geological boundaries. Sub-blocks are only included in blocks that require greater resolution.

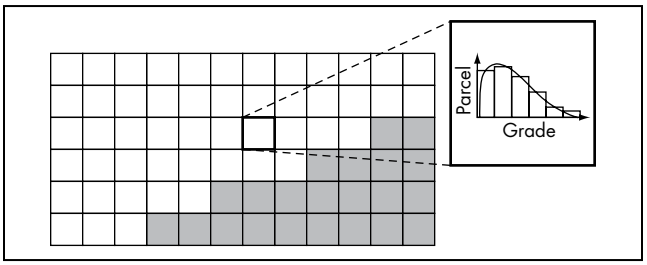

Figure 10.2-21 A set of parcels represents a grade distribution in a block. Each parcel has its own tonnage and grade.

Stockpile Models

The following definitions relate to the purpose of the stockpile and are represented as three different types. Although any given stockpile is usually of a single type, it is certainly possible for a single stockpile to serve more than one purpose.

- **Grade stockpile:** A grade stockpile is a stockpile maintained for the purpose of deferring the processing of low-grade material until later in the mine life. This is done principally to increase project NPV. Grade stockpiles are large (on the scale of years of production). Deposition and reclamation occur over many years. Grade stockpiles are usually associated with precious metals and base metals mines. They are less commonly associated with bulk products (e.g., coal, iron ore, and bauxite) or industrial minerals (e.g., limestone, mineral sands, and phosphates).
- **Blending stockpile:** A blending stockpile is a stockpile maintained for the purpose of storing material with particular grade characteristics, until such time as it can be blended with other material (either from stockpiles or run-of-mine material) so as to achieve a desired blended characteristic. Blending stockpiles are common for many bulk products and industrial minerals. They may also be used to facilitate the feed to an extractive process for precious or base metals, to improve processing recovery or throughput, or to reduce costs.

- **Buffer stockpiles:** Buffer stockpiles are designed to deal with short-term mismatches between the output of one process and the input to another. They are relatively small, representing a few hours or days of production. A common location for a buffer stockpile is on the front end of a comminution circuit to ensure that the process continues without being affected by fluctuations in deliveries of ore from the mine.

Cost Models for Optimization

To perform the optimization, the impact of decision variables on revenues and costs must be incorporated into the model. Revenues are positive cash flows and are associated with product output. Costs are negative cash flows and must be associated with activities in such a way as a change in decisions made in the optimization model will be reflected by an appropriate change in costs.

The following basic modeling definitions are required to conduct the cost modeling effectively:

1. **Capital costs:** These are costs that are incurred once to build or unlock productive capacity. For example, the cost to build an additional processing plant is a capital cost associated with the productive capacity of the new plant.
2. **Variable costs:** These are costs that vary in proportion to activities such as mining, processing, and shipping finished product. There is a generally accepted set of categories used in open-pit mine planning for variable costs, and these are described in Table 10.2-16.
3. **Fixed costs:** These are costs that are incurred regularly (periodically) and are associated with maintaining a level of productive capacity. Fixed costs are sometimes called time costs. For example, the cost to maintain a mining camp for 500 employees and their families is a fixed cost—it does not increase or decrease with the rate of mining, processing, or product produced on a monthly basis, and it only changes with the number of employees.
4. **Terminal costs:** These are costs that are incurred at the cessation of normal mining operations (typically mine closure and rehabilitation costs).

These four cost definitions and the more detailed variable cost categories in Table 10.2-16 are all that are required to build a complete cost model for mine plan optimization.

It is important to make a distinction between the definition for capital cost shown previously and a range of other costs that use "capital" in their title. For example, terms such as *replacement capital* and *sustaining capital* refer to expenditure to maintain the productive capacity of capital assets and should be treated as fixed costs or variable costs.

Capital costs for equipment that has a productive life that is shorter than the expected mine life can also be treated as a variable cost. For example, in a long-life mine, the truck fleet may be replaced several times and at the end of the mine life, the remaining fleet will be sold at a price that relates to the trucks' remaining productive life. In this case, the capital can be prorated into the variable cost of mining.

If a contractor is used for mining, then the capital costs remain in the contractor's accounts, and the only costs that are relevant to the contractee are the ones charged to the contractee. These are framed primarily as variable costs.

Table 10.2-16 Common variable cost categories used in open-pit mine planning

Common Name	Description and Application
Mining costs	This category is applied to all material mined as a dollar amount per unit of mass (e.g., dollars per ton) or volume (e.g., dollars per cubic meter). There may be different mining costs for different areas in the mine, and the cost may be varied by depth, distance from the pit rim, or by rock type. Mining cost is inclusive of drilling, blasting, loading, and dumping material. This cost category should be applied to any cost that varies with the quantity of material mined, including continuous rehabilitation of mining areas. In the event that ore costs more to mine than waste (e.g., because it requires grade control and closer drilling), then the difference should be included in the processing cost.
Processing costs	This category is applied to processed material in addition to the mining cost. Processing cost is applied as a dollar amount per unit of mass (e.g. dollars per dry metric tons) or volume (e.g., dollars per cubic meter) input to the process. A different processing cost will be used for each available process. The cost may be varied by rock type or by one or more grades. Include in this category any costs that vary with the amount of material input to processing, including the rehabilitation of tailings.
Selling costs	This category is applied to the units of product output from the process as dollars per unit of mass (e.g., dollars per gram for gold) or dollars per product unit present (e.g., dollars per Btu for coal). Include in this category costs that vary with the quantity of product output, including freight, freight insurance, royalties, and commissions.
Rehabilitation costs	This category is applied to all waste mined as a dollar amount per unit of mass (e.g., dollars per dry ton) or volume (e.g., dollars per cubic meters). Include in this category any costs that vary with the quantity of waste mined, including continuous rehabilitation of waste dumps.

Sometimes costs can be modeled as either variable costs or fixed costs, and the best method may depend on whether analysis is being done over a very long term or a very short term. As an example, when the cost of labor in mining is considered, as the rate of mining increases and decreases over the life of the mine, labor can be increased and decreased to meet the needs—over the long term, labor is a variable cost. Over short periods—for instance, from one month to the next—if the need for mining labor changes, there is very little that can be done to increase or decrease the supply of labor and its consequent cost—over short periods, labor is a fixed cost.

As it is for the example just presented, so it is for many other costs—in long-term modeling, many costs behave as variable costs, but these same costs may behave more like fixed costs over the short term.

A blend of these two behaviors is also possible: the semi-variable cost. However, rather than thinking of this as a separate category of cost, it can be thought of as a cost in two parts: one part is variable and the other is fixed.

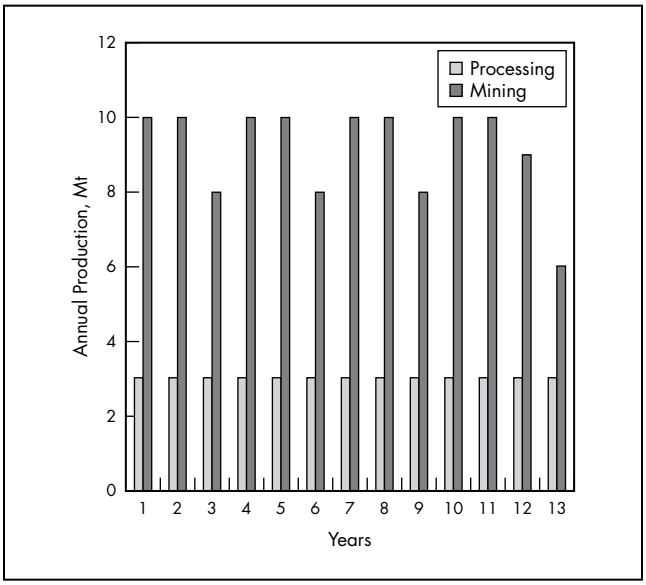

Figure 10.2-22 Example of mining schedule in which the mining fleet (10 Mt annual capacity) is not fully utilized in every period. Using a fully variable cost model for mining in this case may not be appropriate.

Table 10.2-17 Example data to use with Equations 10.2-14 and 10.2-15

Case	Description	X	Y
1	To operate the fleet at full capacity costs $20 million/yr	10 Mt	$20 million
2	To operate the fleet at 80% capacity (mining only 8 Mt) costs $18 million/yr	8 Mt	$18 million

If a mining fleet is considered capable of mining 10 Mt/yr at an annual cost of $20 million, provided that the fleet mines exactly 10 Mt/yr, it does not matter whether the cost is modeled as a variable cost ($2/t) or a fixed cost ($20 million/yr). However, it is not always possible to schedule full utilization of a mining fleet throughout the mine life. The annual mining schedule shown in Figure 10.2-22 can be considered. In this case, the mining fleet cannot be fully utilized in every year. To extend the example, assume that for two common production rates, the following statements are true:

- To operate the fleet at full capacity (10 Mt/yr) costs $20 million/yr.
- To operate the fleet at 80% capacity (i.e., mining only 8 Mt/yr) costs $18 million/yr. (These data are summarized in Table 10.2-17.)

The fixed and variable parts of the cost can be calculated using simultaneous equations as follows:

$$Y_1 = aX_1 + c \tag{10.2-12}$$

where
Y_1 = annual cost for Case 1
a = variable cost
X_1 = annual throughput for Case 1
c = fixed cost

$$Y_2 = aX_2 + c \tag{10.2-13}$$

where
Y_2 = annual cost for Case 2
X_2 = annual throughput for Case 2

$$a = (Y_1 - Y_2)/(X_1 - X_2) \tag{10.2-14}$$

$$b = (Y_1 - X_1) \times (Y_1 - Y_2)/(X_1 - X_2) \tag{10.2-15}$$

By substituting the Table 10.2-17 data into Equations 10.2-14 and 10.2-15, it is seen that the variable cost for the example is $1/t and the fixed cost is $10 million/yr.

The previous discussion focused on a model for NPV maximization and included fixed and variable costs. However, pit optimization, as described in Table 10.2-11, can only use variable costs and, in some special cases, capital costs, as follows:

- Fixed costs cannot be used in pit optimization. Any costs that would ordinarily be modeled as fixed costs should be recast as variable costs for the production activity that determines the life of the mine. When a fixed cost is modeled as a variable cost in this way, it is often referred to as an implicit fixed cost. For example, for a mining operation in which production is constrained by the processing plant capacity, the fixed costs for the entire operation (mining, processing, and shipping) total $20 million/yr, and the processing capacity is 5 Mt/yr. To render the $20 million fixed cost as a variable cost, $4 (i.e., $20 million/5 Mt) would be added to the variable cost of processing (i.e., add $4/t).
- Passive attempts should not be made to build capital costs and terminal costs into the pit-optimization model, as there is no way of doing it without introducing bias to the optimization. There is an exception to this rule: A special technique is available to include the capital cost associated with moving infrastructure, a road, or a river (refer to the "Allowing for Topographical Features" section earlier in the chapter).

The implication of the second point is that pit optimization should proceed with an incomplete cost model, one in which capital costs and terminal costs are ignored. This is correct—the pit optimizer is best thought of as an engine to maximize the difference between the variable revenues and variable costs of the mine. The optimized value of the pit yielded by the pit optimizer only represents the sum of the variable revenues and costs. To get a final pit value, the capital and terminal costs are deducted. This is best done in the context of schedule optimization.

Alternate Method for Modeling Costs for Bottlenecks

In the "Cost Models for Optimization" section, all costs are modeled as capital, fixed, variable, or terminal costs. A fixed cost varies only with time, and a variable cost varies in proportion to activities such as mining, processing, and shipping of finished product. One of these activities will constitute the bottleneck for the business, and for the bottleneck, instead of applying a variable-cost model, it is possible to apply a special kind of fixed-cost model. This is particularly useful when the throughput rate for the bottleneck depends on the type of material sent to it. For example, in a processing plant

with a nominal capacity of 3 Mt/yr and an annual operating cost of $30 million, at its nominal rate, the processing cost is $10/t. However (in this example), soft rock can be processed at 3.5 Mt/yr, whereas hard rock can be processed at only 2.5 Mt/yr. A simple variable cost will not work for both rock types, nor will a simple fixed cost, because the capacity depends on the rock type fed to the process. The alternative is to use a time-consumption model.

To build on the example, assuming the processing plant has 95% availability, there are 8,322 processing hours available in a year ($0.95 \times 365 \times 24$). That means the processing cost is $3,605 per hour ($3 million/8,322). The actual throughput depends on the type of rock type. Soft rock can be processed at a rate of 421 t/h, and hard rock can be processed at the rate of 300 t/h. Another way of stating this is that 1 t of soft rock consumes 0.0024 hours of processing time (about 9 seconds), whereas hard rock consumes about 0.0033 hours of processing time. If processing costs are then applied to the rock based on the time they consume rather than their tonnage, the costs will be modeled correctly, and the throughput will also be modeled correctly. In summary, the time-consumption model for this example is as follows:

- The processing capacity is 8,322 hours.
- The processing cost is $3,605 per hour.
- Soft rock quantity (processing time consumed) is calculated by multiplying the block tonnage by 0.0024, and the hard rock quantity is calculated by multiplying the block tonnage by 0.0033.

Dealing with Tax

Cost modeling for the purposes of optimization is done on a pretax basis. The reason is that optimization software uses simple cash-flow models, whereas a more complicated accrual accounting model must be used to properly model taxation liabilities. This is not to say taxation should be ignored—it is a significant cost. However, it cannot be adequately dealt with in a simple cash-flow model. The solution is to maximize pretax NPV in the optimization software and then to take the pretax cash flows and reanalyze them in an appropriate spreadsheet to calculate tax liabilities and post-tax NPV. The post-tax NPV will, of course, be lower than the pretax NPV, and only projects with positive NPV should proceed. The fact that optimization proceeds on the basis of pretax NPV maximization does not generally present problems because there is a positive relationship between pre- and post-tax NPV—decisions in mine planning that maximize pretax NPV will also (usually) maximize post-tax NPV.

Workshop for Framing

Many techniques are available for value-focused thinking and framing of decisions and analysis. The fundamental concepts are described by Keeney (1992).

One such technique for framing is presented here. The following are two basic parts of the technique:

1. Define the problem/opportunity statement. What is to be achieved?
2. Determine key decisions to be made and the risks and uncertainties to be managed. How is this achieved?

The problem/opportunity statement has already been preempted in this chapter in discussion of the primary objective—to maximize NPV. NPV maximization should feature strongly in most, if not all, open-pit mine planning problem/opportunity statements. Although everyone involved in the mine planning process may think they know and understand the objective of the task, it is worthwhile conducting a workshop in which the key stakeholders state their belief of the objective or objectives of the task. These viewpoints should be collated and a consensus reached on exactly what it is that the team must achieve. The objectives should be made explicit in writing—stating not only what the process seeks to achieve but also a statement of what is in and out of scope for consideration. This exercise clarifies and reinforces for all what the value metric is and focuses all efforts on optimizing that metric within the bounds specified. The following are examples of problem/opportunity statements:

> **Example 3.** "To develop open-pit mine A and maximize NPV. Identifying ore feed from other source mines is not part of this study."
> **Example 4.** "To explore different product mixes by including the low-grade ore up-dip of the current open-pit to maximize NPV. Modifications to the current processing system are not included in this study."

When the problem/opportunity statement is clear, the next task is to determine key decisions to be made, the risks, and the uncertainties to be managed. This part of the exercise is also best carried out in a workshop setting with the key stakeholders participating, and it has the following three steps:

1. **Present and catalog issues.** This step involves reviewing all issues that are considered important and relevant to any of the stakeholders and then cataloguing them as being factual information or known or unknown risks, opportunities, uncertainties, or decisions that need to be made either now or in the future.
2. **Decipher key decisions and generate alternatives.** From the list of decisions in the catalog from Step 1, focus should be drawn to the key decisions that are within the scope of the study and that could have a significant impact on the value metric. Unconstrained thinking or brainstorming should then be conducted regarding all possible alternatives for these key decisions. The alternatives should include known alternatives or choices, as well as new creative ideas. An efficient way of recording this information is in table form, with the key decisions listed as column headings and alternatives for each key decision listed below. An example strategy table is shown in Table 10.2-5.
3. **Develop the hypotheses to be evaluated.** The final step is to design a few hypotheses for the best set of decisions to achieve the objectives. For example, Hypothesis 1 could be to "minimize time to first ore" and Hypothesis 2 could be to "minimize upfront capital investment amount." Each hypothesis is comprised of a choice of an alternative for each key decision consistent with the premise of the hypothesis. Each hypothesis, along with relevant risks, opportunities, and uncertainties, is then further assessed in mine planning. The hypotheses are not a new set of objectives but simply a way of mapping the entire field of possible decision alternatives. Each hypothesis must be measured against achieving the objective set out at the start. Analysis will reveal one hypothesis that most optimally meets the objective. When the preferred hypothesis is found, it can be further refined (e.g., increasing the mine production rate from 6.0 to 6.7 Mt may further increase NPV).

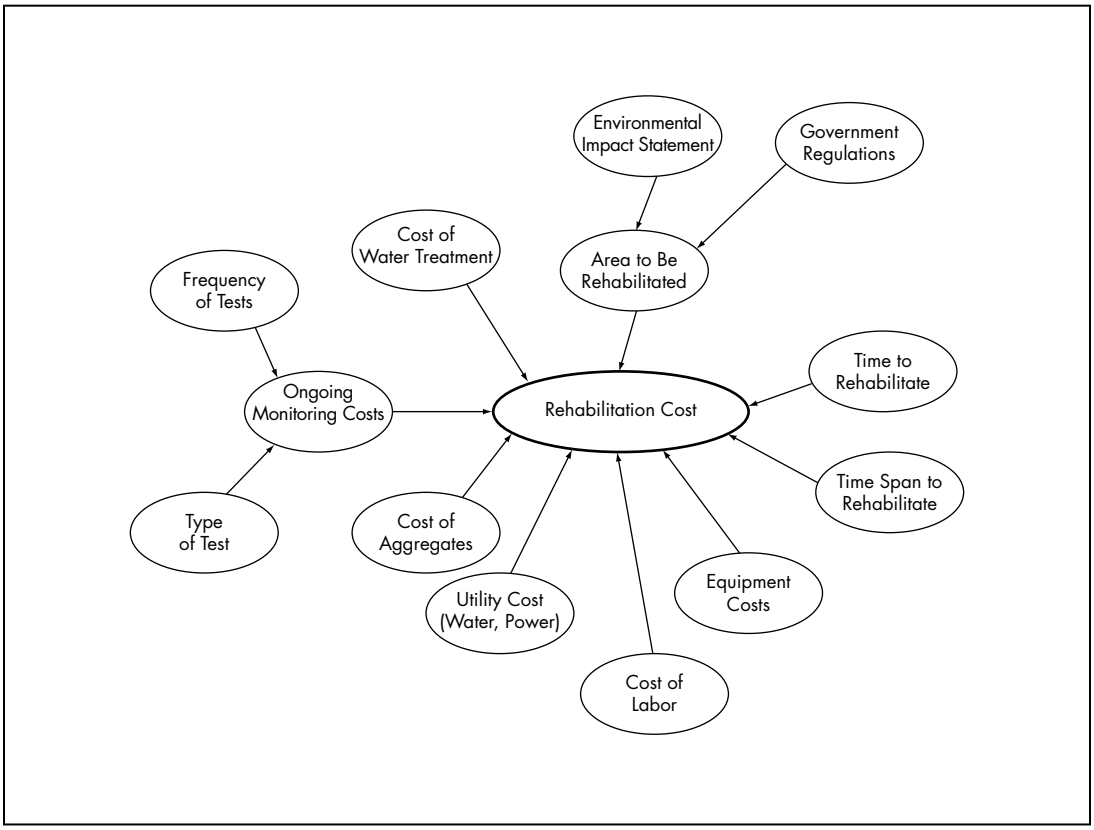

Figure 10.2-23 Influence diagram

Workshop for Building a Model of Highly Uncertain Data

Although most of an individual's education and training drives the person to arrive at a single point estimate for parameters, often the experience with outcomes will show the estimates to be incorrect. With perfect hindsight, a person will look for possible justifications for why the outcome was different from the estimate. Often it will be concluded that because the parameter was dependent on a number of factors, any of which could have played out, the confidence in the single estimate should have been low. In other words, the parameter is highly uncertain. The most common approach for treatment of such uncertain parameters has been to conduct a sensitivity analysis. The parameter is tested for (typically) ±10% variation in value, and the impact on the results is reported. This approach, however, does not consider the possibility that there could be a lot of factors that may drive the value lower than the factors that could drive the value higher (or vice versa). Neither does it answer the question of how much confidence should be placed in the single point estimate as compared to the sensitivities.

This section provides a technique to model parameters that are uncertain. The technique teases out the full range of possible outcomes and also assigns likelihood of occurrence.

The exercise is best conducted in a workshop setting with subject-matter experts participating. It consists of the following steps:

1. **Define the parameter.** The parameter under investigation should first be clearly defined along with the units in which it is to be measured. This is to ensure that no ambiguity arises when using the parameter later. For example, if the parameter is "rehabilitation cost," it should foremost be established (as the case may be) that the cost is in U.S. dollars in real terms; that it is cost per hectare of area rehabilitated and not per volume of material rehabilitated; that it does not include the cost of releveling the waste dump, which is covered under waste dump maintenance cost; and so forth.
2. **Draw influence diagrams.** It is important to recognize and understand what factors, events, risks, and uncertainties could impact the outcome of the parameter. For example, factors that would impact rehabilitation cost are what the rehabilitation involves (e.g., mixing other aggregates with the waste rock, purchasing that aggregate, providing drainage, reestablishing flora, and providing irrigation), the cost of equipment required for the job, fuel costs to run the equipment, time span in which work is to be completed, total area to be rehabilitated at any one time, and so forth. An influence diagram may be used for representing this information in a pictorial format. An example of an influence diagram is shown in Figure 10.2-23.
3. **Explore the maximum and minimum possible values.** The workshop participants should be asked to consider a very unfavorable situation in which all the factors that negatively impact the parameter of interest are present. Participants should be asked to narrate such a situation and work toward exploring the extreme end of the range. The questions posed can include: "How bad can it get?" "Is it remotely possible?" Individual factors on the influence diagram should be assessed, and an overall minimum value derived. A brief narrative should be written

and agreed to. The participants should then be asked to consider a very favorable situation in which all the factors go extremely well. Again, the intention is to explore the extreme end of the range, this time on the optimistic side with questions such as: "How good can it really get?" "Is it remotely possible?" Individual factors on the influence diagrams are assessed, and an overall maximum value is derived. Again, a brief narrative should be written and agreed to.

4. **Revisit the best estimate.** Having completed the exercise of exploring the extreme limits, the participants should then be asked to consider what they think the *best estimate* of the parameter would be after consideration of Step 3.
5. **Explore other point estimates.** The workshop participants should then be asked to estimate a couple of other point estimates: an optimistic estimate and a pessimistic estimate. Again, a brief narrative should be written about how these estimates were determined.
6. **Assign likelihoods.** Likelihoods or confidence levels may be assigned as continuous probability distributions or discrete probabilities of occurrence. Assigning likelihoods is often a partially objective and partially subjective exercise. For parameters that have a lot of information and data available, statistical analysis can be conducted to determine likelihoods. This is then overlaid with subjective information based on the experience and knowledge of the experts. For example, there is a detailed database available for rehabilitation cost in the area based on which statistically determined likelihood is estimated. However, it is anticipated that the environmental regulations will get more stringent with a new incoming government (which may require extra rehabilitation activities). There is also a shortage of labor because of new projects initiated in the neighboring areas, and labor rates are likely to be higher. These pieces of information will mean that there is a likelihood of costs increasing over their statistically determined value.

ACKNOWLEDGMENTS

The author acknowledges the support of the following organizations and individuals:

- BHP Billiton, Gavin Yeates, and the many colleagues who provided support and advice during the writing of this chapter
- Gemcom Software International who permitted me to draw upon short course material developed during my time with Whittle Programming and Gemcom
- V. Vasundhara of BHP Billiton who contributed material to this chapter on the subjects of framing and dealing with highly uncertain data
- Gary Bentel of BHP Billiton who contributed material to this chapter on geotechnical and risk management issues
- Jeffrey Whittle, my father, who has contributed greatly to the field of open-pit mine planning and optimization for many years. He introduced me to the field in 1990 and was my teacher for 10 years. He continues to make important contributions to the advancement of mine optimization

CHAPTER 10.3

Mechanical Extraction, Loading, and Hauling

James D. Humphrey and Joshua D. Wagner

This chapter discusses the characteristics and applications of the following common systems used in modern mining operations to extract, load, and haul waste and ore:

- Dragline systems
- Bucket-wheel excavator systems
- Loader and hauler systems
- Other systems: bottom-dump coal hauler, trolley-assist mining truck, wheel-tractor scraper, and in-pit crushing and conveying system

Whether a mining operation must select a new system or optimize an existing system, it is important to consider far more than just cost or discounted cash flow. Different systems have different operating characteristics and risk exposures. These characteristics and the capability to manage risk rather than cost more often separates the best option from the rest.

An initial evaluation of operational requirements will narrow the choice of systems. However, inevitably the project feasibility comes down to a capital- and ownership-cost evaluation by means of one of several discounted-cash-flow methods. Significantly, two key components of that evaluation, production and operating costs, are likely to be estimates, and the sensitivity of the system to operational variables affects the accuracy of these estimates and hence the project feasibility.

In the sections that follow, the following operating variables are discussed as characteristics of each system:

- Mobility: the capability of the system to relocate
- Flexibility: the capability of the system to change direction or work irregular patterns
- Operational range: the variety of application methods in which the system can be used to address requirements for operational change
- Sensitivity to geologic variance: the impact of unexpected changes in material characteristics or unexpected structural or stratigraphic variations

Each of the systems discussed is a well-established system for good reason, and any can be the best choice for a particular application.

DRAGLINE SYSTEMS

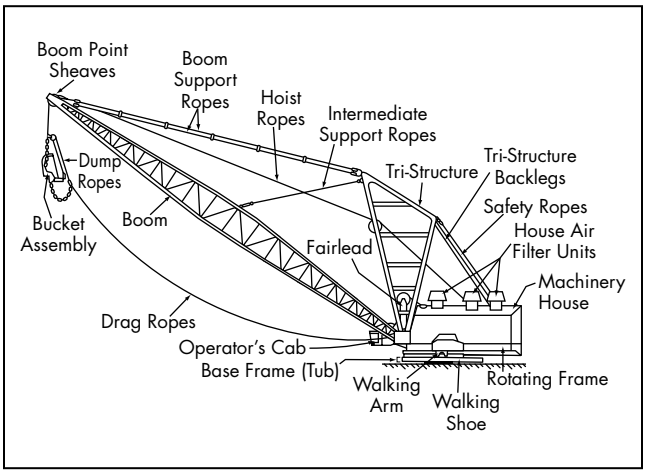
Draglines (Figures 10.3-1 and 10.3-2) are self-contained systems that load and transport material to a dump point. They are highly productive, comparatively low in operating costs and labor requirements, and extremely robust, and subsequently have very long lives, commonly 30 to 40 years.

For purposes of comparison, the dragline system is a high-capital-cost, low-operating-cost system that is moderately flexible and can operate through a moderate range of applications with low sensitivity to geologic variance.

Because of their high productivity and capability of direct disposal of material, draglines are favored for area mining in areas of flat-lying tabular geology with high production requirements. The most common application for large draglines is overburden removal in coal mining. However, because they excavate below their working level and exert very low ground-bearing pressure, they are uniquely suitable for digging very wet materials, occasionally even below water.

A large dragline can operate through a range from about 50 m (170 ft) above to 65 m (210 ft) below its working level. This means that, with advanced techniques, the dragline can handle overburden depths of about 80 m (260 ft).

Although the largest dragline ever built had a 170-m^3 (220-yd^3) bucket, for the last few decades the largest draglines built have had 125-m^3 (160-yd^3) buckets. Draglines of this size are capable of moving 30–35 million BCM (bank cubic meters) (40–45 million BCY [bank cubic yards]) per year.



Dragline applications and operations are generally determined by two major factors: the placement of spoil material in the space available and the three basic bucket controls (hoist, drag, and swing). The patterns of tub positions, dig location, digging sequence, and dump locations are best optimized by a pit design that considers spoil placement and the characteristics and interrelationships of the bucket controls. To a lesser extent, the digging peculiarities of the bucket and the bench space required for operations are also considerations for pit design.

In most basic dragline operations, the dragline removes overburden material to uncover ore that is the most recent in

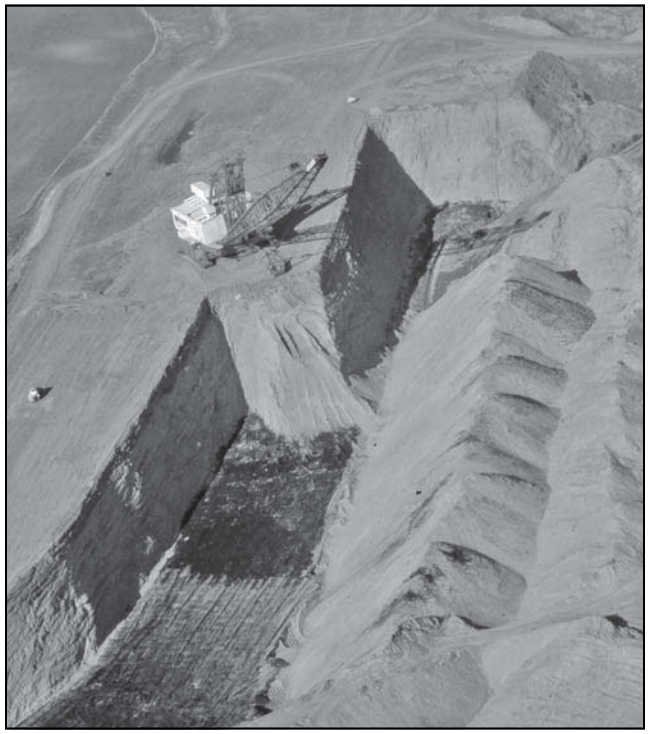
Figure 10.3-2 Dragline design

a series of parallel adjacent pits. Figure 10.3-3 shows a typical dragline pit. Overburden material from the current pit is placed in the previous adjacent pit, from which product has been removed by auxiliary equipment. Pits are narrow and relatively long:

- Pit widths are most commonly 25–60 m (80–200 ft). Widths for rehandle operations tend be on the large side, to reduce the percentage of rehandle. Width is influenced by the maneuverability of the product-removal equipment, depth of the overburden, blasting method, material characteristics, dragline advance rate, and dragline dump radius.
- Pit lengths vary greatly because of the influence of geology, topography, and artificial obstacles. They are most commonly 1,000–2,000 m (3,000–6,000 ft), although some operations have used pits as short as 300 m (1,000 ft) or as long as 3,000 m (10,000 ft). In shorter pits, the sequencing of product removal and blasting becomes complicated and frequent ramp construction is required. In longer pits, power distribution systems become expensive and complex, and dragline propel distances can be excessive.



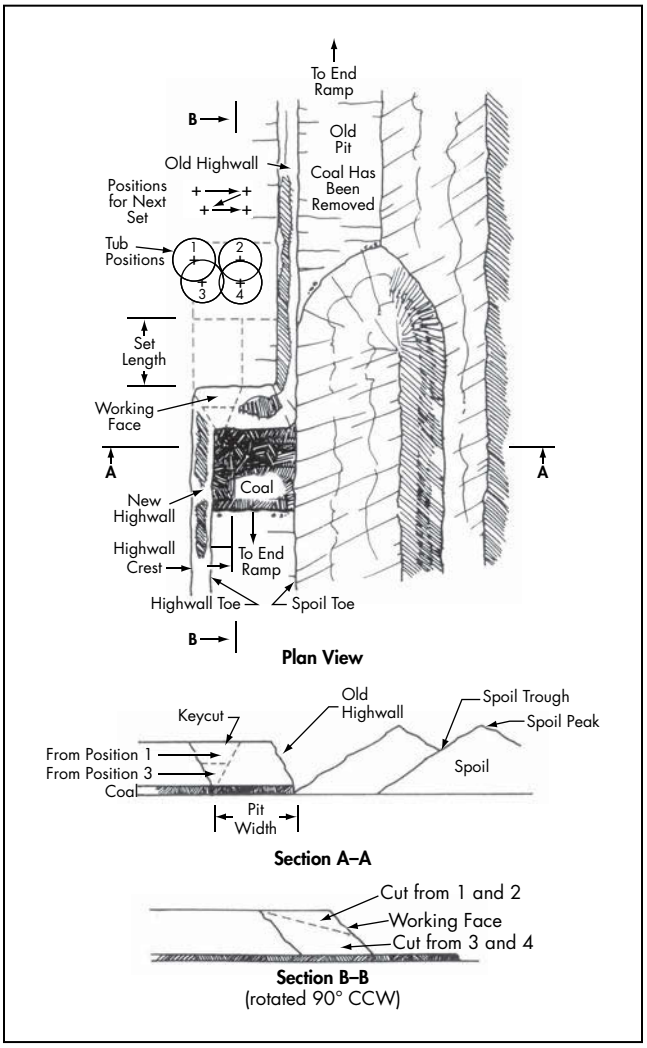


Figure 10.3-3 Typical dragline pit

The pad on which a dragline sits while it works must be clear of hard spots and protruding rocks, and must be relatively level, graded to a slope of ≤2% to provide drainage yet avoid damage due to swing-motor overheating and structural stresses. Modern draglines can propel up and down a ≤10% grade or across a ≤5% grade. When they transition between grades, it is important that they do so gradually, always distributing the load evenly across the tub (the dragline's circular base) and shoes. As a general rule, the rate of grade change should be ≤3% per tub diameter. For example, for a tub 20 m in diameter, the rate of grade change should be ≤3% per 20 m, so a change from 0% to 9% should take at least $9/3 \times 20 = 60$ m. Additionally, when the possibility exists of bridging the shoes, the pad material should be sufficiently compacted to prevent supporting the shoes by the endpoints only.

Draglines are designed to work in soft-underfoot conditions, and as such are designed with tub ground-bearing pressures on the order of 1.2–1.4 kg/cm^2 (17–20 psi). During propel, about 80% of the machine weight is transferred to the shoes, and the remaining weight is carried by the tub edge. This ratio can be changed by carrying the bucket or setting it on the ground. Reducing the tub-edge load by setting the bucket on the ground reduces the probability of pulling a roll under the tub during propel in soft-underfoot conditions.

Rather than remove material from a continuously advancing face as a shovel does, a dragline removes material from a specified length of the pit, called a *set* or *block*. The dragline swings approximately 90° and casts into a pile in the previous pit. Set lengths for larger machines are about 30 m (100 ft), or about 16 steps for the dragline. To remove the overburden from a simple set, a dragline may use from two to four tub positions before retreating to start a new set.

Source: Humphrey 1990.

Figure 10.3-4 Digging positions in a dragline pit

Commonly a dragline follows a pattern of digging positions to excavate a set (Figure 10.3-4). The first two rear positions are set back far enough to ensure that no material is too close to the fairlead to be reached. In shallow pits, these first two positions may suffice to reach the desired depth. In deeper pits, digging may soon reach the point where the drag ropes scour through the crest of the digging face, in which case the dragline must move forward to clear the drag ropes. Thus, from the rear positions, the upper part or *lift* of the set is removed. In the last two positions, the dragline has moved forward to the edge of the digging face to reach down for the lower lift of the set.

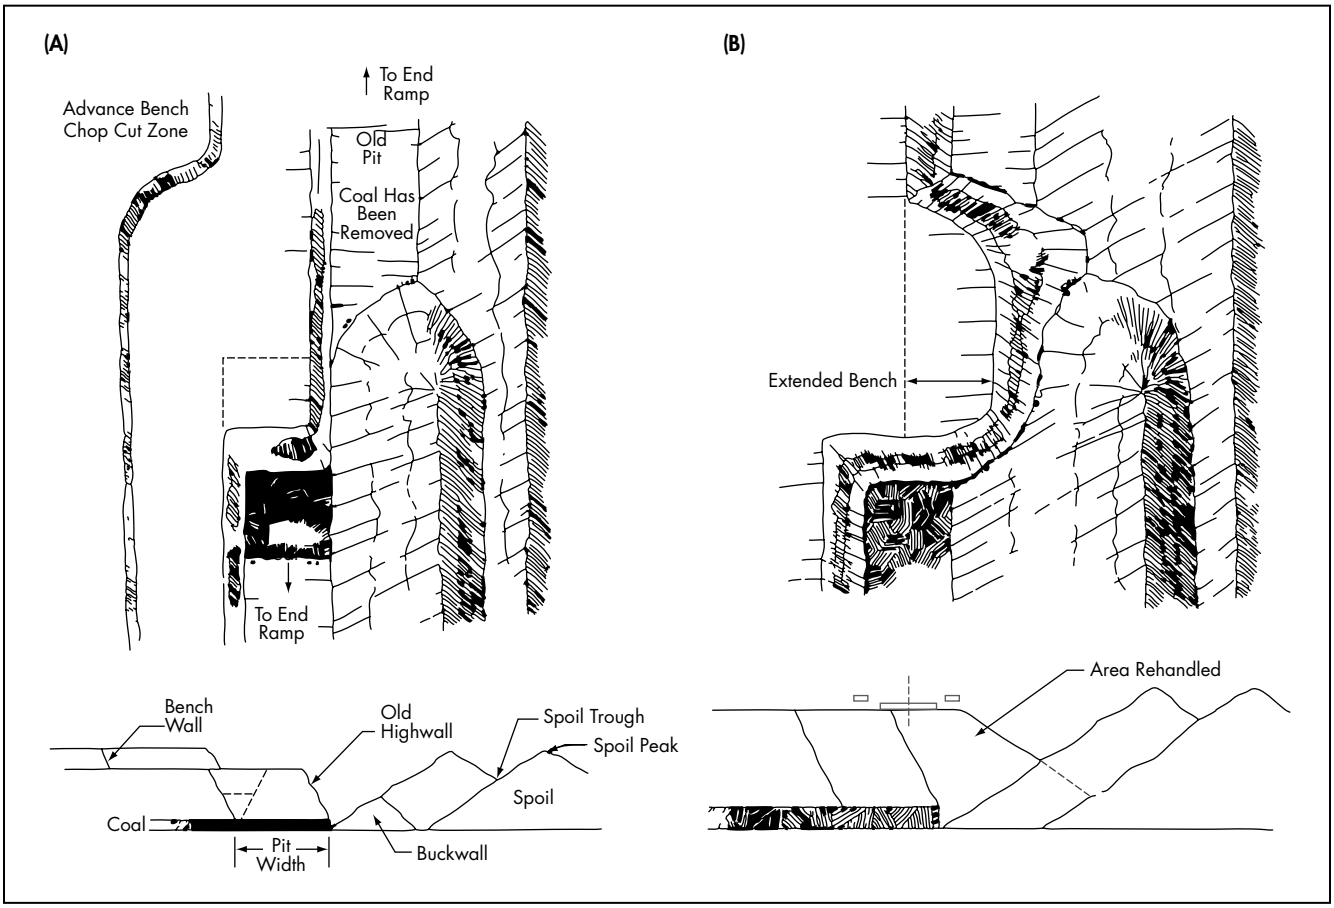
The lateral positions in a pit are also significant. From the positions along the highwall (1 and 3 at the bottom of Figure 10.3-4), the dragline can fix the alignment and slope of the new highwall with the *key cut*. This trench-like cut is confined to a bottom width of only a single bucket as it works down. Such a cut allows maximum lateral control of the bucket with minimal lateral strain on the boom. In addition, if the entire dig path is not directly radial to the dragline, production and mechanical availability can suffer. At the bottom of the lift in position 1, the dragline generally moves laterally to position 2. This *plug* position allows the dragline to spoil at maximum range. This move is made before completion of the key to reduce delay caused by hoisting clear of the key before beginning the swing. As excavation progresses, the plug is removed in lifts comprised of a series of cuts to an equal depth (about one-half the bucket height) made in a sweeping pattern. The sweeps normally progress from the spoil side to the key so as to minimize any hoisting required before swinging the bucket to the spoil. Then the dragline moves forward into positions 3 and 4 to excavate the lower lift in much the same fashion.

In Figure 10.3-3, the dragline has stepped back from the face for maintenance but has completed the first three positions of the set. The top of the set has been removed from positions 1 and 2 and the key cut has been finished from position 3. The dragline is now ready to move over closer to the spoil and finish the plug from position 4.

This description, although typical, should be considered general. Set lengths and digging positions will vary depending on operating conditions and machine capabilities.

Dragline Operating Methods

Draglines can operate by means of several operating methods, described in the following paragraphs.



Simple Side Casting

The standard dragline method is simple side casting, used when the dragline has the required reach to move the overburden to its final place. With typical angles of repose and pit widths, the maximum overburden that can be handled by this method is a little less than half the effective radius, discussed later in the "Dragline Selection" section of this chapter. Variations on simple side casting are common.

Advance Benching

Advance benching (Figure 10.3-5A) is useful in areas of uneven terrain or in overburdens where a top layer of unconsolidated material overlays competent rock. The set is split into an upper and lower bench. The lower bench is removed conventionally; the upper bench is removed by *chop cutting*, which typically means digging above the working level but also can mean engaging the bucket at the dump radius. Either way, the bucket is at least partly pulled down a face rather than up or across it. The bucket is usually held in a dump position, teeth down, then lowered onto the face and dragged in. Chop cutting is sometimes used instead of a key cut in spoil-side operations to clean the highwall. However, chop cutting is hard on the rigging, ropes, and bucket, and can increase downtime and repair costs and decrease productivity. Productivity is further decreased by the lower fill factor and increased drag-to-fill time. Advance benching generally requires a longer swing angle as well. Although efficiency varies, typically a reduction of 10%–20% of the conventional rate should be used for initial estimates. When practical, chop cutting should not be done above the height of the fairlead, or else production and maintenance can be significantly impacted.

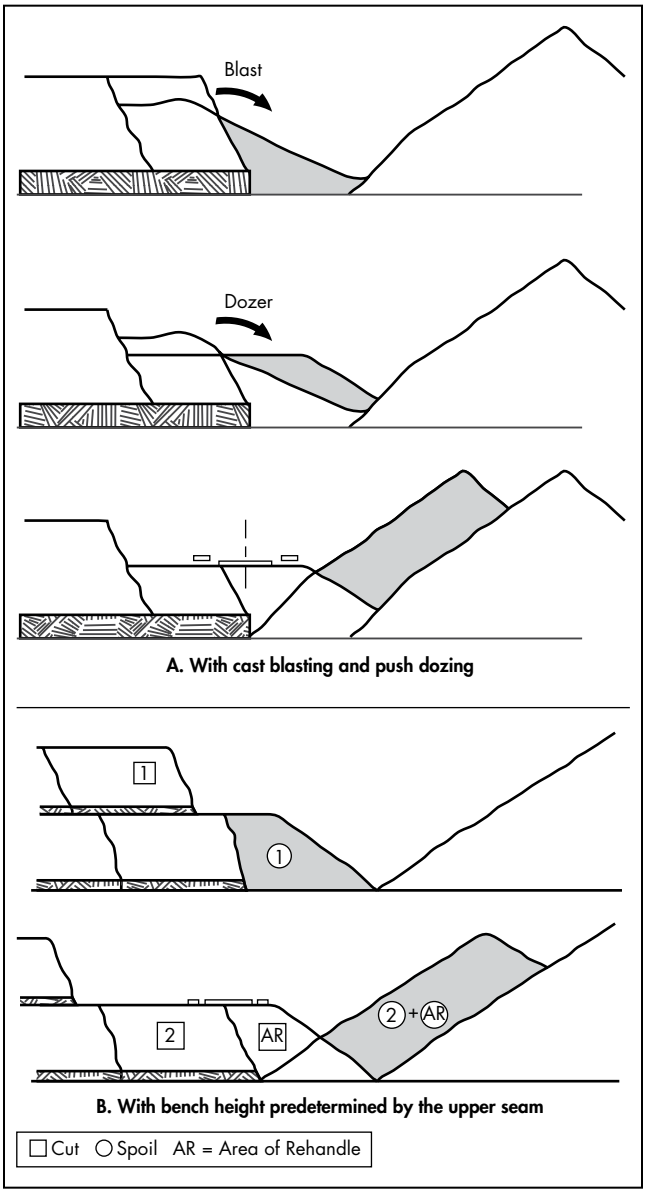
If the material in the advance bench is extremely unconsolidated, it is sometimes convenient to build a *buckwall* (visible in Figure 10.3-5A) out of dry competent material removed from another area of the set and placed as a retaining wall at the toe of the spoil. The unconsolidated material is then placed and contained behind the buckwall. A buckwall can be used to help stabilize any spoil pile.

Source: Humphrey 1990.

Figure 10.3-5 (A) Advance benching and (B) extended benching

Extended Benching

To extend operations in deeper overburdens, the alternative methods of extended benching and spoil-side benching (discussed in the next subsection) can be used to remove material to a depth of about twice that achievable by simple side casting. However, these methods come at the price of increased rehandle, slower cycles, and more complex planning, although the impact on rehandle and cycle time can be reduced by use of auxiliary equipment. These methods can also be used on a temporary or localized basis around ramps, spoil, or highwall slumps, at high spots in the overburden, or inside curves.



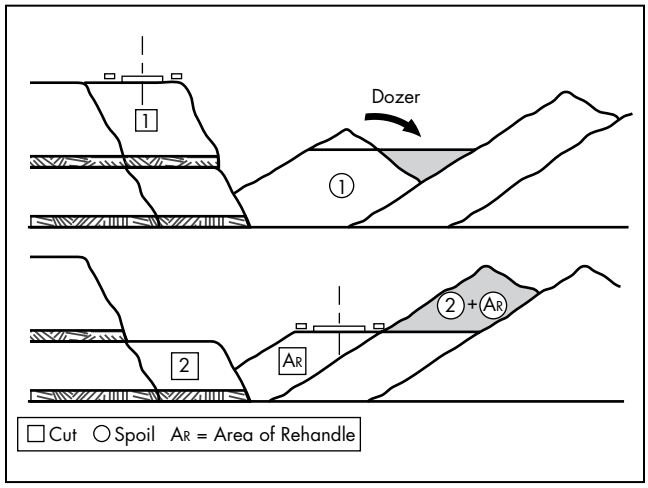
In extended benching (Figure 10.3-5B), the dragline places the driest, most competent material from the set against the old highwall. Enough material is placed so that, after leveling by dozers, it forms a bench. The dragline then moves out onto the bench in a position closer to the spoil. As excavation progresses, the bench is removed. This method can be used in two-seam operations as well. A disadvantage of extended benching is that the swing angle is long, lowering total production.

When calculating production requirements, it is important to remember that the rehandle material in the extended bench is loose material, and therefore has a different bucket factor.

For long-term applications, extended benching is frequently combined with cast blasting and push dozing (Figure 10.3-6A), both of which are effective for moving material short distances downhill. Blasting lowers the bench level, decreasing rehandle; it also moves some material to its final place, increasing production. The cast-blasting profile is then leveled by dozers to form the extended bench.

Bench height and width should be designed to take maximum advantage of dragline hoisting. However, although high hoisting can lengthen cycles, the benefit of a lower bench height with its lower rehandle is usually the determining factor in setting bench height. In multiple-seam operations, the bench height may be predetermined by the upper seam (Figure 10.3-6B).

Two positioning issues often arise in extended benching: cleaning the coal toe and cutting the key. For cleaning the coal toe, because the extended bench covers the coal toe, it is clearly advantageous, especially with thicker seams, to position the dragline just outside the edge of the coal, which is the best position from which to clean the spoil toe away from the coal toe and thus minimize rib loss. However, doing so may require pushing the extended bench out a little farther than is necessary to meet dump requirements. For cutting the key, a lower bench without a setback prevents the dragline from being positioned directly over the key. The dragline can be positioned no closer to the new highwall than the rear-end clearance radius. To keep the highwall clean and well defined, a presplit blast is commonly used. The dragline can be positioned out on the extended bench at a distance from the highwall equivalent to the dump radius and then the key can be chop-cut. Alternatively, the key can be developed by



Source: Humphrey 1990.
Figure 10.3-6 Combinations of extended benching

auxiliary equipment, typically dozers but sometimes backhoes or smaller draglines (Ingle and Humphrey 2004). In the latter case, it is critical to consider in advance the finer blasting fragmentation required for auxiliary equipment.

Spoil-Side Benching

In spoil-side benching (Figures 10.3-7 and 10.3-1), also called *pull-back*, overburden is removed in two independent passes. This method is common in two-seam operations and is virtually required in three-seam operations.

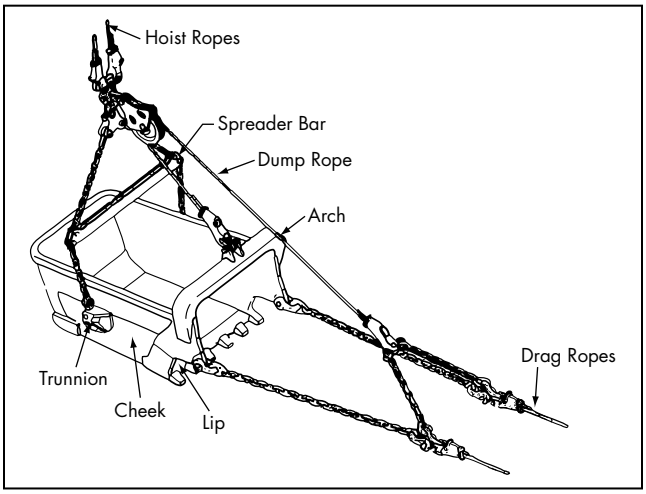
On the first pass, from the highwall side, material is moved by standard side casting. Spoil from that pass is allowed to ride up the highwall, and then the peak is leveled to form a pad for the second pass. The first pass is generally completed for an extended length of pit, whereupon the dragline bridges across to the spoil bench. On the second pass, the spoil bench can be removed in either direction, depending on pit

Source: Humphrey 1990.
Figure 10.3-7 Spoil-side benching

sequencing, spoil-bench development, and cable layout. On the spoil side, the dragline is positioned so that the key can be chop-cut with the boom perpendicular to the highwall.

The design height of the spoil bench, which also determines its width, is based on the reach requirement to chop-cut the key on the spoil-side pass, the dig depth, and, if the coal toe must be cleaned, the dump-height limitations of the dragline and tub position. If the first pass does not generate enough material to achieve the necessary spoil-bench height, material can be removed from the spoil-side position and placed one or two sets behind the dragline, much like an extended bench.

It is best to develop the spoil bench with auxiliary equipment; however, the amount of material to be moved may justify assistance from the dragline. And since the bench is developed in advance (the dragline is chopping in the direction of travel), it is better to develop a finish grade for only the road width of the dragline along the spoil edge, leaving the outer edge of the bench for the auxiliary equipment to finish-grade.



Spoil-side benching requires carefully managed cable moves and layouts, particularly when raising the bench level from the spoil side. With the cable on the bench and the dragline progressing toward the cable, the bench must be raised in halves. This requires moving the cable from side to side and sometimes also swinging over the cable. Swinging over the cable should be done only with a protective covering and carefully controlled operator technique.

Spoil-side benching enables operation of multiple draglines in a pit (Figure 10.3-1). In a fairly short pit, this can afford a very high production rate. However, it is difficult to schedule multiple draglines, primarily because of the complexity of matching the advance rate of draglines working on separate benches. Although production requirements can be proportioned, short-term variability in production rates invariably causes inefficiencies. Very few operations run tandem draglines in this manner for any length of time.

Dragline Production

The amount of material moved by a dragline is determined by the following basic parameters:

- Bucket capacity: how much material is put in the bucket
- Cycle time: how fast the bucket is cycled

Source: Humphrey 1990.
Figure 10.3-8 Dragline bucket rigging

- Operating hours: how many hours per year the dragline is kept digging

Bucket Capacity

Bucket capacity was historically measured in accordance with SAE standard J67 (1998). This standard calls for a struck-top and front-face calculation and then subtracts 10% of the calculated volume to account for the slope of the front face. It also uses estimating factors to assist with the calculations of the complex curves of a typical bucket. However, the final so-called "rated capacity" in no way represents the behavior of material in the bucket. Rather, it simply provides a uniform method for comparing bucket capacities. For calculating production, the rated capacity must be adjusted for material swell and fill characteristics.

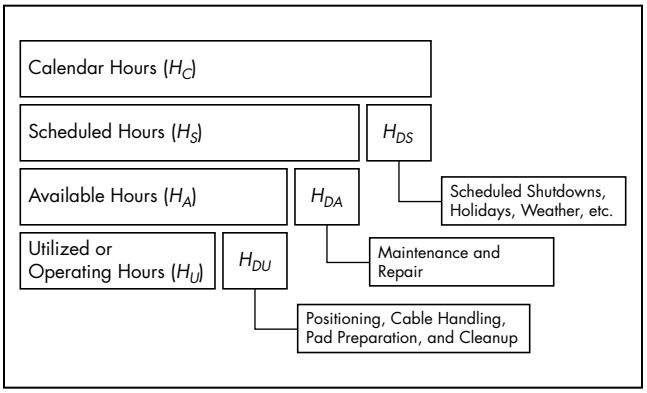
The material in a bucket is loose, so the rated capacity of a bucket can be thought of in terms of loose cubic meters (LCM) or loose cubic yards (LCY). Material swell changes with handling and varies within a bucket or pile of material; within a large pile, it also varies with time. Additionally, it can differ dramatically from the swell in a shovel dipper or truck body.

To account for swell and fill, two factors have been introduced:

1. The *swell factor* F_s is affected most noticeably by fragmentation and material composition, but also by bucket design.
2. The *fill factor* F_f, although more complicated to determine, generally has a larger impact on production variability and should be studied carefully. Fill is affected most noticeably by fragmentation and operator technique, but also by bucket-rigging configuration (Figure 10.3-8) and design.

F_s and F_f depend on material characteristics, digging method, rigging configuration, and bucket design; they do not remain constant if any of these variables change. They are thus best determined from field data, optimally by starting with bucket count and block volume, and then—for a particular material, operating method, and rigging setup—calculating the bank volume moved per bucket.

F_s for material in a dragline bucket is typically about 1.3 loose volume per bank volume. F_f is typically about 0.90 of the SAE J67 rated capacity. F_s and F_f can be combined into a single bucket factor, typically about 0.70, meaning that a bucket rated at 100 m^3 typically carries about 70 BCM. The typical distribution of payloads is about ±10%.



Cycle Time

The digging cycle of a dragline is comprised of five main components: (1) drag to fill, (2) hoist and swing, (3) dump, (4) return swing and lower, and (5) bucket-spot. The time required for each varies depending on a number of factors, most notably dig depth, hoist height, and swing angle. Other variables include material characteristics, dragline performance speeds, and operator proficiency. Because of the diversity of these factors, even machines of the same model and design have different cycle times. Typical designed cycle times for larger machines are in the range 50–60 seconds for a 90° swing with a low dump. A typical cycle is dominated by components 2 and 4; about 70% of a typical cycle is required to get the bucket over to the spoil and back again.

Component 2 of the cycle (hoist and swing) is actually three independent movements: swinging, hoisting, and paying out drag. Each has a specific time requirement. For almost any dump point, one of these movements takes more time than the others. Therefore, two movements are retarded intentionally so that the slower dependent movement has time to coincide at the dump point. However, drag pay speeds are so rapid that they are seldom the dependent movement. It is convenient to think in terms of the curve that the bucket follows at maximum hoist and swing speeds. This swing–hoist coincidental curve represents the points in space that make maximum use of the time available for both functions. Cycles dumped below the curve are *swing dependent*; cycles dumped above the curve are *hoist dependent*. For example, if a particular cycle is a long swing with a short hoist, then it is below the curve and swing dependent. Hoist distance and swing angle can be controlled by pit and digging pattern design, and performance speeds can be affected by operating technique. Thus it becomes obvious that a dragline operator should dump each bucket not at the peak of the spoil but rather near the swing–hoist coincidental curve. Although this is not practical for every cycle, the more coincidental cycles that occur, the more efficient the operation.

Hoist distance and swing angle are minimized by optimizing the bench height and the digging positions of the machine while minimizing the number of relocations (which cause nonproductive propel time). Obviously, machine positioning is limited by the key cut, drag-rope clearance, tail clearance, and reach requirements.

Bucket speed during these independent movements is very dependent on operating technique. Hoist speed is a function of the load in the hoist rope, which is directly related to bucket position. Because hoist acceleration is extremely quick and represents a small proportion of the hoist time, acceleration time does not affect hoist time significantly. To keep the bucket in the carry position, tension must be maintained on the drag rope, which increases the load in the hoist rope. Typically, the hoist load is about 120% of the bucket and payload weight. The closer the bucket is carried to the boom, the greater the hoist load, which ranges from about 110% to 140%. The change in hoist speed is directly proportional to the change in hoist load. So the further out the bucket is carried, the faster it hoists. However, carrying the bucket too close to the dump radius generally causes material to slough off the front of the bucket, reducing the fill factor.

Source: Humphrey 1990.

Figure 10.3-9 Relationship between calendar hours and operating hours

Table 10.3-1 Operating efficiency factor

	Utilization			
Availability	**Excellent**	**Good**	**Fair**	**Poor**
Excellent	0.83	0.77	0.70	0.65
Good	0.78	0.72	0.66	0.61
Fair	0.74	0.68	0.62	0.58
Poor	0.69	0.64	0.59	0.54

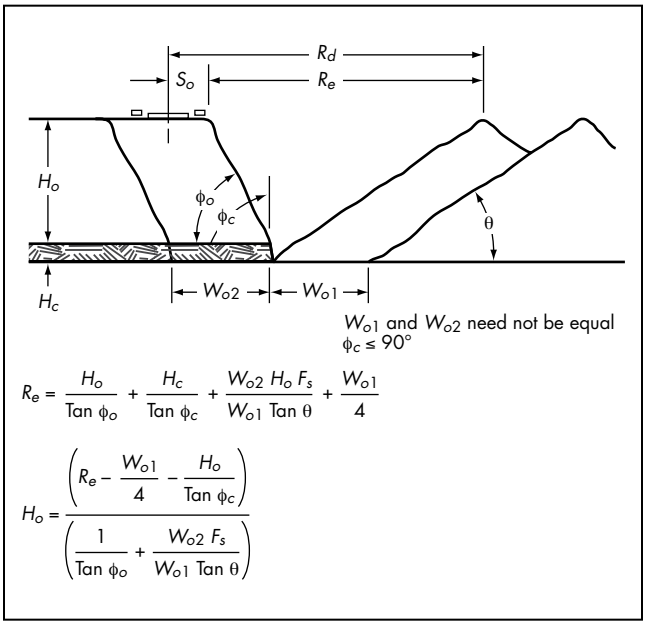
In contrast, swing time is very dependent on acceleration. Acceleration to full speed and deceleration to stop requires about 60° of the swing, which is about 85% of the swing time for a swing angle of 90°. Acceleration and deceleration are relative to the rotational inertia, which is a function of the mass times the square of the radius of the center of mass, so it is greatly affected by bucket location. On longer swings, where hoist is not a factor, keeping the bucket in tight as long as possible improves swing time.

Of bucket capacity, cycle time, and operating hours, inefficiency in cycle time is the most difficult to diagnose and improve.

Operating Hours

Ostensibly the easiest performance parameter to measure is time. In reality, there are more ways to categorize delays and define losses than there are mines around the world. The ubiquitous "hour" is possibly the single most misleading term used in mining. The basic goal is to reduce the number of hours we have to work with down to the number of hours actually worked. Clearly understood definitions are critical to production reporting and estimating.

Figure 10.3-9 shows the relationship between calendar hours and operating hours. Although there are about 8,760 calendar hours in a year, draglines typically operate for 6,000–7,000 hours per year. For initial estimating, it is adequate to combine availability and utilization values into a single operating efficiency factor (Table 10.3-1). Typical availability and utilization values are each about 85%, which provides an operating efficiency of about 72% of the scheduled hours. Availability and particularly utilization can be affected significantly by application. The same dragline on a highwall pass will see a significant difference in operating efficiency on a spoil-side pass where it is chop-cutting and pad-building, typically due to increased propel time, decreased dump-rope life, increased bucket maintenance, and so on.



Apart from the obvious minimization of maintenance and utilization delays, for maximum production it is key to use the available hours efficiently. Most dragline operations can realize significant production gains by reducing cycles that do not contribute directly to ore production. The most significant contributors to inefficient operation are rehandle, nonproductive cycles, and poor planning. To address these contributors, the following are important:

- **Effective management of rehandle.** The use of auxiliary equipment and careful planning are the best tools to manage rehandle. The cost of rehandle should be thought of in terms of incremental costs of ore production, rather than the difference in cost per unit of production for dragline operation compared to that for auxiliary system operation. In addition, in certain applications, a slight increase in rehandle (e.g., changing a bench level or pushing out an extended bench) can improve production due to the effect on cycle and propel time.
- **Productive digging.** Nonproductive cycles are often difficult to measure but can decrease production significantly. There probably isn't an operation at work today that couldn't reduce the amount of time the dragline does pad preparation and cleanup work by better use of auxiliary equipment. Draglines should not waste time heeling the bucket to level the pad or pushing down the roll. In addition, efficient coordination of the ground crew during cable layout and pad preparation can minimize move times.
- **Quality operation planning and coordination.** The amount of detailed planning required to operate a dragline most efficiently should not be underestimated, particularly for nonroutine digging. Specific tub positions, bench levels, and material placement need engineered plans. It is important to involve dragline crews in planning to ensure their understanding and consensus. In addition, it is a mistake to assume that everyone can easily create, from a two-dimensional drawing, a three-dimensional (3-D) operation. Rather, it is wise to use 3-D software or sandbox models to work through operations in advance, especially complex operations such as ramp crossings. In complex operations, the use of "playbooks," with a diagram for every tub position to describe the digging and dumping points, can be extremely valuable.

Dragline Selection

An important concept to keep in mind when sizing or selecting a dragline is to select the dragline for the mine plan, not the mine plan for the dragline. Draglines are engineered systems, generally customized for an application; even when purchased used, they can be modified during reassembly to better fit an application. The two major parameters used to select a dragline are dump radius and allowable load. Occasionally, other parameters such as ground-bearing pressure of the tub, rear-end swing clearance, dump height, and dig depth may also affect selection.

Dump radius R_d is the horizontal distance from a machine's center of rotation to the hoist rope when the bucket is vertically suspended. Part of this radius is consumed by the stand-off distance S_o (Figure 10.3-10), which is the distance from the center of rotation to the crest of the old highwall. The

Source: Humphrey 1990.

Figure 10.3-10 Dragline geometry

remaining dump radius is the effective radius R_e; thus $R_d - S_o = R_e$. Stand-off distance varies depending on machine size, operational history, and overburden conditions. In the absence of field data, for planning purposes the minimum stand-off distance is commonly considered to be 50% of the width of the dragline from the outside of the shoes or 75% of the tub diameter.

The allowable load, sometimes called the maximum suspended load or rated suspended load, is the maximum weight of bucket, rigging, and material for which the dragline is designed to provide optimum performance. Standard-duty buckets including rigging weigh about 1.2 t (metric tons) per rated m^3 (2,000 lb per rated yd^3) of capacity, although they may vary from 1.1 to 1.4 t (1,800 to 2,300 lb), depending on the application. Overburden densities are site specific, but 1.8 t/LCM (3,000 lb/LCY) is a common approximation. The combined weight of a standard bucket and material load is then about 3.0 t per rated m^3 (5,000 lb per rated yd^3). Therefore, an operation that requires a dragline with a 46-m^3 (60-yd^3) bucket requires the dragline to have about a 138-t (300,000-lb) allowable load. Allowable load is calculated for a 100% full bucket (peak bucket load), even though the average fill used for production calculations is less (e.g., 90%).

For a given dragline model, or more correctly a given frame size, the allowable load can be varied by changing the dump radius. Basically, a shorter reach means a larger bucket. This design change is limited by the hoist load that the gearing and motors can handle (maximum allowable load) or, conversely, the longest boom that the frame can handle. The general rule is: the longer the reach, the deeper the depth that can be handled without rehandle and the less rehandle. However, the best choice is almost always the largest bucket at a shorter reach, despite the higher rehandle. The larger bucket more than makes up for the additional rehandle with additional production.

By calculating bucket requirements using a standard range of production values—8,400 scheduled hours, 60-second cycles, 72% operating efficiency, and a 70% bucket factor—it can be calculated that a dragline produces about 250,000 BCM/yr per m^3 (250,000 BCY/yr per yd^3) of rated bucket capacity. This unit of production per unit of bucket capacity is a convenient general factor called the production factor or digging index (Humphrey 1990), and can be used to quickly estimate the annual capacity of a given bucket, or conversely the bucket required for a given production.

The production factor is commonly used to compare differences in dragline operations, either one application vs. another or one dragline vs. another. With historical data, production factors for specific applications can be developed over time and used for planning and forecasting purposes. Operating mines commonly have production factors of 200,000–300,000, depending on application, cycle time, and efficiency. Production factors are often calculated on an hourly basis, with care given, of course, to which kind of hour is used. The hourly production factor can be useful for measuring the efficiency of a specific operation within an application (Kennedy 1990).

The application of production factor presumes that overburden production requirements are known and have been adjusted for any ore losses in the pit and plant and any rehandle expected for the scenario.

Caution should be used with volumetric terminology. Some operations, mostly outside of North America, report production in terms of *prime* (also called *virgin* or *in-situ*) volumes but label them "bank" volumes. The prime volume is the actual volume of overburden above the coal that was uncovered and does not include rehandle. In fact, most mines typically experience 5%–10% of additional operation rehandle for ramps, bench fill, and the like. A production factor based on prime volume is thus smaller than can be expected in actual operation. Prime volume is adequate for comparing machines using the same method at the same mine; however, it is not a true measure of individual dragline productivity. It is advisable to use the terminology *total (including rehandle) bank cubic meters* (TBCM) and *prime (not including rehandle) bank cubic meters* (PBCM), or for cubic yards, TBCY and PBCY.

Draglines as Loaders

Although draglines are normally used to direct-cast material, they are also sometimes used as loaders. In that case, the normally imprecise dumping technique of the dragline must be altered to something as precise as is used when spotting the bucket in the dig. Most experienced operators have little difficulty adapting to point dumping, and the method has been used to load hoppers, trucks, and barges. Generally, it is most useful when the pit bottom is unsuitable for truck traffic and too deep for a hydraulic excavator. For example, it is common in Florida phosphates for a dragline to mine the phosphate matrix and dump it into a slurry sump on the highwall. The sump is about the size of a large mining truck body.

Contrary to the initial mental image of this method, the bucket does not swing over the target. Rather, the swing is stopped with the bucket in the carry position and the drag is payed out to dump. Trucks are positioned facing away from the dragline so that the bucket enters over the tailgate. The

Figure 10.3-11 Typical bucket-wheel excavator

precision required to determine the truck position (i.e., to spot the truck) is no different than is required for any other loading tool. However, because the spot cannot be marked by the bucket as in shovel operation, position markers may have to be provided. As the dump target is generally on the highwall side, it is easy to locate the target so that the dragline has a very short swing angle and a short cycle time.

To reduce the dump distance and place the material in a smaller area, the dump ropes can be shortened. This has the adverse effect of increasing the load in the dump rope and decreasing the dump-rope life. Alternatively, the dump target can be elevated (such as to an advance-bench level) to shorten the dump distance. Of course, elevating the dump target much above the operator's line of sight compromises hoist time and visibility.

Typical dragline operations are viewable by satellite-image software in the vicinity of these coordinates:

- Simple side casting in a lignite mine: 47° 5.19′ N 101° 19.63′ W
- Cast blasting in a thick-seam coal mine: 43° 41.36′ N 105° 18.80′ W
- Cast blasting with spoil side in a multiple-seam coal mine: 21° 28.85′ S 148° 22.60′ E

BUCKET-WHEEL EXCAVATOR SYSTEMS

The bucket-wheel excavator (BWE) (Figure 10.3-11) is one of the grand machines of the mining industry and traces its origins to drawings by Leonardo da Vinci. The original concept from the late 1800s was technologically challenged by advances in the steam shovel, had its practical beginnings in the early 1900s, but had its first real mining applications in German lignite mines during World War I (Rasper 1975).

For purposes of comparison, the BWE system is a high-capital-cost, low-operating-cost system that has limited flexibility and can operate through a limited range of applications with sensitivity to geologic variance.

BWEs are highly customized and vary in design more than do any other mining machines, to the extent that nearly every machine is not just unique but almost dissimilar. The machines are very robust in design and consequently very long lived. Their most common mining applications are mining unconsolidated overburdens and lignite, handling bulk materials such as stockpiles and load-out facilities, and heap leaching pad construction and removal.

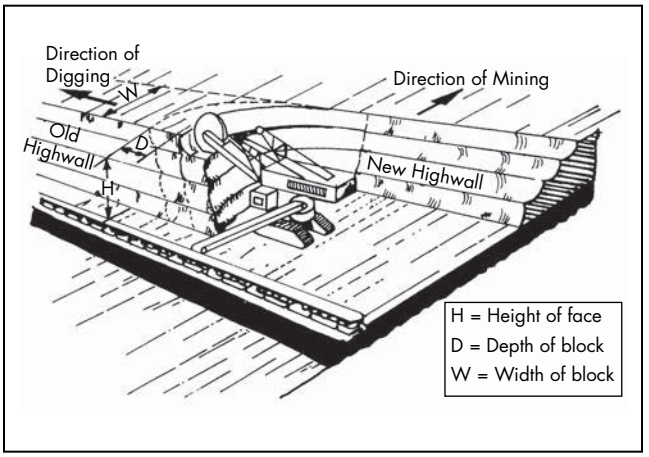
Three major types of BWE exist in mining operations:

1. Systems that direct-feed into a shiftable conveyor system that connects to a series of other conveyors and a discharge system; these machines can weigh up to about 12,500 t (14,000 st) and cut material from a bank height of more than 50 m (160 ft) at rates of more than 10,000 m^3/h (13,000 yd^3/h)
2. Systems with long discharge booms that direct-place material into the spoil
3. Compact systems, generally two crawler machines used for bench heights of about 10–15 m (30–50 ft) with production rates of 1,000–2,000 m^3/h (1,300–2,600 yd^3/h)

When the BWE is used to reclaim stockpiles for rapid loading of trains and ships, it is often rail-mounted. Because the shape of the stockpiles is known, this application is ideal for semiautonomous control.

The numbering system for BWE models is probably the most logical of all mining-equipment numbering systems. The format of a typical German BWE model number is (ThyssenKrupp Fördertechnik 2005)

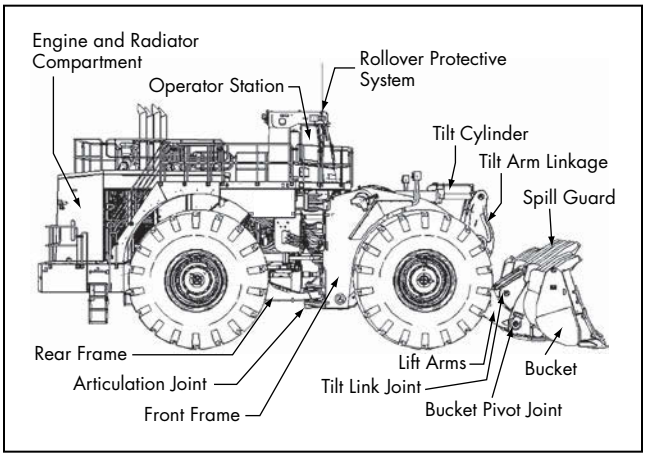
$$\text{Sch Rs}\frac{1{,}600}{2.5}-28\times 12$$



where

Sch = *Schaufelradbagger* (or simply *bagger*), the German name for the BWE; German manufacturers thus lead their model numbers with S, SH, SR, or Sch
R = *auf Raupen*, meaning that the system is on crawlers
s = *schwenkbar*, meaning slewable
1,600 = bucket size, L
2.5 = cutting depth, m
28 = cutting height, m
12 = crowd length, m

Other countries may order the components differently, as, for example, in the Russian ER $1{,}600\frac{28}{2.5}\times 12$. Compact or nonstandard BWEs generally have simpler model numbers, such as C500, which is a compact BWE with a 500-L bucket.



BWE productivity is highly specific to design and application. Cutting forces, wheel-rotation speed, number of buckets, slewing speed, and material characteristics all affect the production rate. As a (very rough) general rule, the peak capacity in cubic meters per hour is from 3 to 6 but usually about 4 times the capacity of a single bucket in liters. So, for example, the German "Sch Rs" example above has a bucket size of 1,600 L so would have a capacity of about 4,900 m^3/h (6,400 yd^3/h), where hours are operating hours, not scheduled hours (for more information, see the "Operating Hours" section).

BWEs are used primarily for unconsolidated materials. Even the largest-capacity BWE has a relatively small bucket, ≤5 m^3 (3.5 yd^3), and so has relatively limited capacity for rocky materials. Additionally, because of the associated conveyors, BWEs require linear, flat-floored mining faces that advance in straight or radial patterns. Thus their main application has historically been large lignite mines, although their largest U.S. application was in the 1960s and 1970s in the Illinois (United States) coal basin where they were used to direct-spoil glacial till covering the sedimentary overburdens.

Source: Atkinson 1992.

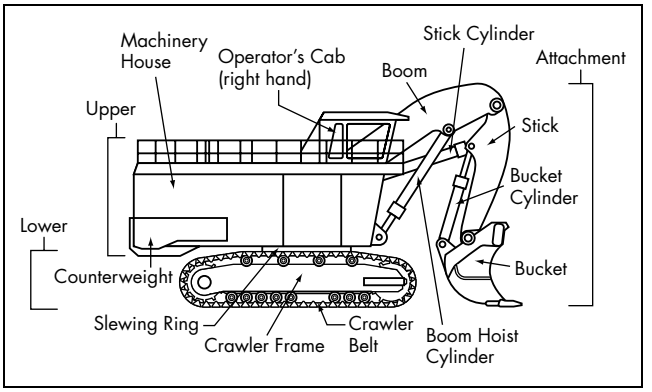
Figure 10.3-12 Bucket-wheel excavator used for block digging a lateral terrace cut

Courtesy of Caterpillar, Inc.

Figure 10.3-13 Wheel loader (smallest-capacity bucket)

BWEs can operate in linear pits with a spoiling process operating in parallel to fill the void a short distance away, or in multiple benches in deep pit mines with outside spoil dumps. Pit-face lengths vary from 800 to 4,000 m (2,500 to 13,000 ft), but are usually 1,500 to 2,500 m (5,000 to 8,000 ft). The BWE advances along the face, taking a cut width consistent with its design, up to 90 m (300 ft). The digging action is either a lateral terrace cut (Figure 10.3-12) or a vertical dropping cut, depending on machine design. At the end of the pit, the BWE can cut perpendicularly to the face conveyor for a short distance by means of its slewable discharge boom and or a belt wagon. This plunge cut enables the BWE to establish a face to work in the opposite direction, eliminating the need to deadhead.

Crawler systems for BWEs have as many as 12 crawler sets, commonly set up in an asymmetric arrangement with independent steering to enable larger machines to steer. Systems for use in soft-underfoot conditions can exert ground-bearing pressures much lower than for shovels, about 1.0–1.5 kg/cm^2 (14–21 psi). Tramming speeds are 4–12 m/min (13–40 ft/min) and a typical turning radius for a larger machine is 50–100 m (150–300 ft).



Typical BWE operations are viewable by satellite-image software in the vicinity of these coordinates:

- Compact BWE with multiple benches in advance: 39° 46′ 26″ N 111° 15′ 25″ E
- Large BWE prestripping in advance of dragline: 26° 43′ 14″ S 27° 57′ 37″ E
- Large BWE in large open pit: 50° 54′ 38″ N 6° 30′ 17″ E

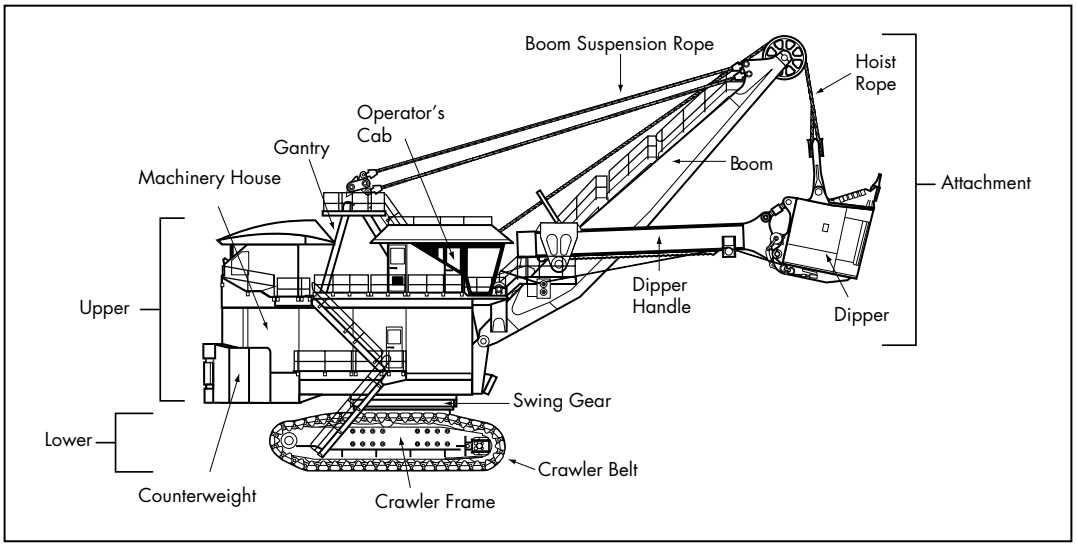
LOADER AND HAULER SYSTEMS

More material is moved by loaders and truck haulers than by all other excavation systems combined. The deciding factors in the selection of this system are typically the qualitative characteristics of flexibility and the probability of achieving production and cost targets.

Loaders and truck haulers excel in flexibility. They are not dimensionally constrained by operating method, and so are able to move in any direction for any distance. They can thus work in constrained or irregular geology and terrain, and can be added incrementally, both of which make them virtually the only choice for use in very deep pit mines. Their flexibility also enables a mining operation to adapt quickly to changes in commodity prices, geology, and other influences that cause the original mine plan to change, as it inevitably does.

Courtesy of P&H Mining Equipment, Inc.

Figure 10.3-14 Hydraulic shovel (middle-capacity bucket)



Because haulers always operate in parallel—and, in large systems, loaders do so as well—the impact of adverse performance on the part of any individual unit is minimized. Additionally, the system can operate through a large range of geologies and climates. This all provides for a dependable system with little unpredictable variation in efficiency, production, or cost.

For purposes of comparison, the loader and hauler system is a low-capital-cost, high-operating-cost system that is very flexible and can operate through a broad range of applications with low sensitivity to geologic variance.

Loading Tools

Loading tools are a specific class of excavator that depend on a separate independent haulage system. The most common types of loading tool, from small to large capacity, are wheel loader (Figure 10.3-13), hydraulic shovel (Figure 10.3-14), and mining shovel (Figure 10.3-15). In mining they are used in conjunction with haulers, most often off-highway mining trucks.

In the past 30 years, and particularly the past 10 years, the development of larger, more reliable wheel loaders and

Courtesy of P&H Mining Equipment, Inc.

Figure 10.3-15 Mining shovel (largest-capacity bucket)

hydraulic shovels has encroached into what was previously the exclusive territory of mining shovels: the loading of large off-highway trucks. These trucks, also called large mining trucks, generally have capacities of >135 t (150 st). The growth in wheel loaders and hydraulic shovels has lead to a new delineation in the loader market, with wheel loaders predominant at the lower end, hydraulic shovels in the middle range, and mining shovels at the upper end of bucket capacity (Figure 10.3-16).

Selection

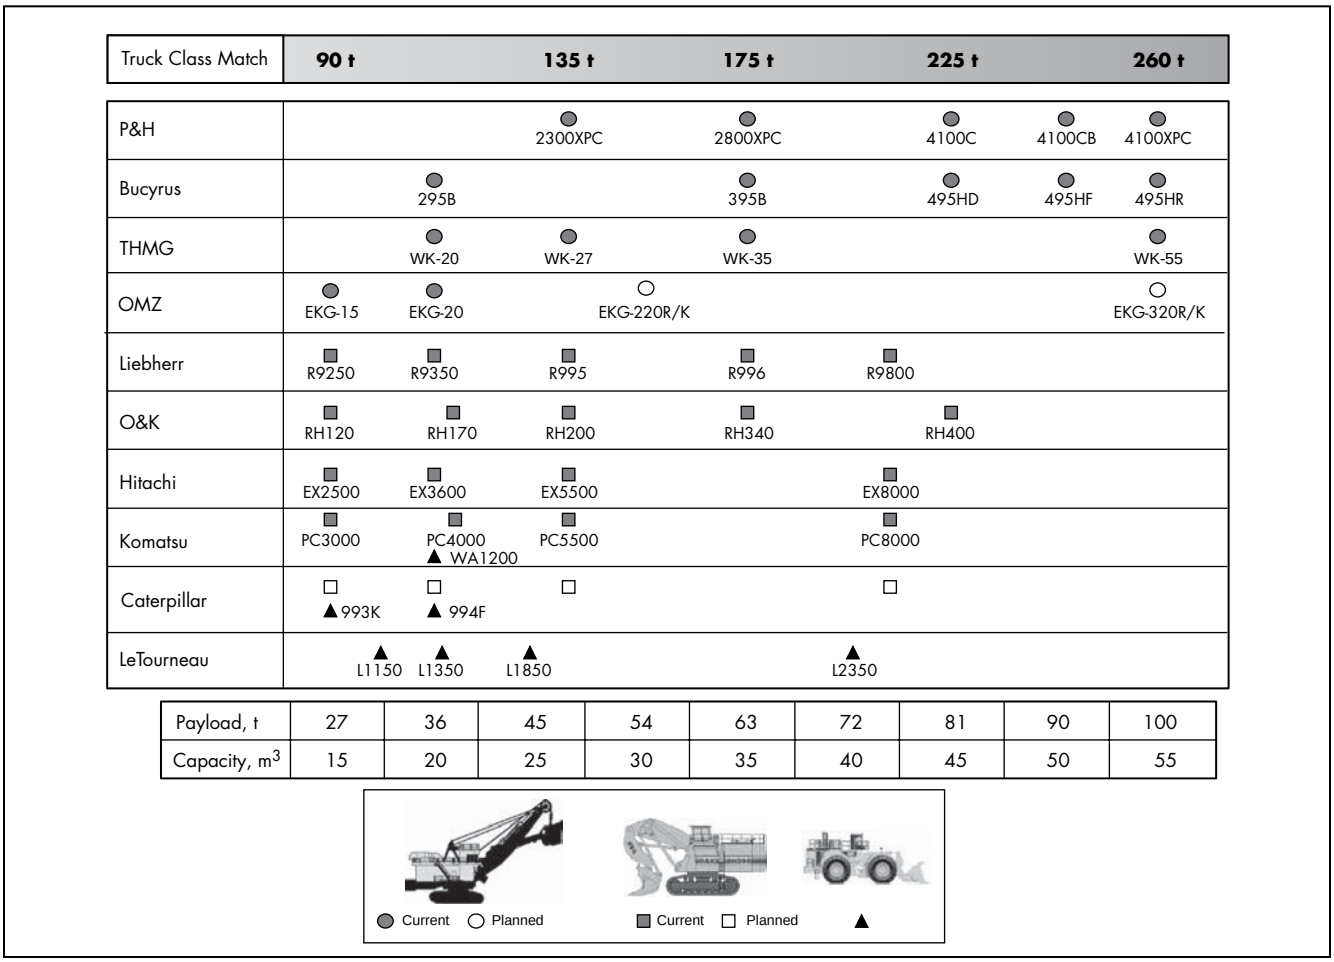
Because all loading tools perform the same basic function (i.e., they load trucks), the differences among them lie in other characteristics. Likewise, due to design differences and resulting differences in capital costs and operating costs per unit of production, evaluations of net present value can prove useless. Deciding factors are more likely the qualitative characteristics of capacity, mobility, flexibility, life, and support requirements.

Capacity. The range in capacity of the three types of loading tool is a differentiating characteristic. For operation with large mining trucks, their capacities are as follows:

- Wheel loader: 27–45 t (30–50 st)
- Hydraulic shovel: 27–81 t (30–90 st)
- Mining shovel: 54–110 t (60–120 st)

These differences in capacity spread even further when compared on an annual production basis, because of cycle-time and operating-hour differences. Generally, when comparing machines of similar size, the mining shovel cycles more times per year than does a hydraulic shovel, which in turn cycles more times than does a wheel loader. This is due primarily to differences in operating hours but also, to a degree, in cycle time. Production is most heavily influenced by the degree of utilization (i.e., the extent to which a tool is kept in use when it is mechanically available). It is also influenced by consistency and efficiency of application, with problems arising when the pit layout is poor, resulting in long swing angles, excessive moves, and other workarounds. Table 10.3-2 shows the influence of swing angle on cycle time and hence production level of a loading tool.

The optimal production factors for loading tools are approximately as follows (the number in units of BCY per year per cubic yard is the same as the number in units of BCM per year per cubic meter; production factors are discussed in the "Dragline Selection" section):



- Wheel loader: 330,000 BCM/yr per m^3 of dipper capacity
- Hydraulic shovel: 350,000 BCM/yr per m^3 of dipper capacity
- Mining shovel: 400,000 BCM/yr per m^3 of dipper capacity

Mobility. If mobility is critical to an operation, the best choice is usually a wheel loader. In operations having multiple faces that require frequent relocations or want a backup unit for multiple loaders, the wheel loader is uniquely capable of rapid relocation. However, recent developments in larger low-boy or float transporters has extended the capability of medium to large hydraulic shovels to rapidly relocate.

Flexibility. The capability to work in faces of different heights or to dig at different levels of a face is an advantage. Wheel loaders are most productive at face heights of at least three times the bucket height, although at shorter face heights they can drive forward through unconsolidated or well-broken material with only slight impact on productivity. In less-consolidated material, hydraulic shovels can penetrate a bank at different levels to separate material at the face with only slight impact on productivity.

Most hydraulic shovels can also be configured as backhoes or mass excavators for digging below grade and loading trucks below or at operating level. Loading trucks below operating level allows use of a number of spotting techniques and shortens cycle times. Loading trucks at operating level, although slower, is obviously desirable when the pit bottom is wet. Backhoes are generally limited to use where face heights are about equal to the stick length.

Mining shovels require a face height of about 50% of their point sheave height, basically about the height of the teeth when the dipper stick is horizontal. However, they can operate at higher bench heights than can wheel loaders and hydraulic shovels, which reduces other operating costs. A higher face

means fewer benches, fewer relocations, and lower drill-and-blast costs.

Life. Economic lifetimes for loading tools are generally as follows:

- Wheel loader: 5 to 7 years
- Hydraulic shovel: 7 to 10 years
- Mining shovel: ≥15 years

Of course, with enough replacement components, the life of any unit can be extended. Longer life is arguably a desirable feature: it is certainly necessary to justify a higher capital cost, but a system with a shorter life but lower operating costs and high resale value can be an equally good or better choice.

Support requirements. Several factors affect support requirements for a loading tool:

- **Drive system.** Large mining shovels are currently available only with electric drives. Wheel loaders and hydraulic shovels generally have diesel drives, although very few wheel loaders and some hydraulic shovels are optionally available with electric drives. Electric drives have lower and more consistent operating costs but require in-pit electrical reticulation systems comprised of electrical substations and power distribution cables involving specialized support equipment, personnel, planning, and operations. Diesel drives require fuel transport for refueling in the field but the equipment involved is usually common to mining operations using large equipment.
- **Digging profile.** Wheel loaders and hydraulic shovels, more so than mining shovels, can flat-pass and thus require minimal cleanup assistance. However, mining shovels, with their greater reach, can stand back farther from the face and so keep the truck back farther from the toe—although one could argue that this class of loading tool should not waste time doing cleanup work that is better left to auxiliary equipment.

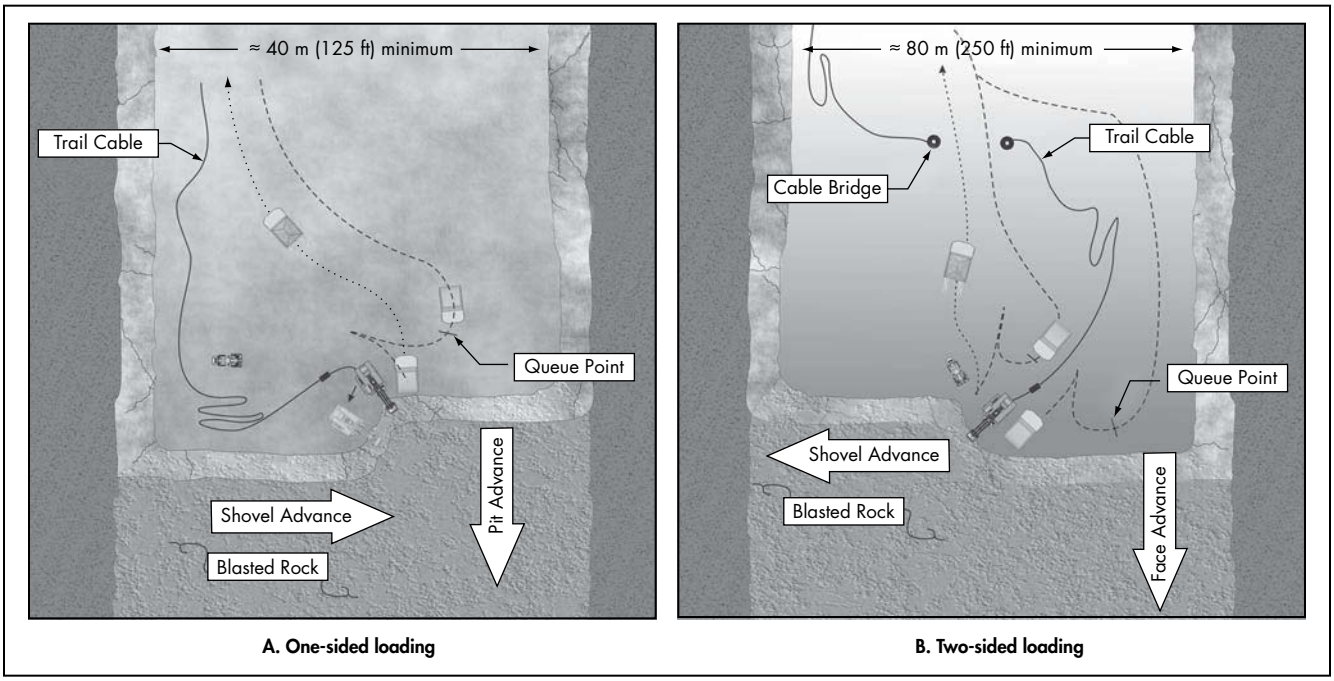

Figure 10.3-17 Loading-tool operating methods

- **Maintenance.** Larger hydraulic excavators and mining shovels have limited mobility and transportability, so all maintenance on these machines must be conducted in the field.
- **Material conditions.** The condition of the floor and bank affects the different types of loading tool differently. A wet or soft floor causes traction problems for wheel loaders, which can significantly impact tire costs and productivity. For soft floors, track shoes can lower the ground-bearing pressure exerted by a shovel. For very soft floors, extra-wide track shoes can minimize the ground-bearing pressure, although they reduce maneuverability due to the increased turning forces required.

Operating Methods

The most common loading-tool operating method is one-sided loading (Figure 10.3-17A), also called single-sided loading. This method requires minimal pit-support coordination and minimizes variations in traffic patterns and truck movements, the latter of which often significantly influences safety. The method also has a relatively small footprint, so it can easily be implemented in benches only 30–40 m (100–125 ft) wide. In the most common variation of the method, the truck stops or queues in a position where it can observe the loading operation, which allows the truck operator to ensure that the area is clear after the previous truck has been loaded and moved off. The location of the queuing and reversing points is generally left up to the truck operator, as it changes so frequently. However, choice of location can significantly influence cycle time, so training on efficient techniques is important. Road constrictions, pit obstacles, poor spot selection, cleanup, and cable handling are common causes of unnecessary delay. Traffic patterns are best designed to allow the truck to reverse with the shovel on the truck operator's left and thus always visible to the operator either directly or in the left side mirror.

One-sided loading has several disadvantages. Mining shovels and hydraulic shovels cycle in 30–35 seconds and spotting takes 45–60 seconds, so the shovel must wait for the truck, reducing production levels. In addition, the time required for a cleanup dozer to work in the spot area can delay operation.

These disadvantages can be addressed to some extent by two-sided loading (Figure 10.3-17B), also called double-sided loading, which reduces the shovel delay between trucks. Although this method appears to be just a doubled-up single-sided loading method, it actually adds some complexity. The road circuit is more complex because it requires a Y intersection, a much larger working face, up to three queuing points, and twice the cleanup and road-maintenance support. Electric-powered loaders also require a cable bridge and have more confined turnaround areas. All of these factors dictate a larger footprint for the loading area, so the method is more suitable for benches at least 80 m (250 ft) wide. Furthermore, near the ends of the working face, the work area becomes restricted and the shovel generally must revert to single-sided loading, so two-sided loading favors wide working faces. Two-sided loading can increase production by 5%–10%, with the general caveat that the more passes per truck, the less the benefit, since improvements come from reducing time between trucks.

Wheel loaders spot trucks somewhat differently than do the other types of loading tool (Figure 10.3-18). From a wheel loader, trucks are best spotted at a 45° angle, which allows the loader to approach the face and the truck at right angles with minimal turning between the two. A good setup requires less than one tire rotation of travel distance in each direction to load the truck.

A less-common method, drive-by loading (Figure 10.3-19), is used with bottom-dump trailers or backhoe loaders. It does not require reversing; rather, the truck merely drives alongside the loader. It requires a very narrow face with a long, clear

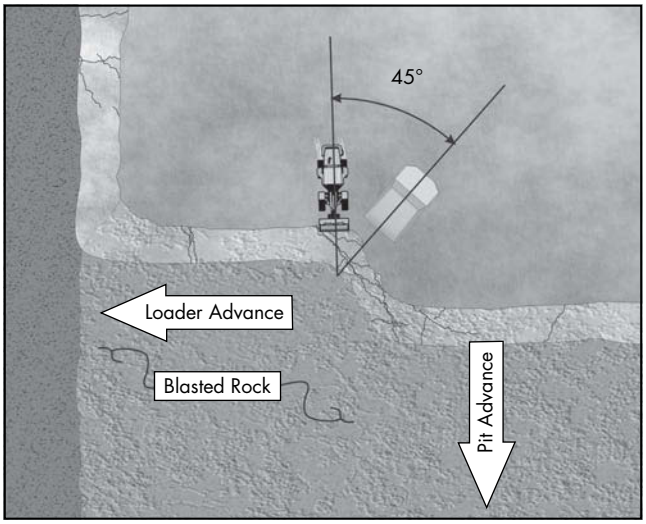

Figure 10.3-18 Wheel loader spotting a truck

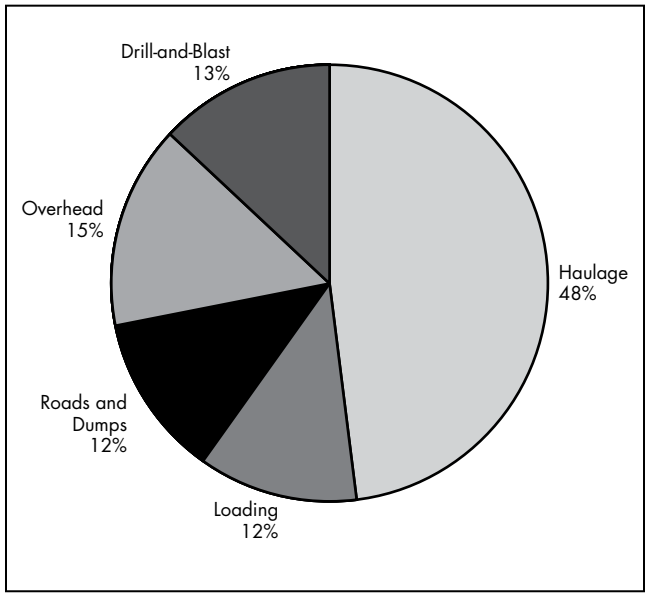
bench adjacent so that the truck can approach along the bench and the loader need never move far from the bench.

Backhoes offer a few variations for loading trucks on the floor because the truck can back to the face at virtually any angle. The truck spot can be set up to bring the material over the side or through the tailgate, depending on the bench configuration. Some hydraulic shovels without independent pumps for hoist and swing can benefit from positions that emphasize either hoist or swing rather than working both together.

Matching Loading Tools to Haulers

Selecting the best loading-tool size to hauler size involves analyzing the number of passes required to load a truck and the number of trucks needed to match the shovel. The primary goal is to optimize the total loading and haulage cost.



Maximum production is determined by the loading tool, not the hauler. However, pit production costs are most significantly influenced by the hauler (Figure 10.3-20). Specifically, haulers account for nearly 50% of the total system cost, and loading tools only about 10%. Thus the following bears repeating: in general, *the loading tool drives production and the hauler drives cost.*

The strategy in matching loading-tool size to hauler size is to consider but not be ruled by the concept of matching passes and minimizing the number of passes per truck. The variety of loaders and trucks available make it virtually impossible to always achieve a perfect match. Another complication is that variations in material density and bucket fill ensure that no two dipper loads will be exactly the same; in fact, the distribution of dipper and truck-load sizes is nearly normal. This distribution pattern is considered in loader design, and some latitude exists in matching dipper loads to truck loads. Target payload should be changed only after consultation with the manufacturer.

Given that spot time cannot be less than shovel cycle time, it follows that the more passes per truck, the more the shovel (and therefore the system) produces. The downside of this premise is that it favors selection of smaller trucks, which of course means higher operating costs and more congestion. The premise is therefore best considered as suggesting that

Figure 10.3-19 Drive-by loading

Courtesy of Caterpillar, Inc.

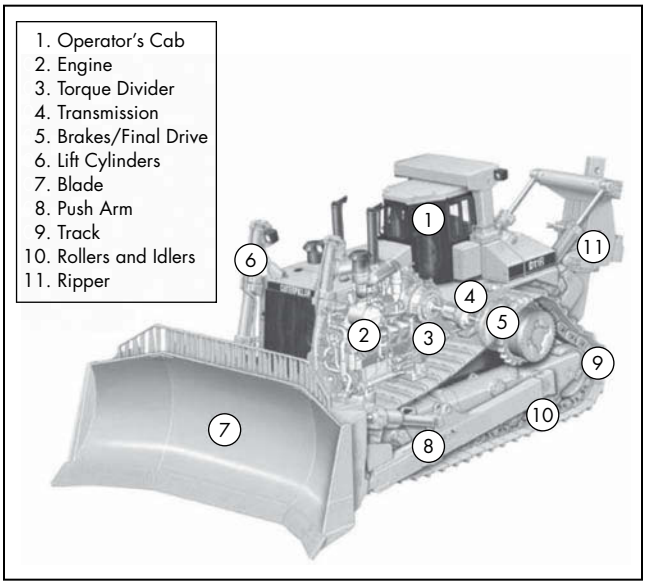


Figure 10.3-20 Relative influence of haulers on open-pit production costs

truck size, not shovel size, determines the number of loading passes.

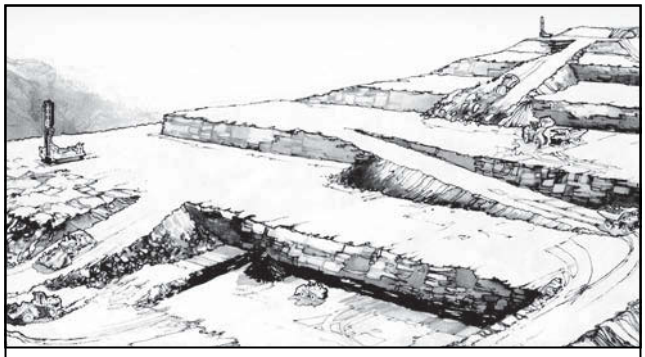
In reality, variations in production or fleet costs caused by pass match are not as significant as the consequences of undertrucking or overtrucking a fleet. Undertrucking a typical fleet by only one truck offsets the production advantage of the additional pass per truck; likewise, overtrucking a fleet by only one truck offsets the cost advantage of a larger truck with fewer passes per truck.

Track Dozers

Large track dozers (Figures 10.3-21 and 10.3-22) are extremely common in all mining operations. They are designed to move the greatest amount of material in the most efficient way, and generally used for both utility and production work. Utility work includes tasks that support a mine's main production fleet, such as dump-site preparation and cleanup, bench preparation, road creation, stockpile work, and reclamation. However, the focus of this section is their use for production

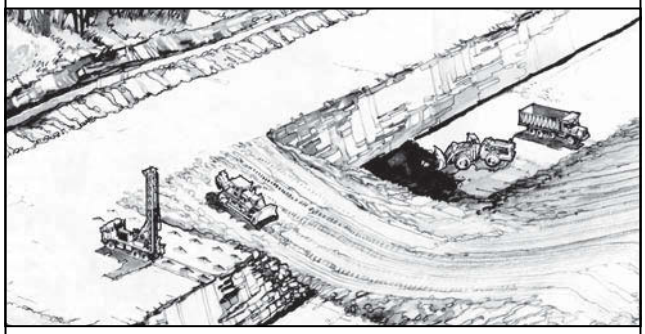
Courtesy of Caterpillar, Inc.
Figure 10.3-21 Track dozer

Courtesy of Eric C. Orlemann.
Figure 10.3-22 Track dozers working in a pit



work, specifically mass excavation, for which they excavate, push, and rip in-situ or blasted material from one area to another. Examples of this use include assisting primary production loaders and slot dozing (Figure 10.3-23).

For purposes of comparison, the track dozer is a low-capital-cost, high-operating-cost system that has moderate flexibility and can operate through a limited range of applications with moderate sensitivity to geologic variance.



Currently, two major manufacturers build track dozers for the mining industry: Caterpillar and Komatsu. Table 10.3-3 compares their specifications for typical large track dozers used for mining production.

The specifications are very similar between manufacturers, except for the Komatsu D575 Super Dozer (SD), whose high-end size class is an anomaly. Most of the industry uses the smaller size classes because of their lower operation costs and flexibility.

Track dozers are complex machines, because of their variety of mechanical, electrical, and hydraulic systems all fitted into a compact design that protects against the elements.

A. Assisting a primary production loader

B. Performing slot dozing

Courtesy of Skelly and Loy, Inc.
Figure 10.3-23 Track dozers

Operating conditions are unlike those for other material-excavation equipment that loads statically and advances as the face moves. Rather, slot-dozing and rip-and-push operations to assist large loaders require the dozer to push material at varying distances and gradients in poor ground conditions. Therefore, machine design must be very robust. To this end, the mainframe is rigid and consists of multiple fabrications and castings. All major components and systems are mounted to the frame. The radiator, engine, torque divider, transmission, brakes, and final drives are housed in the frame and body, and in most cases are modular for ease of removal and installation.

The components that typically require extensive forethought for maintenance are those that engage the ground, commonly referred to as ground-engaging tools (GETs). GETs include blades and wear plates, rippers (if fitted), rollers and idlers, and tracks. All dozer manufacturers provide a large variety of options for these components, except for rollers and idlers. The blade and associated wear plates are customized for each application; for instance, Caterpillar provides five types of blade (semiuniversal, universal, reclamation, coal, and carry-dozer). Two types of ripper (single-shank and multiple-shank) are available. And both regular-size and wide track shoes are available.

The goal is to maximize GET life and productivity by matching the machine configuration and options to the site characteristics. Thorough site analysis by the manufacturer is required to evaluate the production cycle and material characteristics. The longer the push distances, potentially the higher the replacement frequency. Material characteristics such as

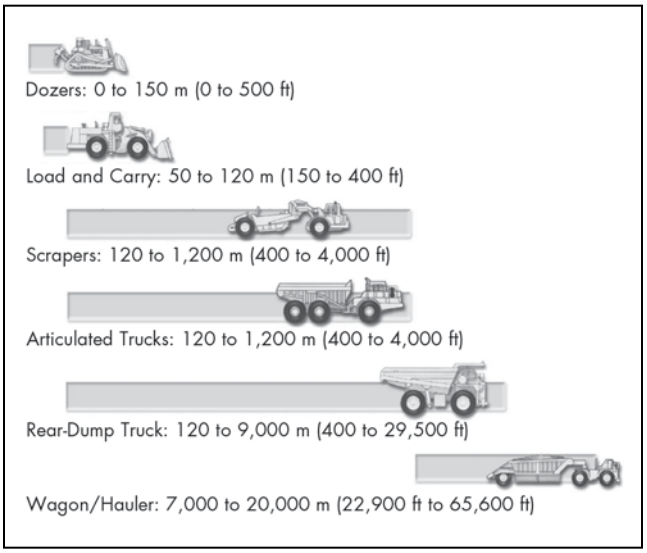
Productivity difference, %	+5	Base

fragmentation (size), abrasiveness, and cohesiveness must be evaluated to determine a dozer's replacement life.

Dozer Productivity

The first step in determining track-dozer productivity is to calculate how much material a particular dozer can push. This narrows the number of suitable size classes and defines some viable configurations before detailed productivity calculations are made.



The following factors are involved in determining dozer capability:

- **Weight.** The dozer cannot push more than its weight.
- **Coefficient of traction.** This is the percentage of the dozer's weight that can be pushed for a given material before the track shears or slips. For most materials, this value averages 60%. For loose sandy material, it can be as low as 30%. Multiplying the coefficient of traction by the dozer's weight gives the weight that a dozer can push.
- **Material density.** The denser the material, the smaller the volume of material that the dozer can push. Blade capacity and selection are directly related to material density.
- **Carry-force ratio.** This is the energy needed to compensate for friction or drag and push material across itself. It is usually about 10% and is included in calculations of drawbar pull, which provides the corresponding machine speed.
- **Slope.** This is the percent grade downhill or uphill. It is included in calculations of drawbar pull, which provides the corresponding machine speed.
- **Push distance.** This is the same as the return distance, although push and return are traveled at different speeds. Both have a large impact on cycle time.

In production dozing, it is critical to plan dozer size and configuration so as to maximize productivity. A common tagline in the industry is "big load slow," which describes how to manage a machine for maximum productivity. Productivity is defined as work done over a unit of time. The industry continues to debate whether dozer productivity is higher when pushing larger loads slower or smaller loads faster. Table 10.3-4 shows a case study of two identical dozer configurations for a slot-dozing application. Cycle conditions are identical and the average push distance and gradient are approximately the same. The average cycle time is about 10% slower for dozer 1 than for dozer 2, in large part because the blade load is 25% larger. The end result is that productivity is 5% higher for dozer 1, pushing larger loads slower.

Among the factors that can improve the operating efficiency of a dozer are technique and technology. Technique has to do with how an operator approaches a particular job. The following technique tips reflect best practices for a variety of dozer operations related to production dozing and ripping, where the highest productivity gains can be made. In some cases, these adjustments can increase productivity by up to 25%.

- Slot: Front-to-back technique (most efficient)
  - Operator works the cut from front to back.
  - Push distance increases with each pass.
  - Efficiency is optimal due to downhill blade loading.
  - Creates the slot and uses it throughout the cut.
- Slot: Back-to-front technique (less efficient)
  - Operator works the cut from back to front.
  - Push distance decreases with each pass.
  - Efficiency suffers from uphill blade loading.
  - Does not fully use the slot throughout the cut.
- Slot: Back-each-pass technique (less efficient)
  - Operator starts each pass at the back of the cut.
  - Each pass uses the entire length of the cut at a uniform depth.

Courtesy of Caterpillar, Inc.

Figure 10.3-24 Haul distances for various types of surface haulers

  - Efficiency and productivity suffer because the machine travels the entire length of the cut in both directions with each pass.
- Berm: Criss-cross removal (most efficient for removing center berms)
  - Operator works the cut from back to front.
  - Push distance decreases with each pass.
  - Existing slots are used to hold in material and increase blade load.
- Berm: Management
  - Berm should not exceed blade height and should be high enough only to trap material for optimum loading.
  - Center berm width should be one-third the blade width.
  - For optimum productivity, the smaller the berm, the easier the disposal.
- Ripping
  - Operator should rip downhill when possible.
  - Operator should reduce speed in shock and impact conditions.
  - Operator should try cross-ripping if material does not free up.
  - Operator should pull the ripper tip forward after penetration.

The final piece to improving dozer efficiency concerns technology. Dozer manufacturers have developed software features that increase safety and efficiency. These features provide automatic control or even real-time data to allow the operator to adjust to conditions. One such feature is Caterpillar's AutoCarry (Caterpillar 2008), which automatically optimizes the blade lift-and-lower functions during the carry segment of push dozing by monitoring, calculating, and integrating data on power-train output, ground speed, track slip, and tractor attitude. Another such feature is an onboard Global Positioning System (GPS) that links directly to survey data in the mine office. The operator obtains needed data via a cab-mounted display rather than by reading surveying maps or looking for grade stakes. GPSs are available from the major manufacturers and from third-party suppliers.

Haulers

The hauling of material (such as coal, ore, sand, gravel, or topsoil) from one point to another in a safe, efficient, and cost-effective manner is critical for mining operations. Selecting the type of surface hauler requires a thorough understanding of the selected mining method and its associated advantages and disadvantages along with the machinery available to the industry.

A number of haulage options are available for mining, all of them with unique characteristics that can be optimal for a particular mine site and haul distance. Figure 10.3-24 compares haul distances for dozers, front-end loaders, wheel-tractor scrapers, articulated dump trucks, off-highway rigid-frame trucks, and belly-dump haulers, each of which has an economic advantage at certain haul distances, with some overlap.

On-Highway Trucks

On-highway trucks are not widely used in mining operations because of their lack of capacity, which is only 6–12 m^3 (8–15 yd^3), and their limited performance capability. However, some mine sites use these trucks for hauling coal (eastern United States), prestripping ttopsoil in contract surface mining operations (Australia), and hauling construction aggregates for road building. Their capability to travel long distances at relatively low cost while meeting local on-highway regulations and their overall flexibility in mining operations where landscape is limited provide a unique hauling alternative.

Three types of on-highway truck are commonly used for mining operations (DumpTrucksGuide.com 2006):

1. **Standard dump truck.** This truck typically has a two- or three- (1 front, 1–2 drive) axle truck chassis with a dump body mounted on the frame. The dump body is hoisted hydraulically by cylinders mounted between the cab and the front wall of the body. The small size of the truck allows for exceptional maneuverability in tight loading areas.
2. **Semitrailer rear-dump truck.** This tractor–trailer combination typically has a three-axle tractor and a two-axle trailer. The trailer body is hoisted hydraulically. Key advantages compared to a standard dump truck are faster unloading and increased payload.
3. **Semitrailer belly-dump truck.** This tractor–trailer combination typically has a three-axle tractor and a two-axle trailer with a C-shaped dump gate. The dump gate, mounted on the trailer, is hoisted hydraulically. A key advantage is the capability to unload material as a wind row.

The advantages of on-highway trucks in typical mining operations are few, but there are applications for which they can provide an adequate hauling alternative. Their small size allows for flexibility in operations where loading areas are small, as for eastern U.S. contour coal-mining operations. Their low fleet cost is advantageous when mining operations need additional hauling capacity for short-term use. They require substantially less investment in up-front capital and subsequent operating cost than do large off-highway mining trucks. They can also be used as a secondary fleet for special

A. With hydraulic cylinders

B. With ejector body

Courtesy of Caterpillar, Inc.

Figure 10.3-25 Off-highway articulated dump trucks

projects such as road construction and prestripping, which are typically contracted from local construction firms.

The disadvantages of on-highway trucks are based primarily on their relative performance compared to that of large off-highway trucks. Payload capacity is an obvious difference; on-highway trucks are smaller and thus have higher overall fleet costs per ton of material due to their lower productivity and the larger number of trucks required. Additionally, they are not designed for use in rigorous mining conditions. Their structural design, electrical and hydraulic systems, brake and steering performance, and power train are designed for highway use, not for 24/7 mining applications. In mining operations, haul road gradients plus rolling resistance can be as high as 20%. On-highway trucks can have difficulty in deteriorating road conditions, to the point where support equipment is needed to recover them, reducing fleet productivity. Thus, they are not considered to be a primary haulage solution for the mining industry, although they will always have limited use in mining applications.

Off-Highway Articulated Trucks

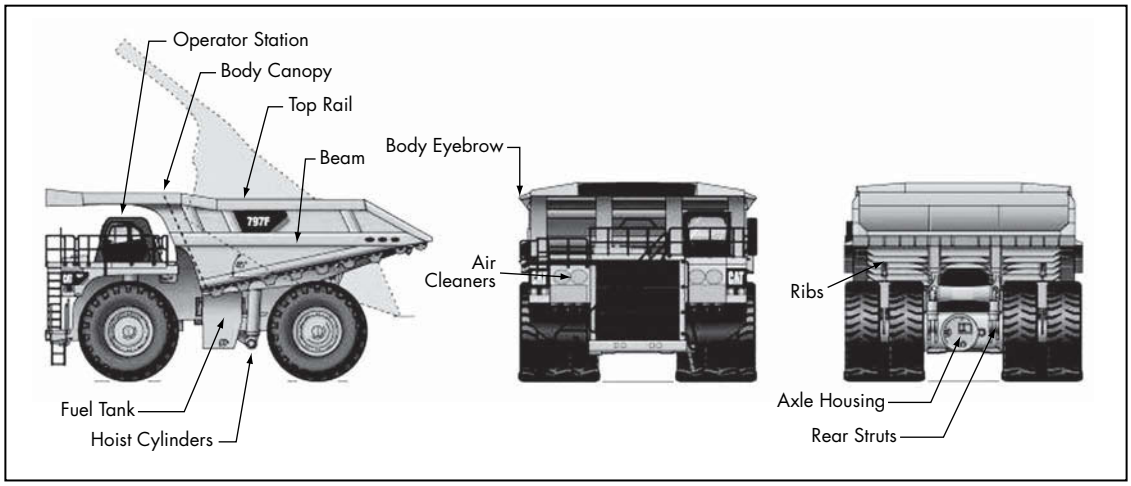
Off-highway articulated trucks are a hauling alternative primarily for middle-to-large-scale construction projects. They are often used for prestripping, road construction, and material hauling for ground preparation for buildings and other infrastructure. When used with small hydraulic excavators or wheel loaders, they can constitute an effective loader and hauler fleet for a mass excavation project. They are widely used for pre- and postmining construction in soft-underfoot conditions, in small loading and dump areas, or on steep (10%–15%) grades.

Table 10.3-5 Articulated dump truck specifications*

Specification	Size Class, t (st)			
	23 (25)	27 (30)	32 (35)	36 (40)
Gross engine, kW (hp)	224 (300)	261 (350)	298 (400)	335 (450)
Net engine, kW (hp)	212 (285)	250 (335)	287 (385)	324 (435)
Top speed, km/h (mph)	56 (35)	56 (35)	56 (35)	56 (35)
Tire size	23.5R25	23.5R25	26.5R25	29.5R25

*Specifications vary by manufacturer.

An articulated dump truck (ADT) (Figure 10.3-25A) is a three-axle machine with an articulation point between the front axle and the two rear axles. The articulation, which is unique to this truck type, is useful where there is limited area in which to operate. The three axles all provide power to ground. This all-wheel-drive capability provides an advantage over on-highway or off-highway rigid trucks whose one or more rear axles are the only source of power to ground. It also allows the ADT to operate well in soft-underfoot conditions, defined as rolling resistances of 10%–20% (Caterpillar 2000). An ADT can vary power to the wheels according to road and haul conditions. For example, a Caterpillar ADT has three operating modes: a standard mode (40/60 split between front and two rear axles), a low mode (50/50 split), and a high four-wheel-drive mode (all three axles have equivalent power to ground).



The dump body is mounted on the rear frame, with traditionally two options to dump material. The first option is similar to that for on-highway dump trucks: two hydraulic cylinders hoist the body, dumping material rearward. The second option is an ejector body (Figure 10.3-25B) with a hydraulically moveable front wall that runs on a rail system fixed to the side wall; the front wall pushes material back and dumps it rearward. Despite its added design complexity, an ejector body increases productivity by decreasing both dump times and the amount of carryback per load. It also allows the machine to safely dump in steep inclines or side slopes.

A number of major global construction and mining manufacturers provide ADTs for the mining industry, including Caterpillar, John Deere, Komatsu, Terex, and Volvo. In addition, a number of regional manufacturers in China, India, and elsewhere have offerings. ADTs generally range from 23 to 36 t (25 to 40 st) in four size classes that increment every 4.5 t (5 st). Table 10.3-5 highlights their specifications by size class (payload).

ADTs providing the surface mining industry a hauling solution that is adaptable to tough hauling conditions. However, because of their limited hauling capacity, they are not viable as primary production machines.

Off-Highway Rigid-Frame Trucks

The primary hauling machine in mining is the large off-highway rigid-frame truck (Figure 10.3-26). In the 1950s and

Courtesy of Caterpillar, Inc.

Figure 10.3-26 Off-highway rigid-frame truck

1960s, it was used as an alternative to locomotives and small dump trucks. Over the years, it has proven to be cost-effective, flexible across a variety of applications, and capable of handling the rigors of 24/7 operation. It continues to be a frequent hauling solution of choice for surface mining.

An off-highway rigid-frame truck has a rigid (unarticulated) frame constructed of multiple steel fabrications and castings. To this frame are mounted the truck cab, body, diesel engine, power train, front and rear suspension, front and rear wheels, tires, and more, all interconnected by sophisticated mechanical and electrical hardware and software. The two most distinguishing characteristics of the various makes and models are payload capacity and power-train type.

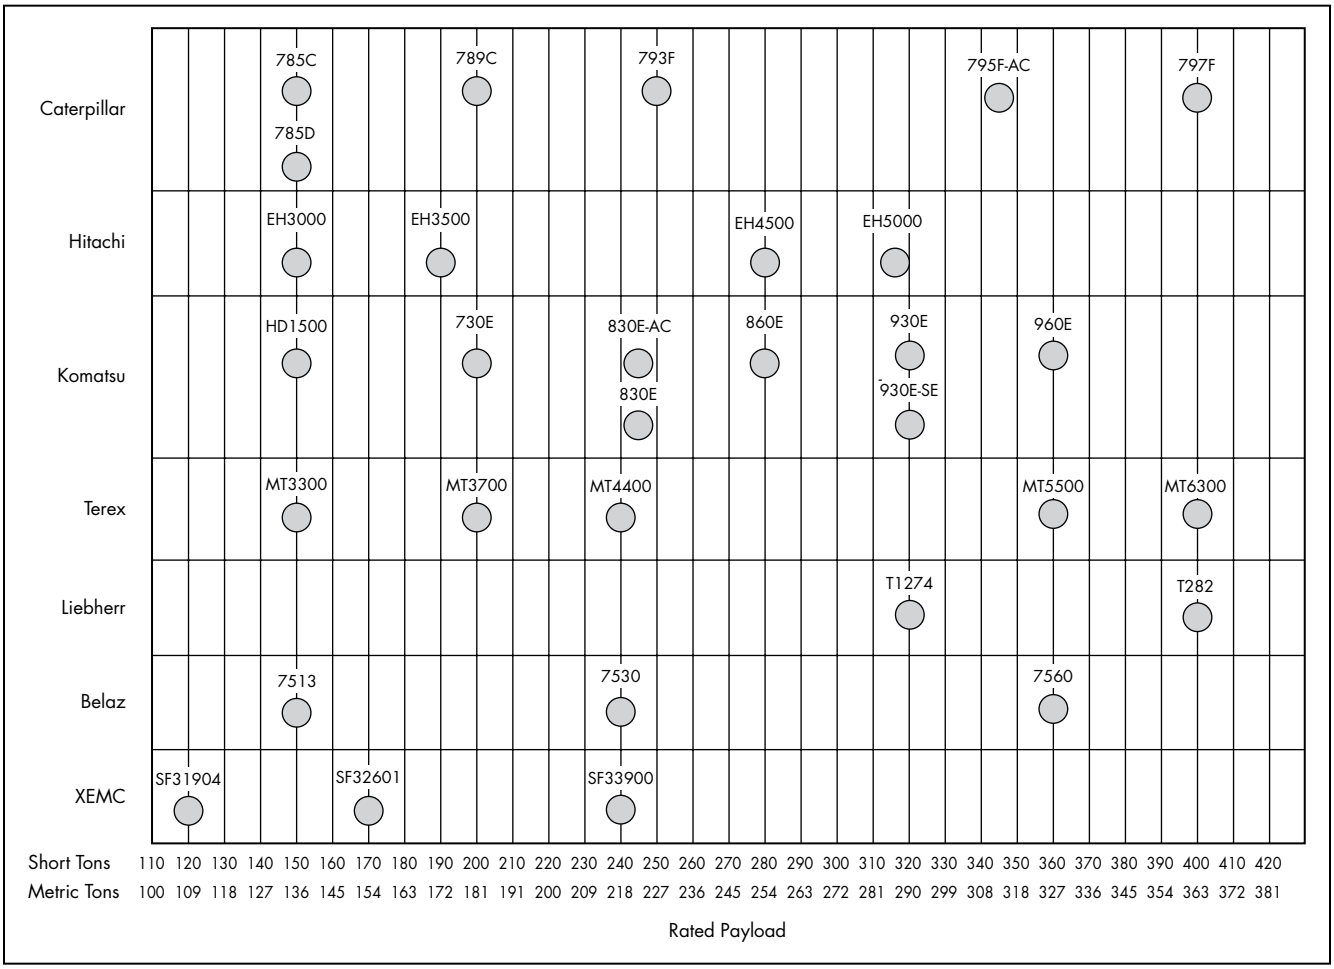
Payload capacity. The size or payload of an off-highway rigid-frame mining truck plays a significant role in determining the viability of a mining operation. For example, for a given mine plan, one could elect to operate either fifty 90-t (100-st) trucks or twenty-five 180-t (200-st) trucks. At first glance, assuming that machine performance is equal, the second choice, at half the fleet size, would seem to reduce costs dramatically. However, each fleet carries a different capital- and operating-cost footprint, and these footprints should not be assumed to be linear.

Trucks for surface mining currently have payload capacities of 90–360 t (100–400 st). These values have evolved over time, driven by the mining industry's desire to go larger in order to maintain or increase production while decreasing fleet size and operating costs. Within this payload range, there are five distinct classes, designated according to size:

1. 90-t (100-st) class
2. 135-t (150-st) class
3. 180-t (200-st) class
4. 220-t (250-st) class
5. >290-t (320-st) ultra-class truck (UCT)

Figure 10.3-27 shows current mining truck models by size class and manufacturer. Some manufacturers are not included because information was not available.

Product strategies regarding payload capacity clearly vary by manufacturer. Most mining truck manufacturers work closely with the industry to determine the appropriate size for an application, typically matching the rated payload capacity to the current and expected future loading tools, using three to five passes as the optimal level. For example, for a truck with a rated payload capacity of 220 t (250 st), an electric cable shovel with a capacity of 46 m^3 (60 yd^3), assuming a 90% fill factor, could load 1,780 kg/LCM (3,000 lb/LCY) of material in approximately three passes.



As important as payload is to a mining operation, the following points continue to be debated:

- Can we get more payload?
- Are our truck payloads at optimal levels?
- Should we upsize?

Some of these questions can be answered by considering the loaders and associated practices, but in some cases the trucks should be considered as well. Thus, after a decision is made about size class, the next decision should concern the type of truck body. There are now a myriad of truck body designs for any type of mining truck, and the choice of design depends on the material characteristics of the mine, which differ from country to country. Truck bodies today can be customized for each operation so as to maximize payload, reliability, and durability. For the purposes of such customization, a mine operation creates a profile listing the following information:

- Material type
- Material density (lightest), needed to ensure that payload is met, regardless of any fluctuation in material density
- Material fragmentation (size), needed to determine liner-plate thickness and dumping characteristics
- Material abrasiveness, needed to predict wear characteristics for determining the appropriate liner package
- Material cohesiveness, also needed to determine the appropriate liner package
- Loading tools (model and type, percent utilization, bucket size)
- Body/mining truck dimension limitations, needed to determine maintenance facilities, hoppers/crushers, loading tool dump heights, and more

Another point of discussion is payload management. The constant push to increase payload for an existing truck fleet is not a bad thing if trucks consistently perform, on average, at under their rated levels. Because pushing trucks beyond their

Courtesy of Caterpillar, Inc.

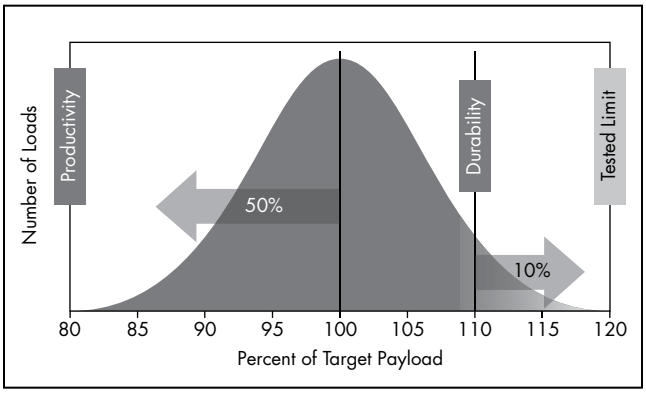


Figure 10.3-27 Off-highway rigid-frame truck models by size class and manufacturer

rated levels can be detrimental, most manufacturers have a payload policy that outlines the levels at which a truck can perform within the certification or design envelope of the machine. Standard practice today is a so-called 10/10/20 payload policy (Figure 10.3-28) that distributes truck payloads over a set period of time to address risks associated with overloading. The highest risk is overloading beyond 120% of target payload.

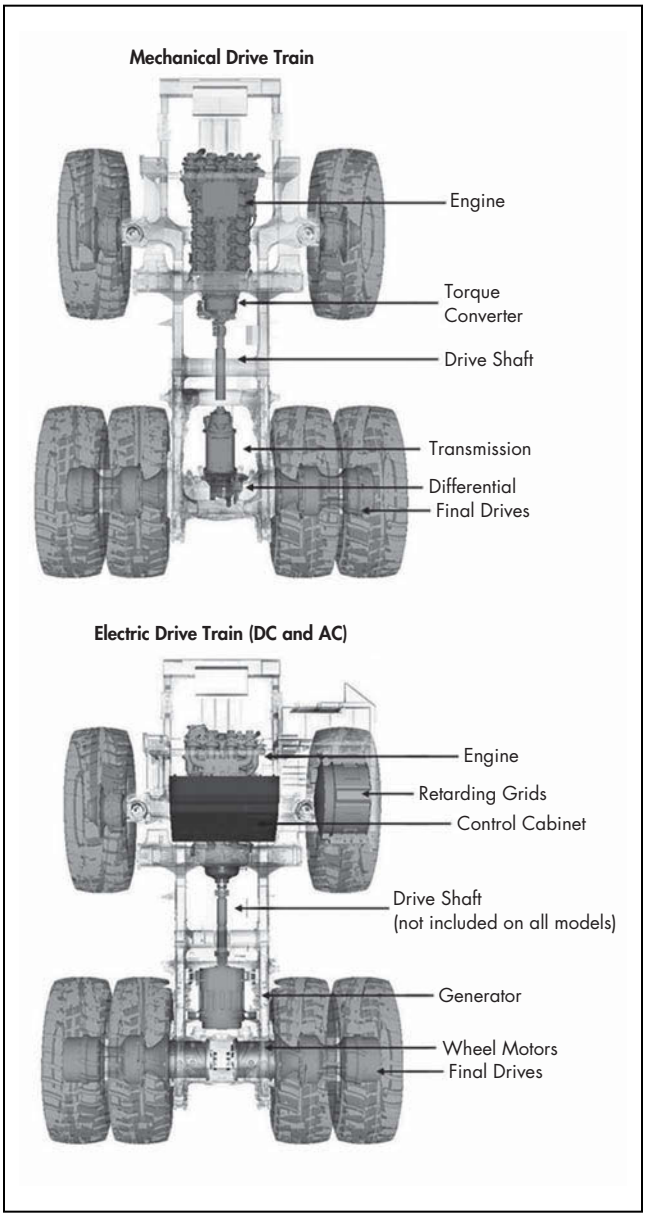
All mining trucks are designed to meet certain Society of Automotive Engineers (SAE) and International Organization for Standardization (ISO) design standards that address not only component and system functionality but also safety. Two particular standards are related to payload: ISO 3450 (1996) concerning brake certification and ISO 5010 (1992) concerning steering certification. The requirement for certification is that a truck loaded to its maximum payload (an overloaded state at the upper end of the normal distribution of payloads) should stay within requirements. Overloading beyond the payload policy risks, among other things, machine durability, as the structural components are designed to certain life targets and, if overloaded more frequently than recommended, become fatigued and prone to fail. Early failure increases maintenance and repair costs dramatically due to unplanned rebuilds and repairs. Payload management can be difficult to apply in practice, but it plays a large role in meeting production requirements and keeping a truck fleet operating safely and efficiently. It is important to check with the manufacturer for the tested limit specific to a truck.

Finally, when should a truck fleet be upsized to a new size class? Moving to a higher size class has many benefits and at least a few barriers, which become more daunting with increasing truck size. The following is a list of considerations (Caterpillar 2009):

- Mine operations
  - Mine design: Larger mining trucks can require changes in haul road design and load and dump area, especially when upsizing to UCTs.
  - Loading tools: It is important to have the proper loaders to meet production requirements with the new fleet.
  - Support equipment: Larger mining trucks place a stronger demand for support equipment to maintain haul roads and loading/dump areas.
  - Operator training: Curriculum and training tools must be changed.
- Mine maintenance
  - Facilities: Maintenance facilities (such as shop, lube islands, and parts and component storage) may need to be upgraded to handle the larger machines.

Courtesy of Caterpillar, Inc.
Figure 10.3-28 10/10/20 Payload policy

– Tooling: Tooling requirements must be upgraded to handle larger components and any specialized tools.
– Training: Significant training may be required when upsizing, regardless of system commonality.



Drive-train type. Truck performance is the next key piece of the puzzle. Three types of drive train are currently in use:

1. Mechanical drive, similar to those used in on-highway automobiles and trucks
2. Direct-current (DC) electric drive
3. Alternating-current (AC) electric drive

Figure 10.3-29 shows a side-by-side comparison of the mechanical and electric drive trains.

The mechanical drive train contains five major components: engine, torque converter, transmission, differential, and planetary gear sets (wheels). The power source is the diesel engine plus torque converter; the latter transmits rotational power from the engine to the main driveshaft. The transmission controls machine torque and speed during operation. The differential transfers output torque to the wheels. Two hydraulic brake packs are mounted on each of the axle shafts on the two rear wheels. The entire system is activated by means of a variety of electronic control modules and hydraulic control systems.

DC and AC electric drive trains contain six major components: engine, generator, power converter, wheel motors, planetary gear sets (wheels), and retarding grid. The power source is the diesel engine plus generator; the latter converts mechanical power from the engine into electric power. AC current from the generator is then converted into useable form. In a DC-drive truck, a rectifier converts it into DC power; in an AC-drive truck, a rectifier converts it into DC power and inverters convert it back to a controllable version of AC power suitable for managing the amperes, volts, and frequencies of the wheel motors in order to create machine speed and torque. The DC or AC wheel motors receive the electric power and feed it mechanically to the planetary gear sets (wheels). The retarding grid—a bank of resistor elements—provides braking force by turning the wheel motors into generators, creating power rather than receiving it. This power is sent through a control cabinet and on to the resistor elements. The resistors impede the flow of the electric power, which causes the wheel motors to slow rotation. Heat generated is cooled by an electric fan.

Courtesy of Caterpillar, Inc.
Figure 10.3-29 Mechanical and electrical drive trains

The three types of drive train have unique performance characteristics that impact productivity and operating costs. The major points to compare are the following, examined in more detail in Table 10.3-6:

- System limitation on grade
- Speed on grade (propelling)
- Speed on grade (retarding)
- Top speed
- Fuel consumption
- Maintenance and repair costs

OTHER SYSTEMS

These additional systems deserve serious consideration:

- Bottom-dump coal hauler
- Trolley-assist mining truck

Table 10.3-6 Points of comparison for three types of drive train

Point of Comparison		Mechanical	Electric, DC	Electric, AC
System limitation on grade	Define	Stall torque gradeability (STG) is the maximum percent grade that a loaded mining truck can pull out at zero speed. Trucks can stall in load and dump areas with poor underfoot conditions, requiring them to be pulled out. In addition, open-pit mines continue to go deeper. To make doing so economically viable, ramp gradients have increased from 8% to ≥10%. When rolling resistance is added, mining trucks must overcome ≥12% total effective grades, causing unexpected wear on a number of power-train components.		
	Compare	Is best in class. The maximum STG is about 28%–30%. The design accommodates all mining operations that continually operate at gradients up to 15%.	Is the least effective. The standard system has a peak STG of 23% but can be modified to reach 25%. Has thermal limitations during long uphill hauls on gradients of >8%. A thorough site evaluation must be conducted.	Is superior to the DC electric drive system due to the higher power density of the wheel motor. STG is ≤26%, depending on configuration. Has thermal limitations during long uphill hauls on gradients of >10%. A thorough site evaluation must be conducted.
Speed on grade (propelling)*	Define	Performance is dictated by truck weight, engine horsepower, and power train efficiency, and can vary from one model to another depending on a manufacturer's design strategy. However, power train efficiency is a point of differentiation and is the cumulative efficiency of all of the major components. The higher the efficiency, the lower the required engine horsepower. Most surface mines have haul-profile segments at a positive grade; thus the higher the speed, potentially the higher the productivity.		
	Compare	Has the highest gross power train efficiency at its peak, 88%. At an engine horsepower equivalent to the other power trains, has a higher speed-on-grade performance.	Has the lowest gross power train efficiency at its peak, 81%.	Has a gross power train efficiency at its peak of 83%.
Speed on grade (retarding)*	Define	Performance is dictated by truck weight and braking/retarding power. In loaded downhill applications, this is a key performance metric. As long as a truck can travel safely at its optimum level, this point of comparison can optimize productivity.		
	Compare	Is significantly improved since its inception due to addition of another gear.	Has the lowest speed on grade in retarding. However, changes in retarding systems have closed the gap.	Is best in class. The wheel motor power is capable of high levels depending on truck class, and thus has high-speed capability in retarding.
Top speed*	Define	Top speed, both empty and loaded. This is typically a point of differentiation with applications that have long flat hauls. However, except for DC-drive trucks, the systems do not differ significantly.		
	Compare	Depending on truck model, either 61–66 km/h (38–41 mph) or 55 km/h (34 mph).	55 km/h (34 mph)	Is best in class, at 64 km/h (40 mph) regardless of truck-size class.
Fuel consumption	Define	Fuel consumption is one of the most debated performance characteristics of mining trucks. So much depends on the application, engine type and fuel efficiency, condition of the engine and other machine systems, and even how the operator handles the machine. Thus, for a proper evaluation, a site study is required. However, the functionality of a power train is focused on reducing fuel consumption.		
	Compare	Power train efficiency permits engine horstepower to be less than that of an equivalent electric-drive model. Less horsepower equals less fuel consumed for an equivalent speed on grade. Also has a feature that allows the truck to consume zero fuel while retarding (Caterpillar 2006). When the truck approaches a downgrade and the operator's foot is removed from the throttle, gravity takes over. With a mechanical linkage between the wheels and engine, no combustion (and thus no fuel) is needed to maintain engine rotation.	Possesses unique operating characteristics that save fuel. The engine does not cycle during acceleration, as does a truck with a mechanical drive train. Rather, it runs at constant speed, allowing control software to manage speed and torque. Also, the engine actively manages horsepower demand from the engine as it cycles through the engine power curve, matching requirements to operating conditions. Finally, the engine applies a partial-power feature on minimal grades, reducing power draw from the engine to the drive system.	
Maintenance and repair costs	Define	The second most debated performance characteristic is the cost for maintenance and repair, defined as the life-cycle operating costs associated with replacing parts and components, along with labor required for removal, installation, and repair. This characteristic is difficult to compare, as much depends on the severity of the application, maintenance practices, on-site support infrastructure, and more. A fleet-selection process should provide site-specific comparisons of the impact of these costs on the operating cost of a drive system.

- In-pit crushing and conveying system

Bottom-Dump Coal Hauler

A semipopular haulage solution for surface coal is the bottom-dump coal hauler. It has become a staple in thermal coal operations because of the need to haul coal from the pit to a nearby power plant.

The truck–trailer configuration (Figure 10.3-30A) of the bottom-dump coal hauler has a mining truck chassis as the tractor, modified with a hitch assembly to receive a trailer. The most common size class is the 90–136 t (100–150-st) standard truck chassis. The high-volume trailer has typically 1.5 to 1.7 times the payload capacity of the corresponding truck fitted with a rear-dump body. This high capacity is well suited to long hauls with few high-gradient segments, and the bottom-dump coal hauler provides a higher production rate than does a traditional mining truck, thus lowering haulage costs per ton for the truck fleet.

The main players in this market segment for the chassis are Caterpillar (777 and 785 models), Hitachi (CH120, CH135, and CH150 models), and Komatsu (785 and HD1500 models), all of whom provide the necessary chassis modifications from the factory. The trailers are designed and manufactured by smaller specialty firms such as Kador Engineering (Australia), Maxter-Atlas (Canada), and Mega (United States). These firms provide the trailer and hitch assembly, whereas truck OEMs provide the additional axle to be fitted to the trailer, in the interest of product consistency. One firm provides the complete package: Rimpull (United States) provides an entire lineup of tractor–trailer options with their CW160, CW180, and CW200 models.

The truck–trailer configuration of the bottom-dump coal hauler has limited application due to the design specifications of the chassis. A fully loaded rear-dump truck has a continuous rating that allows for total effective gradients of 10%–15%. When the additional weight of a trailer is added and payload is increased, performance drops, limiting the machine to effective gradients of just 5%–10%. This is suitable for a number of surface coal operations, especially where the coal seam is relatively shallow and there is a limited amount of cover or overburden. Another point of limitation is haul distance. The truck–trailer configuration is economically viable only for haul distances of ≥3.2 km (2 mi). For shorter distances, this configuration, with its added costs associated with the trailer, tires, higher fuel consumption due to an increase in cycles, and lower performance characteristics does not compete well against a traditional truck configuration. However, for one-way haul distances of 8–16+ km (5–10+ mi), all of the benefits associated with this configuration outweigh those for the rear-dump truck.

A variant of the truck–trailer version of the bottom-dump coal hauler is the unibody configuration, or unibody coal hauler (Figure 10.3-30B), currently manufactured only by Kress (United States). This machine has a built-in bottom-dump body (i.e., it is unitized). Among its advantages compared to the truck–trailer configuration, it has a significantly higher payload-to-weight ratio, a higher horsepower-to-weight ratio, and a 50-t- (55-st-) lower empty weight. It also has higher fuel efficiency (fuel consumed per ton) and lower metric-ton kilometers per hour (ton miles per hour), which improve tire life. Its higher horsepower-to-weight ratio can enable it to, for example, operate at higher effective gradients to increase productivity. In addition, its drive train is capable of achieving higher top speeds—typically up to 30% higher—than is the drive train for the tractor–trailer configuration, which is limited to the speed capability of the chassis. This can increase productivity measurably on long hauls.

Trolley-Assist Mining Truck

A trolley-assist mining truck (Figure 10.3-31) is a unique application for mining trucks, and strictly exclusive to electric-drive models. Its use for large-scale material transport dates back to the late 1930s in Italy's full-trolley systems; its use for mining began during the energy crisis of the 1980s. With upgrades in technology, it still has relevance in the mining industry. Currently, two suppliers offer a trolley assist on their mining trucks: Hitachi and Komatsu. Four operations use it today, all in Africa.

A trolley-assist mining truck draws its power from overhead power lines that are run on haul segments where the largest benefits can accrue, such as where the loaded truck operates on a positive grade. The truck is fitted with a pantograph that acts as a conduit between the line and the truck's electric-drive distribution system. As the truck approaches the line, the operator lifts the pantograph until it contacts the line. When the two engage, the operator removes his or her foot from the throttle and continues to steer while the truck draws power from the line. Power is fed to the wheel motors, temporarily replacing the diesel engine and generator.

Figure 10.3-31 Trolley-assist mining truck

Trolley assist has several benefits:

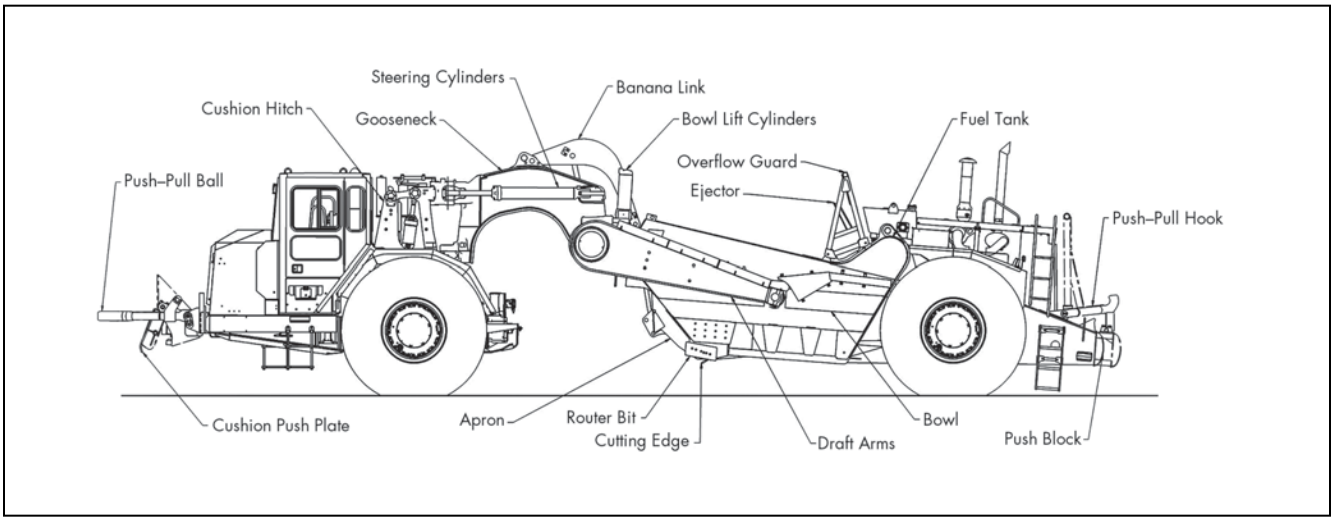
- Decreased fuel consumption, achieved by running the engine at idle for the length of the line. Depending on the length of the ramp, fuel savings can be as high as 50%.
- Increased productivity per cycle, achieved by using the excess power capacity in the wheel motors. The power rating of the wheel motor is almost twice the engine gross horsepower, in order to meet the technical requirements for continuous operation under diesel power. That is the primary reason for the significant speed-on-grade performance in retarding, when the wheel motors use their full potential. The same principle applies during trolley assist, when power from the diesel engine is replaced by power from the overhead line. The result is an increase of up to 80% in speed-on-grade performance. Depending on the haul cycle, this can translate into an increase in production of up to 10%.
- Increased diesel engine lifetime. The heaviest toll on an engine in a haul cycle normally occurs when the truck is fully loaded on a grade—the very point at which trolley assist kicks in. The life of a diesel engine is calculated in terms of the total quantity of fuel consumed during the design life. With the engine operating at idle on grade rather than at maximum, the life can be extended significantly, potentially eliminating one complete engine rebuild over the life of the truck.

Trolley assist also involves additional operational costs and constraints, including the following:

- **Relative costs of electric power and diesel fuel.** This is one of the single largest variables to consider when evaluating trolley assist. The cost for diesel fuel can be enormous for a medium to large fleet, but the ultimate question is whether the savings in fuel can offset the cost of electric power.
- **Capital cost of trolley wayside equipment.** This consists of mine power distribution, substations, masts, and wire.
- **Capital cost of truck trolley equipment.** This consists of a pantograph, auxiliary cooling, and truck controls.
- **Mine plan.** Trolley assist does not allow for operational flexibility. After the equipment is in place, it typically is not moved until doing so makes economic sense, often 5 to 10 years from the initial installment. Therefore, it is critical to evaluate the long-term mine plan and determine whether or not a permanent main haul road is possible.
- **Haul profiles.** Determining which haul cycle benefits from trolley assist is one of the most critical pieces to the evaluation. A long haul segment with a grade that the truck travels loaded is the best choice.
- **Capital cost for additional mine-support equipment.** Costs associated with additional motor graders or wheel dozers may need to be included. Haul roads where trolley assist is used must be kept in pristine condition, since spillage and rutting can cause the truck to lose connection with the overhead line.

The industry will continue to support trolley assist. Technology improvements now under consideration include concepts such as auto-control when ascending a grade and regeneration of power when retarding during a return cycle.

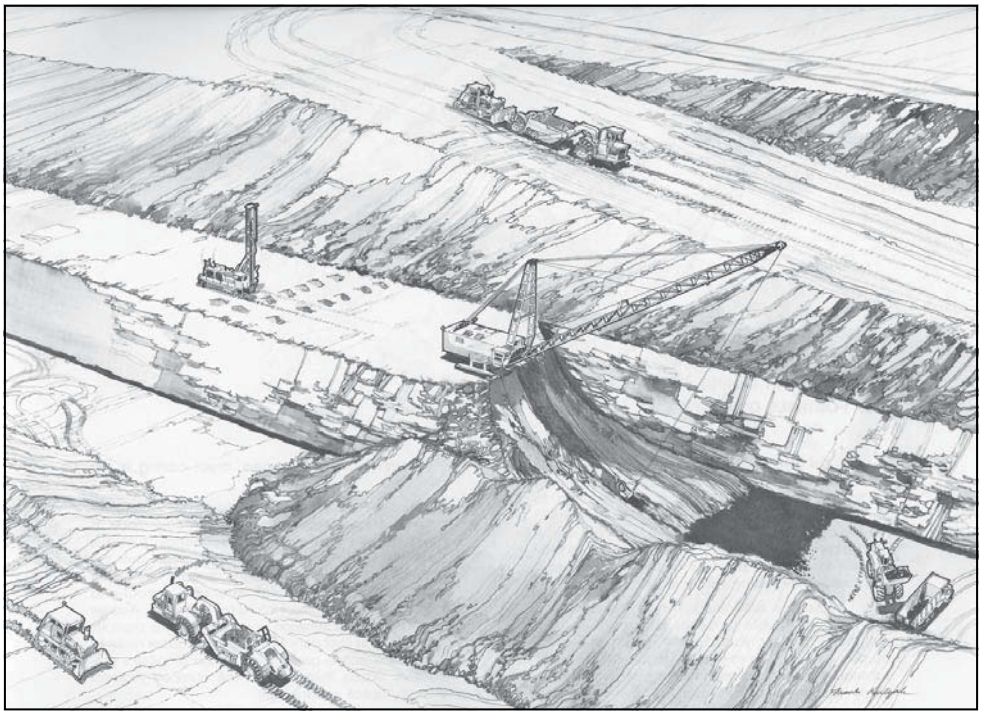
Wheel-Tractor Scraper



One of the oldest concepts of bulk material handling is the wheel-tractor scraper (WTS) (Figure 10.3-32), which traces its roots back to horse-drawn slip scrapers in the late 1800s (ASME 1991). Today the WTS is the only machine that can self-load, haul, and dump with a single operator. For purposes of comparison, the WTS is a low-capital-cost, high-operating-cost system that is very flexible and can operate through a limited range of applications with high sensitivity to geologic variance.

Mobility and flexibility are key characteristics of the WTS, which makes it ideal for small, short-life mining projects. Its capability to remove and place material in controlled lifts makes it the machine of choice for topsoil relocation in reclamation operations.

WTSs are available with three types of loading: pan, elevator, and auger. The pan uses the motion of the machine to force material in to the bowl; the elevator and auger have mechanical apparatus that assist the material into the bowl. The pan is slower to load but is better suited for blocky materials. The largest units have a bowl capacity of $\leq$34 m^3 (44 yd^3) for earth and rock densities, and can be larger for lighter materials such as coal.



WTSs are either single-engine or twin-engine systems that can be pushed, usually by a dozer, to assist with loading. Larger units can also configured in a push–pull arrangement for connecting two scrapers during loading, thus putting the horsepower of two machines on one cutting edge. Because of its cutting mechanics, the WTS best suited to unconsolidated materials.

Production is obviously affected by haulage distance, but for a moderate haul of 450 m (1,500 ft) a large WTS can produce at a rate of about 300 BCM/h (400 BCY/h). It is capable of speeds >50 km/h (30 mph). Optimal one-way haul lengths are 200–1,200 m (400–4,000 ft). The basic haul cycle is similar to that for a truck: load, haul, dump, and return. Because the load and dump components of the cycle can be 50–100 m (150–300 ft) long, it is most efficient to set up the haulage route so that the loaded haul is shorter than the return. The effect of haul distance on production rate is not quite 1:1; for example, doubling a mid-range haul distance decreases the production rate by about 40%. Properly designed and well-maintained roads are as critical to a WTS as to any other hauler, although this fact is often overlooked, possibly because the load and dump areas are relatively rough. A smooth haul

Figure 10.3-33 Wheel-tractor scrapers performing typical operations, including dozer-assisted downhill loading

not only lowers rolling resistance, it also makes for a smooth ride with reduced loping and therefore higher speeds.

Under most conditions, WTS load times are in the range of 30–60 seconds. Production can be enhanced by downhill or assisted loading (Figure 10.3-33). A dozer assist or a push–pull system delivers additional horsepower, increasing the production rate by about 10%. Having a ripper-equipped dozer handy can help to loosen hard-packed material between scraper loads. Loading is accomplished by lowering the bowl until the material flows steadily. Cutting too deep may take longer, resulting in higher fuel consumption and spinning tires with their associated costs.

WTS dump or spread time is about 20–30 seconds and the total fill time is 35–45 seconds (Caterpillar 1998). A significant feature of the WTS is its capability to spread a load in a controlled manner. Laying material down in thin lifts improves compaction on multiple lifts or allows material to be spread to a specified thickness.

Figure 10.3-34 In-pit crushing and conveying system

In-Pit Crushing and Conveying System

A relatively recent and increasingly popular entry into large surface mining systems is the in-pit crushing and conveying (IPCC) system (Figure 10.3-34). This system uses a crusher/sizer unit to process material from a cyclic loader to a size that is suitable for conveyor transport, extending the application of around-the-pit conveyor systems to include consolidated waste and overburden.

For purposes of comparison, the IPCC is a high-capital-cost, low-operating-cost system that has limited flexibility and can operate through a limited range of applications with moderate sensitivity to geologic variance.

In-pit or near-pit crushing of ore has always been common, primarily because the location of the crusher station has only a very small impact on the total comminution costs. Crushing of waste, on the other hand, until the advent of this technology, has been difficult to justify on the basis merely of enabling greater use of conveyor transport.

Although IPCCs have been used since the 1950s, the first large-scale mining systems capable of working with feed direct from a mining shovel were implemented only in the 1980s. With the implementation of compact twin-roller sizers, in about 2002, the system finally gained wider acceptance.

The IPCC is a mobile crusher/sizer machine. Historically "mobile" meant relocatable, usually with significant cost, infrastructure, and time requirements. However, the IPCC is self-propelled or easily transportable with no fixed infrastructure requirements and travels with its own loading tool.

For crushing, the IPCC crushes material to a size suitable for feeding to a conveyor belt: in all three dimensions, the material can be no more than about 30% of the width of the belt, and a significant percentage of the material must be smaller than that, in order to cushion the belt and prevent damage to it. Although the IPCC's crushers and sizers can handle materials with extreme rock strengths, to date, the IPCC (for waste) is most cost-effective for use with materials whose compressive strengths are 50–90 MPa (7,000–13,000 psi) and somewhat less cost-effective for harder or softer materials.

For conveying, the IPCC relies on a series of components that feed material from one to the next. A cyclic loading tool such as mining shovel feeds into a mobile sizer that follows along with the shovel. The sizer feeds into a face conveyor, much as for a BWE. The face conveyor feeds into a series of other conveyors, eventually leading to a discharge conveyor at the dump.

Because of the multiple conveyors, the IPCC is suitable for pit geometries that favor use of draglines and BWEs (i.e., those with long linear faces). Because its loading tool is a shovel, it can handle materials with rock strengths greater than a BWE can handle. At the time of this writing, however, IPCC systems are still finding their niche application but show favor for waste transportation in linear pits with geometries that require long hauls with relatively limited elevation change.

The digging face of the IPCC has a large footprint, similar to the case for the BWE, which needs to be considered when planning other pit operations such as blasting or pit access. Conversely, the conveyor route has a relatively small footprint, which can reduce costs for ramps, earthen bridges, and the like. Likewise, the dump area can be configured with some flexibility and material can be placed in final form with very little rework required for rehabilitation.

The IPCC has an electric drive system. Although this type of system requires electrical infrastructure in the pit, it does not depend on diesel fuel, whose costs tend to fluctuate independent of the product market. It also does not have tires; certainly the tire shortage of 2006–2008 had a significant influence on a number of IPCC purchases.

The IPCC generally requires minimal operating labor per unit of production. Operational and maintenance labor requirements are cyclic, with significantly higher demand during

conveyor relocation. These cycle demands are relatively easy to manage where maintenance contractors are available. The operating method lends itself to semiautonomous operation of some components, further decreasing labor demand.

The newest IPCCs have been matched to the large mining shovels with peak capacities of about 10,000 t/h (11,000 st/h). Because the system components are arranged in series, overall efficiencies are similar to those for a BWE system, about 55%–60%, resulting in an average production rate of about 6,000 t/h (6,600 st/h).

Typical IPCC operations are (or in the second case will be) viewable by satellite-image software in the vicinity of these coordinates:

- IPCC prestripping in advance of dragline: 21° 43′ 33″ S 147° 59′ 23″ E
- IPCC open-pit application with truck and shovel: 22° 43′ 23″ S 147° 38′ 08″ E

CHAPTER 10.4

Selection and Sizing of Excavating, Loading, and Hauling Equipment

Eric N. Berkhimer

INTRODUCTION

Taking a very simplified approach, mining consists of four distinct steps: rock breakage (if required), excavation, loading and hauling (as necessary), and processing. This applies to any type of mineral from precious metals to coal, sand and gravel, and crushed stone. In this very basic reasoning, it is easy to see the importance that the mine must place on the sizing and selection of the excavation, loading, and haulage equipment as this can have a tremendous impact on the economics of the mining operation. For example, according to Blackwell (1999), the operating costs for haul trucks alone may account for one-third to one-half of the total mine operating costs.

Prior to equipment selection, mine planning should have defined the ultimate pit limits based on economic conditions, pit geometry, and production rates. These have a major impact on equipment sizing and selection, which in turn can also affect the design parameters in a circle of refinement throughout the process. Therefore, even during the mine planning stage, considerable attention must be paid to equipment sizing.

For much of the 1990s, the mining industry ran under the assumption that "bigger is better," and this led original equipment manufacturers (OEMs) to develop larger loading and haulage equipment in order to take advantage of economies of scale. As noted by Bozorgebrahimi et al. (2003), there were even several mining industry conferences on this subject, such as the World Mining Equipment Haulage 2000 Conference. But sometimes theory does not match reality; only a few years later, the same forum rearranged the words in the title and asked, "Is bigger better?" The answer coming out of the conference was: "It depends." Based on the application and operating conditions of the mine, the economies of scale anticipated may not be realized because other costs, such as dilution of the ore, complexity of the operating system, and production delays when a larger unit is down, have increased more than enough to offset the savings in operating labor.

Therefore, the issue of selection and sizing of surface excavation, loading, and haulage equipment is more critical than ever. Poor selection can result in higher costs and significantly lower economic performance of the mining operation. After the mining method is defined, it is important to consider the selection of equipment and advantages/disadvantages of one mining "system" over another.

LARGE EXCAVATION EQUIPMENT SELECTION

As defined here, *excavation equipment* refers to equipment that digs material and dumps it directly into an area with limited additional handling. Equipment in this category includes walking draglines, stripping shovels, and bucket-chain and bucket-wheel excavators. Walking draglines and stripping shovels are considered "cyclic" excavators; chain and bucket-wheel excavators are considered "continuous" excavators.

In past mining practices, excavation equipment often played a significant role in the mining operation. However, as modern legal and environmental practices have increased in importance, their application and usage has diminished greatly as mining companies find it difficult to meet modern environmental standards and regulations while using excavation equipment such as stripping shovels and bucket-chain and bucket-wheel excavators. Walking draglines are still used in some geographic areas, but to a lesser degree than in the past. Because of the reduced use of excavation equipment, the following information is provided for introductory purposes.

Walking Draglines

Walking draglines are used most frequently to cast material directly because they have higher bucket capacities and greater reach abilities than other excavation equipment. Designs of

Eric N. Berkhimer, Senior Applications Engineer, P&H Mining Equipment, Milwaukee, Wisconsin, USA

tubs to provide lower ground bearing pressures and various walking mechanism systems have been developed over the past 30 years to provide a longer life at a lower operating cost. A dragline with a 170-m^3 (220-yd^3) bucket, a 122-m (400-ft) boom, and a mass of 12,700 t (14,000 tons) had been in use in the United States. However, because of environmental considerations, most of the largest draglines, particularly in the United States, have been removed from service.

Good bench preparation for walking draglines requires that the material be well blasted for good bucket loading yet remain sufficiently stable for the dragline to operate and move without the highwall collapsing. It is common for the dragline bench to be prepared so that any point loading that can damage the tub is kept to a minimum. The costing of equipment, such as tracked bulldozers, used for this bench preparation needs to be included when calculating system costs.

Stripping Shovels

A stripping shovel with a bucket size similar to a dragline will be more productive because of its crowd and breakout ability, shorter cycle times, and its ability to handle dense rocks. Although a competent floor is necessary (and may require some preparation), stripping shovels do not require the more extensive bench preparation necessary for draglines, so this additional cost is saved.

The largest stripping shovel used to date had a 138-m^3 (180-yd^3) bucket with a 65-m (215-ft) boom and installed power of 22,500 kW (30,000 hp). As with draglines, the largest stripping shovels have been taken out of service in favor of truck/shovel operations largely because of environmental considerations.

Size Selection

The primary steps in selecting a cyclic excavation machine involve (1) bucket capacity selection, (2) determination of machine geometry, and (3) reassessment of the first two steps into a standard model.

The first step in loading tool selection should be to determine (from the mining method planned) the planned production rate—in whatever units are applicable—and then convert these units into a loose volume to be moved per hour. Table 10.4-1 shows applicable factors for material densities and swell factors for a list of common materials. This will allow the calculation of the required bucket size using the following equation:

$$Q = \frac{P \times T}{3{,}600 \times B \quad \text{FE} \times A} \tag{10.4-1}$$

where Q is the bucket (dipper) capacity, P is the required production (loose volume per hour), T is the theoretical cycle time, BF is the bucket fill factor, E is the job operating efficiency, and A is the mechanical availability expected over the period of operation.

Theoretical Cycle Time

Values for theoretical cycle time (T) can be obtained from information supplied by the OEM or from time studies of similar machines in similar conditions. Table 10.4-2 provides average cycle time for a range of bucket capacities for draglines and stripping shovels.

Bucket Fill Factor

The bucket fill factor (BF) is a factor of the material sizing condition and the ease or difficulty of filling the bucket. Ideally, this factor is best determined by field measurements. However, if this information is not available, typical bucket fill factors can be found in Table 10.4-1.

Job Operating Efficiency

Job operating efficiency (E) is the percentage of time that a machine will actually operate (as dictated by maintenance, scheduling, and operating practices). Good management of the operation, typified by excellent management and supervision, planned maintenance programs, high availability, and so forth, will result in a better operating efficiency. Conversely, poor management, as typified by sloppy maintenance practices, low machine availabilities, and so forth, will result in a lower operating efficiency. Average operating efficiency figures should range between 0.75 and 0.90 (0.83 average).

Mechanical Availability

Mechanical availability (A) is the percentage of time that a machine is running and available to work. In good operating conditions with good maintenance practices, availability will be higher. As conditions deteriorate (extreme temperatures, dusty conditions, etc.) and maintenance practices become poorer, availability will be reduced. Availabilities of 85% to 95% should be achievable in most operating conditions during at least the first few years of equipment operation.

One further adjustment that needs to be made for cyclic excavation machines is to divide the calculated bucket capacity by a propel factor to make allowance for time required for the machine to move. The typical propel factor for a walking dragline is 0.94; a typical propel factor for a stripping shovel is 0.96.

Machine Geometry

Now that the bucket capacity has been selected, the next step is to consider machine geometry—primarily the dumping radius and the dumping height. Normally, the cut width is equal to the pit width and all exposed material is loaded out. In a typical dragline pit, the minimum cut width is determined by the mineral loading and transport equipment requirements. For small stripping shovels, cut width can be as narrow as 15 to 18 m (50 to 60 ft) with larger shovels requiring a pit width of 24 to 30 m (80 to 100 ft). In practical considerations, a narrow pit width allows more efficient use of the spoil space and reduces the dragline cycle time. Allowances will also need to be made if the overburden to be removed has widely variable thickness.

The geometry of cyclic excavation machines can be detailed more effectively by drawing or computing average and extreme pit sections and plans showing both the stripping and loading operations. Multiple iterations can be done to finalize the geometry.

Final Selection

After bucket size and operating geometry (dumping radius and dumping height) are determined, the optimal machine can be selected from OEM literature. Although it may be impossible to match exactly with calculated numbers, the nearest model can be adapted. For example, a reduction in dumping

Table 10.4-1 Bulk density, swell factor, and digability of common materials

Rock	Bank Density (t/m³)	lb/yd³	Swell Factor	Fillability	Digability*

28–45	36–59	65	53
46–150	60–200	68	56

*These values are based on a 120° swing for a dragline and a 90° swing for a stripping shovel, which approximates average field conditions.

radius will result in a reduction in dumping height, and vice versa. Because these units often involve customization, the mining company should work closely with the OEM on final design specifications.

Cost Estimation

Figure 10.4-1 can be used to calculate the estimated hourly ownership and operating costs for the various machinery and equipment referenced in this chapter based on information available from the OEMs and/or actual experiences in similar applications.

1 Machine Sales Price (less tires) Including All Options, Taxes, etc. _____

Figure 10.4-1 Estimating ownership and operating costs

Bucket-Chain Excavators

A bucket-chain excavator (BCE) excavates material below the grade of the main house unit and transports it upward and away from the unit. It can mine high outputs in weak, unconsolidated ground. Its primary advantages are its excellent downward-digging ability and its moderate ability to dig upward. Its greatest disadvantages are its inability to dig hard ground or to excavate materials selectively.

Bucket-Wheel Excavators

Bucket-wheel excavators (BWEs) are very effective for mining large volumes of unconsolidated material, although they also offer some productive ability in harder formations. They are also more selective than a BCE and can accurately cut bands as narrow as 100 mm (4 in.), albeit at a lower output. One primary disadvantage is their inability to achieve downward-digging action without special modifications.

The BWE digs with a series of evenly spaced buckets attached to the circular wheel at one end of the unit. The excavated material is fed via a transfer point in the wheel to the belt conveyor system of the excavator for discharge.

Advantage of Continuous Excavation

Continuous excavators have reduced dynamic stresses, lower service weights, reduced maintenance costs, and lower power consumption when compared to cyclic excavation tools. Because of the way they operate and transfer the load, BWEs have a lower ground-bearing pressure, allowing more efficient operation in softer underfoot conditions.

Output of Continuous Excavators

Continuous excavators are normally rated in terms of their theoretical output where

$$Q_{th} = \frac{60Fs}{\text{swell factor}} \tag{10.4-2}$$

where Q_{th} is the theoretical output in bank cubic meters per hour (cubic yards per hour), F is the capacity of each individual bucket, s is the number of buckets discharged per hour, and the swell factor is that of the material being excavated (from Table 10.4-1). It is necessary when comparing multiple models or OEMs to define bucket capacity in the same way in all cases.

The annual output capability can be calculated by

$$Q = Q_{th} \times OH \times SF \tag{10.4-3}$$

where Q is the annual output in bank in m^3 (yd^3), Q_{th} is the theoretical output calculated in Equation 10.4-2, OH is the annual scheduled operating hours, and SF is a service factor reflecting operating efficiency and machine availability. Common service factors range from 0.5 to 0.8, depending on ground conditions, climate, managerial efficiency, and so forth.

Bucket-Chain Versus Bucket-Wheel Excavator

Factors favoring the BCE, provided selective mining is not required, include

- Soft, nonabrasive rocks with high, deep cuts;
- When the initial box cut is already opened;
- Wet pit operations;
- Where transport gradients must be reduced;
- Where cuts must be taken below grade;
- Where specific slope profiles are required; and
- Where there are large undulations in the surface of the mineral bed.

Factors favoring the BWE include

- When selective operation is required;
- Where harder ground and/or some boulders are encountered;
- When higher availabilities and lower machine maintenance costs are of critical importance;
- When high upward digging capability is needed; and
- Where sticky materials are encountered.

LOADING EQUIPMENT SELECTION

A number of different types of loading tools are available for use in the mining industry, including front-end loaders, hydraulic excavators, and electric cable shovels. These are used to directly load material into a haulage unit for transport to a dump or processing facility.

Size Selection

As with cyclic excavation machines, the first step in loading tool selection should be to determine (from the mining method planned) the planned production rate—in whatever units are applicable—and then convert these units into a loose volume to be moved per hour. Equation 10.4-1 can be used to calculate an estimated bucket capacity using the same parameters previously defined.

Theoretical Cycle Time

Again, values for T can be obtained from information supplied by the OEM or from time studies of similar machines in similar conditions. In the absence of other data and as a basic assumption to calculate the required bucket capacity, a cycle time of 30 to 40 seconds per pass can be used.

After a specific loading tool is selected, a reiteration of this calculation can be performed to calculate a bucket (dipper) capacity more specifically. This range is based on truck positioning on the same level as the loading tool and an 80° to 100° swing. If this is not the case, allowances should be made to use a slower cycle time.

Bucket Fill Factor

This is a factor of the material sizing condition and the ease or difficulty of filling the bucket. Table 10.4-1 can be used to approximate the bucket fill factor.

Job Operating Efficiency

As previously defined, average operating efficiency figures should range between 0.75 and 0.90 (0.83 average).

Mechanical Availability

Availabilities of 85% to 95% should be achievable in most operating conditions during at least the first few years of equipment operation.

After this calculation is completed, one additional adjustment should be made to allow for time lost to exchanging trucks. To allow for this lost time, if the calculated figure is divided by 0.80 if using a front-end loader or single-side loading and 0.9 if using a shovel and double-side loading (alternately loading on either side of the shovel), a final bucket capacity requirement can be defined.

The next step in loading tool selection is to consider the type of loading equipment. Figure 10.4-2 shows the applicable range (by bucket capacity) for front-end loaders, hydraulic excavators, and electric cable shovels.

Type of Loader

From the chart in Figure 10.4-2, one or two of the loading tool types may be eliminated in this step. For example, if the required bucket capacity is 15 m^3 (19.6 yd^3), then no electric cable shovels fall into this classification, so the choice comes down to a front-end loader or a hydraulic excavator. Likewise, if the required bucket capacity is 60 m^3 (78.5 yd^3), then the only choice (unless using more than one loading tool to achieve the necessary production) is an electric cable shovel.

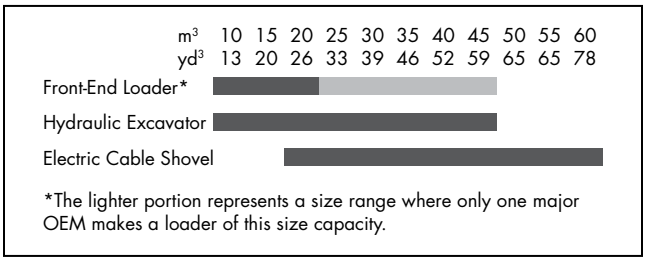

Figure 10.4-2 Loading tool bucket capacities

Table 10.4-3 is a comparison of key points to be considered when selecting among front-end loaders, hydraulic excavators, and electric cable shovels.

If a hydraulic excavator is selected, then a further choice needs to be made between a backhoe front and a loading shovel front. A hydraulic front shovel offers many of the same advantages as the electric cable shovel—high digging forces, good operator visibility—along with the additional advantage of better selectivity because the operator can easily see and control where the bucket is placed into the face. A backhoe front offers the advantage of less required bench preparation, excellent operator visibility into the truck bed to place the load, and the ability to reach more material without moving the unit. The choice between front shovel or backhoe front is often driven by local preferences. Most hydraulic excavator manufacturers also offer machines, particularly the larger size machines, with electric power (rather than diesel engine power). This allows the mine to take advantage of less expensive electric costs (where applicable), but some mobility is also lost.

Productivity Estimation

After a specific loading tool has been selected, the productivity estimate can be recalculated using Equation 10.4-1 but rearranged to yield the production. If truck loading, the calculated production rate should be adjusted by multiplying the

Table 10.4-3 Comparison of loading tool types

Front-End Loaders	Hydraulic Excavators	Electric Cable Shovels
Lowest capital cost	Moderate capital cost	Highest capital cost
Highest operating costs (particularly if tire wear is high)	Moderate operating costs	Lowest operating costs (dependent on costs for electricity)
Very mobile, particularly useful where blending of different material types is required	Mobility to move between faces, but not enough for blending operations	Lack of mobility due to connection to electric grid system
Most efficient bench height at 75% of maximum digging height (lowest of loading tool options)	Most efficient bench height at 75% of maximum digging height	Most efficient digging height with bench height equal to boom point height
Tires make unit susceptible to soft underfoot	Lowest ground pressure for use in soft underfoot conditions	Good ground pressure (but higher than hydraulic excavator) because of much higher operating weight
Bucket must be lowered to ground level to begin dig cycle	Ability to dig from the top down by penetrating the loading face at some level aboveground	Bucket must return to ground level to start dig cycle
Lowest lifetime operating hours; easy transportation and assembly so loader can be moved between mining operations	Lifetime hours 60,000 to 100,000; can be disassembled and reassembled on a different site relatively quickly	Highest lifetime operating hours; requires longer-life mine to take advantage of this
Relatively simple technical training and tooling required	Some specialized training and tooling required	Requires specialized technical training and tooling
Requires very good blasting in order to allow bank penetration and good productivity	Ability to load from the top down provides ability to handle more poorly blasted material	Best suited to work with well-blasted material
Typical cycle times of 30 to 45 seconds	Typical cycle times of 25 to 35 seconds	Similar cycle times to hydraulic excavators
Wide bucket and the need to return to ground level to dig limit ability to mine selected layers or pockets of material	Can selectively mine layers or pockets of material	Difficult to mine selectively because of requirement to return to ground level to begin dig cycle
Mobility provides excellent loading area cleanup	Can use reach of front attachment to keep floor of loading area clean	Typically uses a loader or rubber-tired dozer to keep floor of loading area clean
Material in bucket discharges quickly into truck bed, creating a higher shock load to be transferred onto frame and other components	Allows measured discharge of material from bucket to truck to ease forces acting on truck frame and other components	Allows measured discharge
Develops more greenhouse gases as a result of diesel engine	Develops more greenhouse gases as a result of diesel engine (eliminated with electic-powered hydraulic excavator)	More environmentally friendly because power supplied by electric trail cable
Very strong used market for good quality front-end loaders	Good used equipment market for hydraulic excavators	Limited used equipment market for electric cable shovels due to transportation and reassembly requirements

Table 10.4-4 Passes to load typical articulated truck size*

Truck Size, t (tons)	2.3 m^3 (3.0 yd^3)	3.4 m^3 (4.5 yd^3)	4.6 m^3 (6.0 yd^3)	5.7 m^3 (7.5 yd^3)
18.1 (20)	4			
22.7 (25)	4–5	3		
27.2 (30)	5–6	4	3	
36.3 (40)		5	4	3
45.4 (50)		6	4–5	4

*Based on 100% bucket fill factor and 1.8 t/m^3 (3,030 lb/yd^3) material.

Table 10.4-5 Passes to load typical rigid-frame haul truck size*

Truck Size, t (tons)	15 m^3 (19.5 yd^3)	20 m^3 (26.2 yd^3)	25 m^3 (32.7 yd^3)	35 m^3 (45.8 yd^3)	45 m^3 (58.9 yd^3)
136 (150)	5	4	3		
181 (200)	6	5–6	4	3	
217 (240)		6	5	3–4	
290 (320)			6	4–5	3–4
360 (400)				6	4–5

*Based on 100% bucket fill factor and 1.8 t/m^3 (3,030 lb/yd^3) material.

result by 0.8 or 0.9 (based on operating conditions) to allow for truck exchange time (as described previously).

HAULAGE TRUCK SELECTION

The three types of haulage trucks used in mining operations include on-highway trucks, articulated trucks, and rigid dump trucks. The selection will depend on operating conditions and production required.

On-Highway Trucks

On-highway trucks in mining applications have a fairly limited application and are most often used to transport materials such as coal (commonly in the eastern United States) and construction aggregate (sand and gravel, crushed stone) for further processing and/or delivery to a customer's site. These trucks may be mine owned or (more likely) are contracted from a local trucking company. The size of such units is limited to a maximum of 18 to 20 t (20 to 22 tons). Selection is normally driven by factors such as availability and cost (if leased/contracted) rather than on productivity or size.

There is, however, at least one manufacturer of off-highway style trucks that manufactures up to a 36-t (40-ton) truck for use within the mine site. They purport lower tire costs and lower fuel consumption, resulting in a lower operating cost truck than either articulated or rigid-frame trucks. Depending on operating conditions and longevity of the mine, though, this type of truck could experience a much different pattern of maintenance costs. If a mine is considering a truck of this size-class, a detailed economic analysis should be undertaken to better understand the economics of the different types of trucks. Figure 10.4-1 can be used to calculate estimated ownership and operating costs. A haul study, usually done with the assistance of the various OEMs, will assist in calculating production rates. Several commercially available haul simulation programs are also available; however, these programs do not normally include on-highway trucks in their fleets.

Articulated Trucks

Like on-highway trucks, articulated trucks have a limited application in mining. Articulated trucks have a significant advantage over other haulage equipment in areas with soft underfoot conditions and on distances ranging from 120 to 1,200 m (400 to 4,000 ft). In longer-distance applications and with solid haul road construction, rigid dump trucks are the most likely common choice. Articulated trucks can also be used on steeper grades than rigid dump trucks.

Most OEMs manufacture articulated trucks with capacities from 22.7 to 36.3 t (25 to 40 tons) with a few now manufacturing 45.4-t (50-ton) trucks. Articulated trucks are most commonly loaded by construction-class hydraulic excavators with bucket capacities ranging from 2.3 to 4.6 m^3 (3.0 to 6.0 yd^3). The excavator size selection would be made in accordance with the production requirements, as shown previously in Equation 10.4-1.

At that point, an acceptable guideline is that a truck should be loaded in four to seven passes. Table 10.4-4 provides a pass-match chart assuming various-sized articulated trucks are loaded by various-sized hydraulic excavators.

The number of trucks required can then be calculated by using the number of passes and the pass cycle time to calculate a load time, adding "fixed" times such as positioning at the loading tool and dump time as estimated from experience or from information obtained from the OEM, and finally adding estimated travel times as calculated using either a haul simulation program or the rimpull-speed-gradeability curves and retarder charts available from the OEM. Rolling resistance—a factor related to how far the truck tires penetrate the haul road surface—must also be considered in this calculation when using the charts indicated.

Rigid Dump Trucks

Rigid dump trucks are the backbone of haulage equipment for the worldwide mining industry. Available primarily from five global OEMs—Caterpillar, Komatsu, Bucyrus, Hitachi, and Liebherr—along with other locally manufactured and supported units, capacities range from 36 to 360 t (40 to 400 tons) with the smaller trucks of 36 to 90 t (40 to 100 tons) considered as construction/quarry trucks (also used in smaller metal/nonmetal mining operations) and the larger trucks—greater than 90 t (100 tons)—considered as "mining-class" haul trucks.

Size Selection

Mine operators typically target to load a haul truck in three to five passes from the loading tool. With hydraulic excavators and front-end loaders, the range is four to seven passes; with electric cable shovels, the range is three to four. If a truck is loaded in fewer passes, the large amount of material dumped at one time can cause excess stress on tires and structural components of the truck. If it takes more passes to load, the truck waits excessively in the loading area, producing inefficiencies.

Table 10.4-5 shows the number of passes required to load different haul truck sizes with various loading tool bucket sizes ranging from 15 to 45 m^3 (19.5 to 58.9 yd^3). Major electric cable shovel manufacturers have started to rate buckets by the amount of material carried in each (i.e., 90-t [100-ton] load). The bucket capacity is sized to match the mine's material density, making it an easy calculation to determine the number of passes required to load a truck.

Mechanical Versus Electric Drive

One of the primary decisions to be made in haul truck selection is whether to use a mechanical-drive truck or an electric-drive truck. Some OEMs offer both mechanical- and electric-drive trucks in the mining class (greater than 136 t [150 tons]) while others offer only electric drive. Within the electric-drive option, there is also a choice between direct current (DC) and alternating current (AC), although AC-drive offers additional advantages over DC-drive and is becoming the more common choice in today's market.

Electric-drive trucks typically travel at higher speed on grades ranging from 4% to 10%, have potentially lower maintenance costs, offer slightly better fuel economy, have a smoother operator ride, and offer better retarding capacity to stop the truck. However, they do have a higher capital cost and require more specialized technical training and capabilities. Most OEMs also offer the ability to convert the electric-drive truck to a trolley-assist truck, resulting in much higher speeds on steep grades.

Mechanical-drive trucks can more effectively travel on steeper grades (greater than 10%), have a larger market presence resulting in more knowledge in the field, have a lower capital cost, and require a lower level of technical specialization. They are also lighter-weight vehicles.

Productivity Estimation

After a loading tool and truck capacity are selected, the productivity of the "system" should be calculated in order to determine the number of trucks necessary and to ensure that the estimated productivity of these discrete units operating together will still meet the required production.

By far, the most efficient way to calculate this productivity is to utilize either one of several commercially available simulation programs or to utilize an equipment manufacturer's program. These programs will estimate a production based on the unit load time, fixed times for the loading tool and the truck, and other data input. At least one haul road profile will be required so that the simulation can be performed based on a specific site condition. Alternatively, the only way to estimate fleet productivity is to calculate travel speeds for a given grade using an OEM's rimpull-speed-gradeability chart and add in the applicable fixed times for the loading tool and truck. Use of computer programs will also allow much quicker evaluations of different loading tools and truck fleet sizes.

OTHER EXCAVATION TOOLS

Many mining production systems incorporate some combination of excavation and transportation of material. These include wheel loaders used in a load-and-carry application, tractor scrapers, bulldozers, loading draglines, and surface miners. These are often "auxiliary" production systems or used in applications with lower production requirements.

Load-and-Carry Wheel Loaders

In addition to truck-loading applications, wheel loaders can also be used in load-and-carry applications, either to dump directly into an adjacent mined-out area (such as in an overburden stripping application) or to dump into a portable crusher (and conveying system). The key here is to minimize the distance the loader must travel, as longer distances result in slower cycles and increased tire wear, a significant cost factor in load-and-carry operations. Load-and-carry applications should be limited to less than 120 m (400 ft).

Productivity of a load-and-carry operation can be calculated as follows:

$$t_c = \text{time to load bucket} + \text{travel loaded} + \text{dump time} + \text{travel empty} \quad (10.4\text{-}4)$$

where t_c is the loader cycle time in seconds. Travel time is calculated by dividing the distance to be traversed (meters) by the travel speed (meters per second). Travel speeds can be determined from OEM literature and specifications.

$$P = (3{,}600 \times Q)/t_c \quad (10.4\text{-}5)$$

where P is the productivity in cubic meters per hour, Q is the bucket capacity in cubic meters, and t_c is the cycle time in seconds calculated in Equation 10.4-4.

Tractor Scrapers

Another excavation tool found in some mining applications, particularly overburden stripping (with haul distances ranging from 120 to 1,200 m [400 to 4,000 ft]) is the tractor scraper. They may also be found in some medium hardness rock applications that fragment well after blasting. Many models of scrapers are available, with most capacities ranging from 15 to 34 m^3 (20 to 44 yd^3). As noted in the *Caterpillar Performance Handbook*, four primary types of scrapers are available: single-engine conventional scrapers, tandem-powered units, elevating scrapers, and auger scrapers (Caterpillar 2008).

Single-engine conventional scrapers have the widest range of applications and commonly require the use of a pusher tractor (bulldozer) to be loaded most effectively and economically. Conventional scrapers operate most effectively with lower haul grades, lower rolling resistances, and better floor conditions.

Tandem-powered units offer higher tractive effort capabilities, meaning they can be used in softer underfoot conditions and in higher rolling resistance applications. Normally, tandem-powered units are also pushed by a pusher tractor to assist in loading.

Elevating scrapers are self-loading and best used in applications with short to medium haul distances. They also do not perform well in adverse grades and with high rolling resistances. Elevating scrapers do not perform well in sticky materials (such as some clays) or material containing rock.

Auger scrapers are also self-loading units and, like elevating scrapers, do not work well with sticky or rocky materials. The auger scraper does offer improved tire life and excellent ejection characteristics, and is suitable for a range of conditions.

Type Selection

As detailed in *A Reference Guide to Mining Machine Applications* (Caterpillar 2001), there is some overlap between applications of the different types of scrapers, but the following can be used as a basic guideline:

- Short distances, lower grades—elevating or auger
- Short distances, higher grades—tandem-powered
- Longer distances, moderate grades—conventional
- Low rolling resistances, short distances—elevating or auger
- Moderate rolling resistances, longer distances—conventional
- Higher rolling resistances, variable distances—tandem

Productivity Estimation

Production with a scraper can be estimated using a methodology similar to that used previously with other types of equipment, by considering both fixed times (time to load and dump the scraper) and variable times (travel times loaded and empty), utilizing OEM rimpull-speed-gradeability charts.

$$\begin{aligned}\text{total cycle time (TCT)} = {} & \text{fixed time} \\ & + \text{travel loaded} \\ & + \text{travel empty}\end{aligned} \tag{10.4-6}$$

Fixed time for scrapers will include the load time (typically 0.5 to 1.0 minutes, depending on type of scraper and actual conditions) and the time to maneuver and spread or maneuver and dump the material (typically 0.6 to 0.7 minutes).

Scraper productivity can then be calculated as

$$P = \frac{\text{scraper heaped capacity} \times \text{fillability} \times 60 \times E \times A}{\text{swell factor} \times TCT} \tag{10.4-7}$$

Bulldozers

Bulldozers are not usually considered as primary excavation tools but can be used to supplement the primary excavation tools. One particular application is in coal mine overburden stripping where cast blasting is employed and bulldozers are used to push a significant amount of material into an already-mined adjacent pit. Excavation with a bulldozer should be limited to less than 100 m (328 ft).

To calculate the production that can be achieved by a bulldozer, the blade capacity of the bulldozer under consideration can be obtained from the OEM literature. This would provide a volume per pass in loose cubic meters and can be converted to bank cubic meters by dividing the blade capacity by the swell factor (from Table 10.4-1).

The cycle time can be calculated as

$$t_c = \frac{\text{distance}}{\text{dozing speed}} + \frac{\text{distance}}{\text{reverse speed}} \tag{10.4-8}$$

Generally, dozing speeds of 1.5 to 2.5 km/h (0.9 to 1.5 mph) will be the most economical. Reverse speeds (generally in third gear) can be found in OEM literature.

When considering bulldozer production, the following should be noted:

- If a ripper is used, the production (when dozing) will be increased, but the time required to rip will need to be accounted for.
- Any available slope should be taken advantage of to doze downhill.
- Steady dozing pressure should be maintained.
- Speeds should be reduced in areas of heavy shock and impact conditions.

Loading Draglines

Crawler-mounted draglines used to load directly into haul trucks have limited application in modern mining methods for many reasons: (1) they have limited crowd and breakout action compared to shovels, backhoes, and front-end loaders; (2) cycle times are longer when compared to other loading tools, resulting in lower production rates; and (3) they have limited ability to spot the bucket and dump into a truck.

Several areas in which loading draglines do find an application are in deeper wet pits (such as underwater sand and gravel operations) and in secondary roles such as excavating box cuts, digging sumps, final pit cleanup, and other areas where they are not the primary production tools.

Estimating production and operating costs of loading draglines can be completed using previously introduced methods adapted to this type of equipment.

Surface Miners

Relatively new to use in surface mining excavation, surface miners can be used to excavate material where drilling and blasting is prohibited (such as in some quarry applications) or where selective mining is required or where materials have a relatively lower compressive strength. Surface miners can be used in either a discontinuous system (where the surface miner cuts the material and loads it into a haul truck) or in a continuous system (where the material is wind-rowed behind or to the side of the machine for later loading (usually by a front-end loader into a haul truck). Combinations of a surface miner with a conveyor system can also be achieved.

In a discontinuous system, minimum operating cost is achieved where the truck body is sized so that the truck remains still while the surface miner moves forward and loads the truck uniformly over the full length. The maximum volume of each cut can be calculated as

$$\begin{aligned}0.6 \times {} & \text{bucket-wheel diameter} \\ & \times \text{width of the bucket-wheel head}\end{aligned} \tag{10.4-9}$$

In a discontinuous system, the overall productivity will be limited by the number of haul trucks to be used and the distance and haul profile over which the material can be moved.

According to information from Wirtgen (2000)—one of the leading surface miner OEMs—in continuous cutting operations, the surface miner can achieve outputs up to 1,400 m^3/h (1,831 yd^3/h) (bank) depending on material compressive strength. Maximum productivity is achieved in materials with a compressive strength up to 40 MPa (6,000 psi). Reduced productivity is achieved in materials up to 80 MPa (12,000 psi), and in special cases, such as small lenses of material or thin layers of up to 120 MPa (18,000 psi). Some information sources have shown a range of five to seven times higher productivity in material with a compressive strength of 10 MPa (1,500 psi) versus a material with a compressive strength of 80 MPa (12,000 psi).

CHAPTER 10.5

In-Pit Crushing

Ronald W. Utley

To establish and maintain competitiveness in international markets for mineral, coal, and stone products, it is necessary to adopt the latest proven technology and economic systems in open cast mining. In today's markets, overburden of increasing thickness has to be stripped, transported, and dumped; distances to the stockpile are becoming longer; depths of mines and quarries are increasing; ore grade is decreasing; and costs for energy and labor are continuously escalating.

Trucking of waste and ore from mines, quarries, and pits is a flexible materials-handling transportation system. Mine planners, especially at the start of a greenfield project, find that trucking is the easiest transportation system to design and plan for. As the pit or quarry becomes deeper or farther away from the delivery points, mine planners and designers should perform trade-offs between cost and flexibility of transportation systems. This will ensure that their operations will continue to have the best and most economic materials-handling systems for their operations.

As pits have become deeper and their capacities increased, in-pit crushing and conveying (IPCC) has become the comminution and transportation method of choice for most mine planners. In response to the IPCC option, truck manufacturers developed larger trucks. When long-term planning is possible, IPCC is preferred for the materials-handling transportation system.

There are three main steps in designing an excellent crushing plant: (1) process design, (2) equipment selection, and (3) layout. The first two are dictated simply by production requirements and material characteristics, but the layout can reflect the inputs, preferences, and experience of a large number of parties. These can include the owner's engineering staff, operations and maintenance personnel, equipment manufacturers, and especially the mine planners.

The types of in-pit crushers usually reviewed by mine planners for hard ore are fixed plants mounted at the rim of the pit and semimobile and fully mobile plants within the pit. The gyratory crusher is the crusher of choice for capacities over 2,500 t/h (metric tons per hour) [2,755 stph, or short tons per hour]). For soft-rock applications, including overburden, coal, and oil sands, fully mobile continuous mining systems are becoming increasingly attractive. The crushers most often selected for these applications are low-speed sizers and double-roll crushers. Two types of conveyor systems being selected for these systems are the conventional conveyor and high-angle conveyor. The high-angle conveyor system has yet to be put in operation in a high-tonnage mining operation.

IPCC DEVELOPMENT

In 1956, the first *mobile*, or self-propelled crusher, was installed in a limestone quarry in Hover, Germany. Use of these earliest mobile crushers solved the major problem of wet, soft ground conditions that did not permit the use of haulage trucks because of the high cost of building and maintaining haulage roads. Quarry operators also wanted to take advantage of continuous belt conveyor haulage systems and the resulting cost savings.

European mines, particularly in the coalfields, are frequently characterized by soft materials, allowing the use of bucket-wheel excavators, followed by a continuous haulage system of belt conveyors. In the late 1950s, contemporary quarry operators with background knowledge of belt conveyors in mining easily accepted the concept after in-pit mobile crushing solved the problem of run-of-quarry size reduction required for conveyor application.

Large-capacity in-pit crushing started as early as 1969–1970 in Alcoa's bauxite mines in Western Australia. In the late 1970s the first fully mobile gyratory crushers 1,370 × 1,880 mm (54 × 74 in.) were installed in South African open cast mines. All of these crushing plants were fully mobile (with walking feet), although one was used with dump trucks and stayed in position for several years while the others were working at the face in conjunction with shovels and were moved several times a shift.

Three events took place in the early 1980s that laid the foundation for the worldwide acceptance of IPCC:

1. The oil embargo of 1979 put mine operators on notice that they should not tie their future to conventional truck haulage systems. Approximately 50% of truck operating costs are related to fuel, lubrication, and tire consumption, which are either directly or indirectly dependent on

Ronald W. Utley, Consultant, FLSmidth, Inc., Bethlehem, Pennsylvania, USA

the cost and availability of petroleum products. In the late 1970s and early 1980s, petroleum costs (and thus the cost of their derivative products), as well as availability, were unpredictable because of cartel pricing policies and an extremely volatile world market. Severely increased truck haulage costs, coupled with potential fuel shortages, forced greater emphasis on the development of haulage systems that either eliminated the need for trucks or at least greatly reduced truck haulage distances.

2. Duval Corporation installed a movable, indirect feed crushing and conveying system that incorporated a 1,500 × 2,260 mm (60 × 89 in.) primary gyratory crusher with a rated capacity of 3,629 t/h (4,000 stph) in the company's Sierrita copper-molybdenum open-pit mine, located near Green Valley, Arizona (United States).
3. The U.S. Bureau of Mines presented its highly published treatise, "Movable Crusher Systems—Concepts and Application" at the American Institute of Mining Engineers In-Pit Crushing and Conveying Symposium in Salt Lake City, Utah (United States) in 1980.

This combination of need, visibility, and credibility built on 25 years of related experience and was the springboard for change. In the 30 years since the Sahuarita IPCC in Arizona became operational, the mining industry has made great strides in improving efficiency. IPCC systems have significantly contributed to increased profitability through reduced production costs. By limiting truck haulage to short distance material transport between the face and the crusher, and, in some cases, by completely replacing trucks, the installation of IPCC systems achieved a marked reduction in overall mining costs. Due to the economies provided by IPCC, mines have been able to operate economically with lower ore grades, greater pit depths, and at higher capacities.

A series of events have taken place since 2006 which is again changing IPCC:

- The larger hard-rock mines of the world are operating at or approaching 10,000 t/h (11,000 stph). Overburden removal for some of the hard-rock mines is exceeding 10,000 t/h and soft-rock mines, including coal and oil sands, are approaching 14,000 t/h (15,432 stph).
- It appears that truck sizes have reached their maximum of 363 t (400 st) while shovels have continued to get bigger. Truck manufacturers have stated that construction of a 500-ton truck is possible, but to date none has been built. The development of an efficient mine plan can only be achieved through an analysis of the integration of material removal, loading, hauling, and dumping. With the larger shovels, the largest trucks are now the limiting factor in optimizing load-and-haul production. For large production mines with long-haul distances, IPCC has become more attractive.
- The hard-rock crusher of choice, the gyratory crusher, has either reached or is close to its maximum practical size. From the outset, in 1985, the 1,500 × 2,260 mm (60 × 89 in.) size was the crusher of choice for IPCC. The 1,500 × 2,970 mm (60 × 117 in.) size followed in 1990. Manufacturers have been offering 1,800 × 3,250 mm (72 × 128 in.) size machines for IPCC, but, to date, no orders have been placed.
- Double-roll crushers and low-speed sizers have been developed for soft rock, coal, and oil sands for capacities of 12,000 t/h (13,228 stph) and designed for 14,000 t/h (15,432 stph).
- The world went through another round of oil price increases, which, in turn, caused another round of increases in mining costs based on fuel for truck fleets—a reminder that the best way to ensure stable power costs is with electric power rather than oil.
- Deliveries of new truck tires for haul trucks increased to more than 2 years (briefly from 2006 to 2008), threatening the shutdown of some operations and increasing the cost of tires.
- The concern over global warming has heightened the awareness of minimizing carbon dioxide (CO_2) emissions. These requirements may favor IPCC in general and continuous mining in particular. However, the plant designer needs to consider the delivered cost of electric power when comparing electric power–driven systems with diesel truck systems.
- IPCC plants have been required to add dust suppression and/or dust collection systems.

CONTINUOUS IPCC SYSTEMS DEVELOPMENT

The use of continuous mining systems is primarily dependent on the type and properties of the ore being mined. In the case of light and loose earth, bucket-wheel excavator technology, combined with a system of conveyors, offers the advantages of a continuous mining system. In order to take advantage of continuous mining in harder ore, such as minerals and hard coal, crushers are required to reduce the run-of-mine (ROM) ore to a conveyable size.

The objective of the fully mobile continuous crushing system is to totally eliminate the need for trucks by having the shovel feed the ROM ore directly to a continuous materials-handling system. The crushing needs to be fully mobile, such that it follows the movements of the shovel, and has to be designed to suit the movement of the shovel boom and bucket, and match the operating capacity of the shovel.

The ore is fed directly from the shovel to the crushing plant, is crushed to conveyable size, and discharges to a system of shiftable and fixed mine conveyors. To increase flexibility, a short mobile transfer conveyor can be added to the system. In most cases, existing cable shovels or hydraulic excavators can be used if a mobile crushing plant replaces the truck fleet. The hopper height and geometry are similar to the truck box, so the shovel operation is similar whether loading trucks or the mobile crushing plant.

A characteristic feature of continuous open-pit mining technology is its long life expectancy. The large number of such examples includes the in-pit crushing system at the Morenci open-pit copper mine in Morenci, Arizona, which commenced operations in the late 1980s. Another example is the fully mobile primary gyratory crusher system at the Foster Yeoman limestone quarry in England, which also dates to the mid-1980s.

Advantages of IPCC

The main reason for the implementation of semimobile and mobile crushing plants instead of fixed crushing plants is the optimization of material transport around and out of the pit on its way to the waste dump or processing plant. In this case, *optimization* means the overall cost comparison of truck and conveyor transport in combination with crushing plants, stockpiles, and dumping equipment.

The basic design of crushing plants has not changed much in the last few years. Only the environmental protection requirements for mining companies to install dust suppression and/or dust collection equipment have been added. (Almost all IPCC gyratory crusher plants built in the past years are of the semimobile direct-dump design.)

The selection and design of a crushing plant depend on evaluation and consideration of the following:

- Kind of material to be crushed
- Tonnage of material to be conveyed
- Area, depth, and development of the open pit
- Space availability (height, area) at the favorable crusher locations, taking into consideration the mine design and especially the ore that becomes inaccessible underneath the installation
- Conveying options out of the pit
- Type of downstream material flow in connection with the utilization of the entire crushing and conveying system
- Comparison of maintenance for feeding the crushing plant by direct dump or with an apron feeder

Advantages of belt conveyor haulage as compared to truck haulage include the following:

- Stationing the crusher in the pit reduces cost by shortening the haulage distance between the loaders and crushing plant.
- Operating costs associated with fuel, tires, and lubricants are reduced. These products tend to increase in price at a rate that exceeds the rate of monetary inflation.
- Labor costs are reduced. Although most in-pit systems, either operating or planned, use truck haulage, the haulage distance is shorter and the number of trucks can be partially or totally reduced. This reduction produces a corresponding decrease in operators and maintenance personnel.
- Compared with truck haulage, safety risks are reduced.
- Because mining ventures are long term, in-pit crushers and conveyors offer greater predictability for future costs.
- Dependence on the availability of fuel is greatly reduced.
- Dependence on rubber tires is greatly reduced.
- Conveyors can traverse grades of up to 30° versus approximately 10–12° for trucks. This ability facilitates shorter haulage distances and reduces haulage road construction.
- Conveyors can easily cross roads, railways, waterways, and other obstructions.
- With the reduction of haulage costs, lower-grade ore bodies can be mined economically. This is particularly important because many established ore bodies are decreasing in grade with an increase in depth.
- CO_2 emissions are greatly reduced.
- Downhill conveyors can produce regenerative electrical power instead of dissipating heat, as is the situation with trucks braking.
- Conveyors are more energy efficient than trucks.
- Conveyors require less skilled labor for maintenance than trucks.
- IPCC equipment can achieve maximum operational availability because of greater independence from weather conditions such as fog, rain, snow, and frost.
- The cost of haulage road maintenance is significantly reduced by using conveyors.
- Continuous flow of material can be maintained by using conveyors.
- With the availability of technologies such as finite element analysis and computer simulation, in-pit crushing stations have been refined to a point where their performance and integrity is equal to that of traditional crusher stations. By allowing for future relocation as the mine expands, long-term mine planning is more flexible.

Disadvantages of IPCC

The principal drawbacks of belt conveyor haulage as compared to truck haulage are the following:

- Short-term flexibility is reduced. The great mobility of trucks allows mine managers extreme flexibility in the mine plan. Once an overland conveyor is installed, it is prohibitively expensive to move as part of a mine plan change.
- Upfront costs are higher.
- While the semimobile system is being moved, truck capacity may be insufficient to feed the process or to strip waste.
- Remote sites are particularly susceptible to parts shortages. Truck haulage offers a range of capacities, while conveyor systems offer no capacity if parts are not available.
- Capacity increments are easier to achieve with trucks compared to large IPCC systems.
- In mines where ore blending is important, truck flexibility provides an added advantage.
- Lump size is limited. Once blasted, ore and waste in hard-rock mines can be loaded directly into a truck and hauled out of the pit. Generally, for conveyors, it is necessary to crush the blasted ore or waste.
- A key issue with the IPCC concept has been the inability to maintain projected production over extended periods and maintenance problems, since the shutdown of any one piece of equipment in an IPCC system would shut down the whole system.
- The production of the IPCC system is dependent on how it is loaded. If the excavator/shovel is not working in harmony with the rest of the IPCC system, maximum production cannot be obtained on a consistent basis.
- Maintenance of the complete IPCC system has to be monitored on a continuous basis. The purpose is to minimize the downtime potential of the entire IPCC system while any one individual component is being maintained.

DESIGN PARAMETERS

The principal design parameters that drive IPCC selection and configuration include

- Production requirements,
- Truck sizes,
- Capital and operating costs,
- Ore characteristics,
- Ore-body geometry,
- Reserve life,
- Estimating infrastructure and equipment,
- Availability of power and diesel,
- Country risks,
- Safety and environment,
- Project location (climate, geography, terrain),
- Life-of-mine/expansion plans,
- Operational considerations, and
- Maintenance requirements.

Table 10.5-1 Requirements for process design

Process	Requirements
Process description	General
	Primary crushing
General material characteristics	Maximum rock size
	Material specific gravity
	Material bulk density
	Material hardness
	Material abrasiveness
	Clay content
	Material moisture, wet season
	Material moisture, dry season
	Angle of repose
	Angle of withdrawal
Operating schedule	Days per year
	Hours per day
	Nominal annual throughput
	Mining shifts per day
	Crushing plant shifts per day

Production Requirements

The process design criteria define the project's production requirements. Typical requirements are shown in Table 10.5-1.

Crusher station–receiving hoppers have to be designed to handle, as quickly as possible, ore that is delivered by the largest trucks (of loading equipment) in the fleet. The typical design capacity of the feed hopper is two truckloads and in some cases up to three trucks' capacity. The discharge chamber below the crusher has typically been designed to hold a minimum of 1.25× the capacity of the receiving hopper to prevent the crushed ore from backing up into and damaging the crusher. As the standard size of today's mine trucks are 300- to 400-ton capacity, the size of the crushing stations must be very large and high just to contain the ore. Some of the semimobile crushing stations now being designed are direct-dump stations with high-speed crushed-ore-receiving conveyors capable of removing the material at rates in excess of the crusher's maximum capacity. The crushed rock is then taken directly to the out-of-pit transport conveyor or into an in-pit surge bin. Use of the high-speed belts has reduced the discharge chamber capacity by as much as 50%. The initial semimobile gyratory crushers were fed with an inclined apron feeder, which allowed the overall height of a station to be contained within two bench heights and allowed for instantaneous dumping of material into the hopper.

Capital Costs

Large semimobile primary crushing plants can be very costly, especially if they include the inclined apron feeder. It is unwise to estimate crusher installation costs based simply on equipment price plus a contingency allowance for other costs. The following direct costs, including installation labor hours, must all be taken into account:

- Earthworks and civil engineering
- In-pit construction planning, in order to prevent the interruption of ongoing operations
- Concrete
- Structural steel
- Architectural
- Mechanical
- Electrical and instrumentation

Indirect costs can be at least half as much again as direct costs and include

- Engineering, procurement, and construction management;
- Start-up and commissioning;
- Construction equipment;
- Spare parts;
- Freight;
- Taxes;
- Escalation; and
- Owner's costs (relocation, hiring and training personnel, permits, licensing fees, etc.).

Ore Characteristics

Ore characteristics are a critical element in both crusher and conveyor selection. Dry ores require greater provisions for dust suppression and collection. Wet, sticky ores can plug chutes and crushers, reduce surge capacity, and misalign belts.

For mines at which ore characteristics change over time, it can be costly to initially design a plant without the necessary flexibility. Some owners stipulate that initial capital investment be kept to a minimum, with design modifications paid for out of the operating budget. This is not always easy to achieve.

Project Location

A project's geographical location, topography, remoteness, and climate all affect the crusher plant design. Construction costs are generally much greater at high altitudes, in cold climates, and at remote sites. Modular construction and subsequent transportation to the site can improve the economics of such a project.

Geography dictates what material can be best used economically in a particular region. A flat quarry operation lends itself to having the conveyor installed in one position for long periods of time. A deep copper pit will sometimes require that the crushing station and receiving conveyor need to be moved. Naturally, it would be best to find a wall that requires no more setbacks. The conveyor could then be installed either up this face with a high-angle conveyor or in a slot designed to install a conventional conveyor. Another alternative would be similar to the setup at the Island Copper installation on Vancouver Island in British Columbia (Canada) where the operator installed a conveyor in a tunnel up at 15° out of the pit.

Life-of-Mine/Expansion Plans

The life of the mine is a key element in the design of any crushing plant. The selection of a fixed crusher versus a semimobile plant is an important design consideration in the overall life of a mine. Moving a crushing plant and adding feed conveyors to the takeaway conveyor can be expensive.

Any expansion plans for most IPCC systems should be built into the crusher and conveyor systems at the start of a project. A conveyor system's tonnage can be increased in the future simply by speeding up the conveyor and, if required, adding additional drives.

Operational Considerations

It is important to provide a comfortable, well-ventilated workspace with drinking water and restroom facilities nearby. Also, the operator should be able to see all the main parts of the crushing facility under his control, either through a good window or by means of TV cameras/monitors. Vibration and

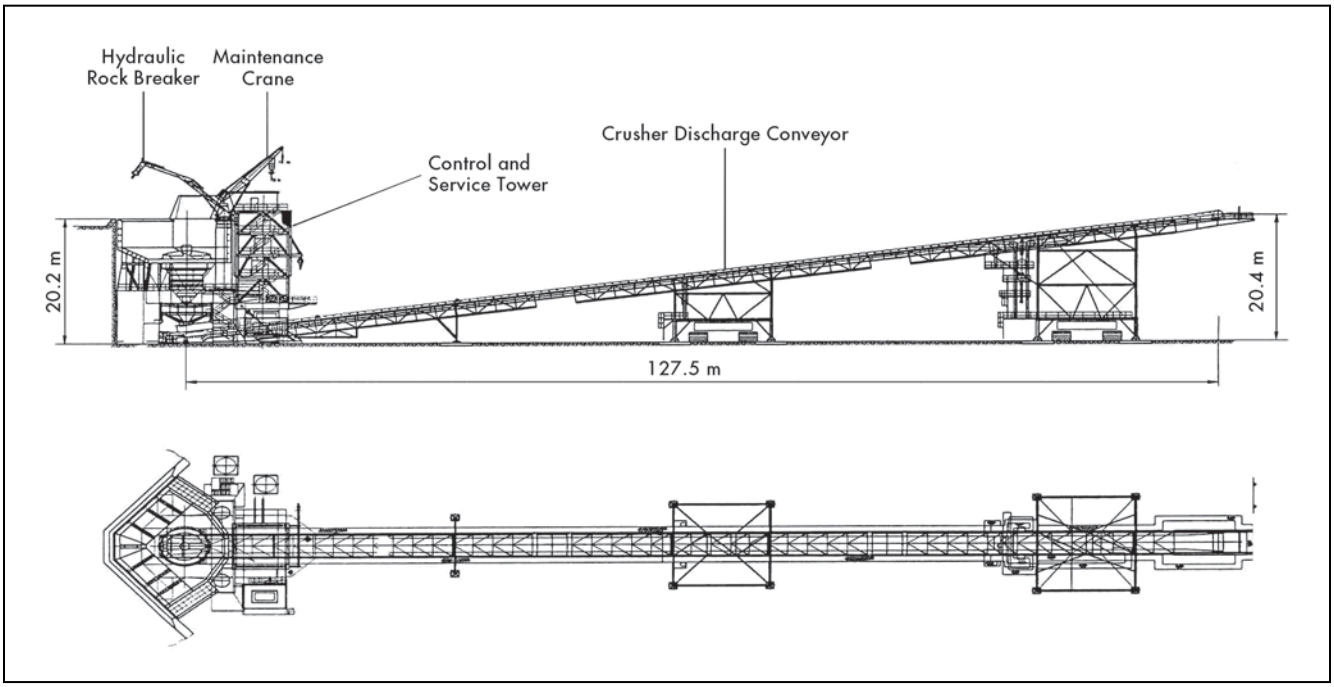

Figure 10.5-1 Typical IPCC semimobile crushing plant layout

noise at any crusher station must be kept to a minimum. The conveyor should have vehicle access along at least one side.

Maintenance Requirements

Keeping maintenance requirements to a minimum helps achieve higher overall operating availability. Scheduled preventive maintenance at the crusher station and conveyor involves a number of elements, including

- Crusher wear parts,
- Feeder wear parts,
- Conveyor skirting and adjustment,
- Oil and lubrication,
- Conveyor belt repair,
- Electrical and instrumentation adjustments, and
- Visual inspections.

Provisions must be made for either jib or mobile cranes to remove and replace crusher wear parts, concaves, and the main shaft. Trolleys, jib cranes, and pull-points should be designed to facilitate equipment maintenance. Oil and lubrication systems should be centralized and designed for easy, automatic changes, with provisions for well-ventilated, centralized lubrication rooms, where possible.

PROCESS DESIGN CRITERIA

Typically, the information required to develop IPCC system design criteria include

- Geographic data,
- Climatic data,
- Process design data (process description, ore characteristics, etc.),
- Civil design criteria,
- Structural design criteria,
- Mechanical design criteria, and
- Electrical/instrumentation design criteria.

PLANT LAYOUT AND DESIGN

A carefully designed layout can save significant investment dollars, because structures and infrastructure (rather than major equipment items) represent the major cost element of the crushing plant (Figure 10.5-1). The mine planner and plant designer must prepare a layout that meets the needs of the design criteria and flow sheet, as well as selecting the equipment in the most economic possible configuration. It is important to keep structural costs down, to design for ease of maintenance and operation, and to combine best practices with advances in fabrication and erection. Most in-pit crushing plants are designed by crusher manufacturers, so it is imperative that the designer works closely with the selected equipment supplier. The manufacturer must remember that the production, process, economic, safety, and operational design needs come first.

Three-dimensional (3-D) computer-aided design (CAD) systems tied up with the mine planning 3-D modeling assists greatly in being able to visualize the finished and phased effects of any IPCC-installed materials handling transportation system.

PRIMARY CRUSHER SELECTION

The crusher is the key to success with any IPCC system. The in-pit crushing plant can be provided with almost any type of primary rock crusher. Selection of the primary rock crusher is based on three fundamental considerations:

1. Type and characteristics of the ore, which determine the type of crusher required
2. Plant capacity, which determines the size of the crusher
3. Plant layout and design

As the term *primary* implies, primary crushers are used in the first stage of any size reduction cycle. The gyratory crusher is the workhorse of the hard-rock crushing industry. Primary

Table 10.5-2 Primary crusher capacity

Crusher	1,500 stph	3,000 stph	6,000 stph	9,000 stph	12,000 stph	15,000 stph
Gyratory						
Double-toggle jaw						
Single-toggle jaw						
Double-roll						
Low-speed sizer						
Hybrid roll/sizer						
Impactor						
Hammermill						
Feeder breaker						

gyratory crushers are capable of taking blasted ROM and run-of-quarry feed in size up to 1,500 mm (60 in.) and producing products ranging in size from 50 to 300+ mm (2 to 12+ in.). This type of crusher can sustain production at rates between 318 to 9,072 t/h (350 to 10,000 stph), depending on the feed characteristics, crusher setting, and crusher size of the application.

The primary gyratory crusher is only one of a family of primary crushers that include the following:

- Gyratory crusher
- Gyratory jaw
- Double-toggle (DT) jaw crusher
- Single-toggle (ST) jaw crusher
- High-speed double-roll
- Low-speed sizer
- Hybrid roll sizer
- Impactor
- Single-shaft hammermill
- Double-shaft hammermill
- Feeder breaker

All primary crushers can be used in mobile plants. Impactors and hammermills are compact and generate a high reduction ratio. The high speed of the machines requires special attention to dynamic forces.

The jaw crushers are good for small-tonnage plants, and the ST jaw crusher has the advantage of being lighter in weight than the DT jaw crusher. Large-capacity jaw crushers result in large crushing plants.

Double-roll crushers are large machines in which the two rolls rotate inward so the out-of-balance forces are minimized. These machines are limited to relatively soft and nonabrasive materials.

However, since the return on investment for crushing and conveying systems in the mining industry is heavily dependent on both high capacity and the ability to handle hard and abrasive ores, the gyratory crusher has been the reducer of choice throughout the evolution of IPCC (Table 10.5-2).

PRIMARY CRUSHER TYPES FOR LARGE CAPACITY

Gyratory Crusher

Primary gyratory crushers (Figure 10.5-2) are typically furnished with radial feed openings of 1,065 mm (42 in.), 1,370 mm (54 in.), and 1,500 mm (60 in.). The largest radial feed opening of any primary gyratory crusher operating in the world is a 1,800-mm (72-in.) Traylor crusher. The capacity of even the smallest standard unit, the 1,065-mm (42-in.) gyratory crusher, can be sustained at about 2,500 t/h (2,572 stph). The 1,500-mm (60-in.) gyratory crusher can crush up to 10,000 t/h (11,000 stph), depending on the crusher design, ore characteristics, and desired product size.

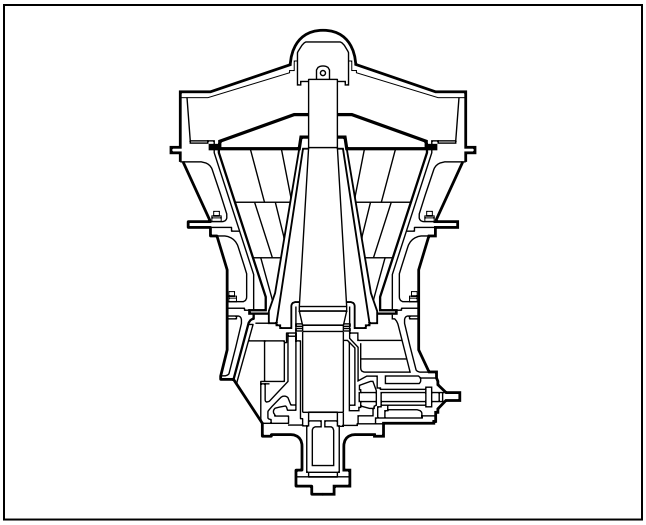

Figure 10.5-2 Gyratory crusher

The first 1,500-mm (60-in.) gyratory crusher was manufactured by the Traylor Engineering & Manufacturing Company in 1919. At that time, the largest haulage trucks available had a 34-t (35-ton) payload, and shovels were manufactured to match. In 2009, the operator had at his disposal 90-yd^3 shovels and haulage trucks with a 363-t (400-ton) payload. Truck manufacturers have advised that 500-ton trucks are a possibility. Tires are the only limitation. The result of larger haulage trucks is an obvious mismatch between the top size of ore fed to the crusher and the largest radial feed opening available. The consequence of this mismatch is the bridging of two or more large lumps that have been fed to the crusher at the same time. Bridging has been partially compensated for by the use of hydraulic rock breakers installed on pedestal-mounted booms. In some installations, the hydraulic rock breaker is employed up to one-fifth of the total time the crusher is in operation with 20% spent breaking oversize rock and 80% spent breaking bridges. Bridging has also been mitigated by improvements in blasting technology.

The largest standard size gyratory crusher, the 1,500 × 2,970 mm (60 × 117 in.), typically operates at the upper limit of the capacity range. These machines have been optimized. With improvements in gearing, bushing materials, and lubrication systems, the speed has been increased. Greater horsepower is available from the manufacturers. The crushing chambers have been optimized with CAD. Larger-size

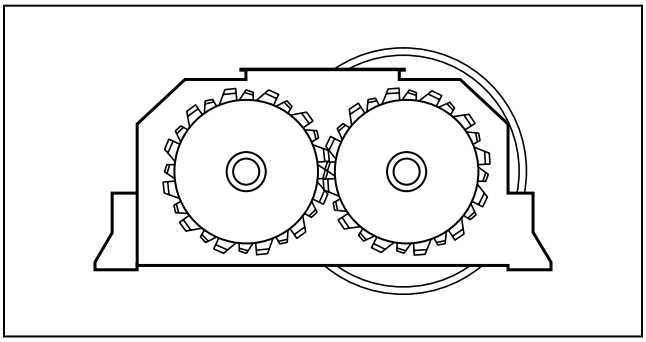

Figure 10.5-3 Double-roll crusher

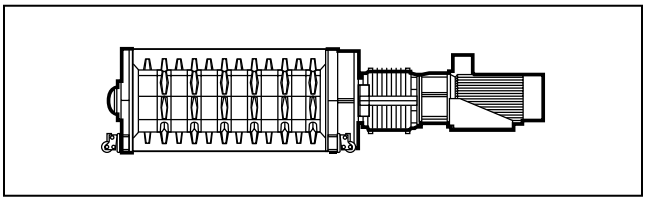

Figure 10.5-4 Low-speed sizer

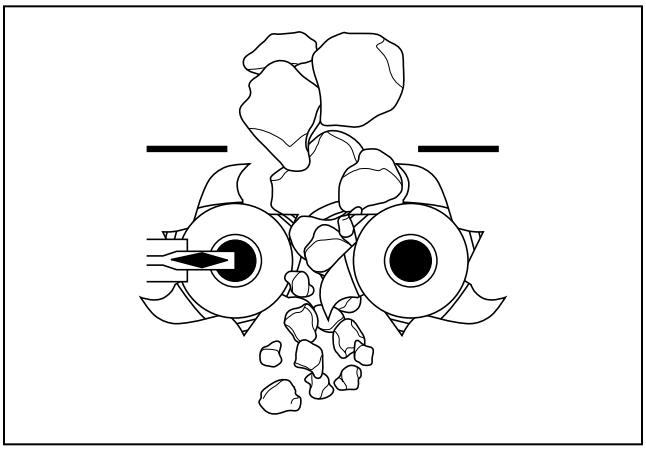

Figure 10.5-5 Hybrid roll sizer

crushers are available, and the next size will most likely be a 1,800 × 3,250 mm (72 × 128 in.). However, the increased capacity of between 7% and 10% does not seem to provide a cost-effective benefit because of the increase in weight, height, and cost for both the crusher and the auxiliary equipment to support the crusher.

Double-Roll Crushers

In the past few years, the high-speed double-roll crusher (Figure 10.5-3) has been gaining respect in many circles, primarily oil sands and overburden.

The capacity of the double-roll crusher can exceed 14,000 t/h (15,432 stph) because of its size and method of processing the ore. At this capacity, the product size is generally –400 mm (–16 in.), which is acceptable for oil sands because secondary processing and ablation during slurry transport will reduce the lump to a mixture of sand, bitumen, clay, and water. This degree of size reduction is also acceptable for waste handling, as the ore needs to be crushed to a size suitable for conveyor transport.

The double-roll crusher is suitable for ore that is wet, sticky, compactable, or has a high silica content—indeed every set of properties that causes problems for just about every other type of crusher.

The wear elements are the crusher teeth, which can be easily replaced. In fact, the double-roll crusher operates best with a mixture of new and worn teeth, so a "worn" crusher is still a performing crusher.

The double-roll crusher is capable of processing massive lumps which, in oil sands, can exceed 7 m (23 ft) in one dimension. The shovel operators try to mine selectively, but in the dead of winter, the steam rising from the working face usually obscures the operator's view of the face, especially at night, and, as a result, selective mining is not very accurate.

Low-Speed Sizers

In the early 1980s, low-speed sizers were introduced (Figure 10.5-4). This represented one of the only fundamental developments in primary crushers in three-quarters of a century.

The main technical feature of the low-speed sizer, which can broadly be considered a variety of toothed roll, is that it exploits the fact that the ratio of compressive strength to tensile and shear strength in the majority of rocks is approximately 10:1. The low-speed sizer breaks the rock in tension or in shear by snapping and chopping action rather than in compression as conventional crushers do.

Additionally, the positioning of the teeth on the rolls allows undersize to fall directly through the machine, resulting in high throughputs at very low rotational speeds, which means greatly reduced wear, energy savings, better control of discharge size in three dimensions, and greatly reduced fines.

Low-speed sizers are used for soft- to medium-hard nonabrasive, sticky types of materials up to 200 MPa (29,000 psi; for example, coal, oil sands, medium hard limestone, kimberlite, gypsum, clay, shale, schist, and gold ore. These sizers are also used to crush bauxite and overburden where the host rock is relatively soft and the inclusions range up to 400 MPa (60,000 psi). The low-speed sizer is not particularly sensitive to abrasion if the reduction ratio is low.

Low-speed sizers can be fabricated so that the frame can accommodate material larger than 2,000 mm (70 in.) as truck capacities continue to grow and ROM feed continues to increase.

Hybrid Roll Sizer

The hybrid roll sizer (Figure 10.5-5) features a compact design as a result of the roll diameter made possible by the aggressive tooth geometry. Thus, minimum space requirements and the distinctive advantages of a classic double-roll crusher, such as hydraulic gap adjustment and overload protection, are combined in one machine. Furthermore, the hybrid is able to compensate peaks with energy storage in the flywheels.

The advantages of a hybrid roll sizer are

- Compact design,
- Minimum generation of unusable fine material,
- High throughput capacities up to 11,000 t/h (12,125 stph),
- Hydraulic gap adjustment system,
- Overload protection, and
- Processing of wet and sticky materials.

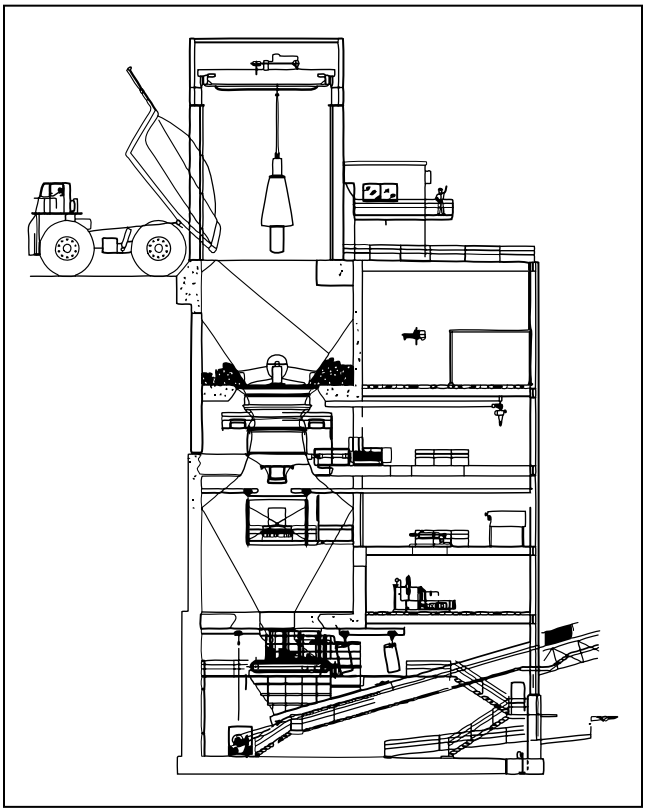

Figure 10.5-6 Fixed crusher: stationary rim-mounted crushing plant installed in a concrete structure

The disadvantages are

- Unsuitable for very hard and extremely hard materials,
- Low reduction ratio, and
- Not economic for low tonnages unless the material is difficult to handle.

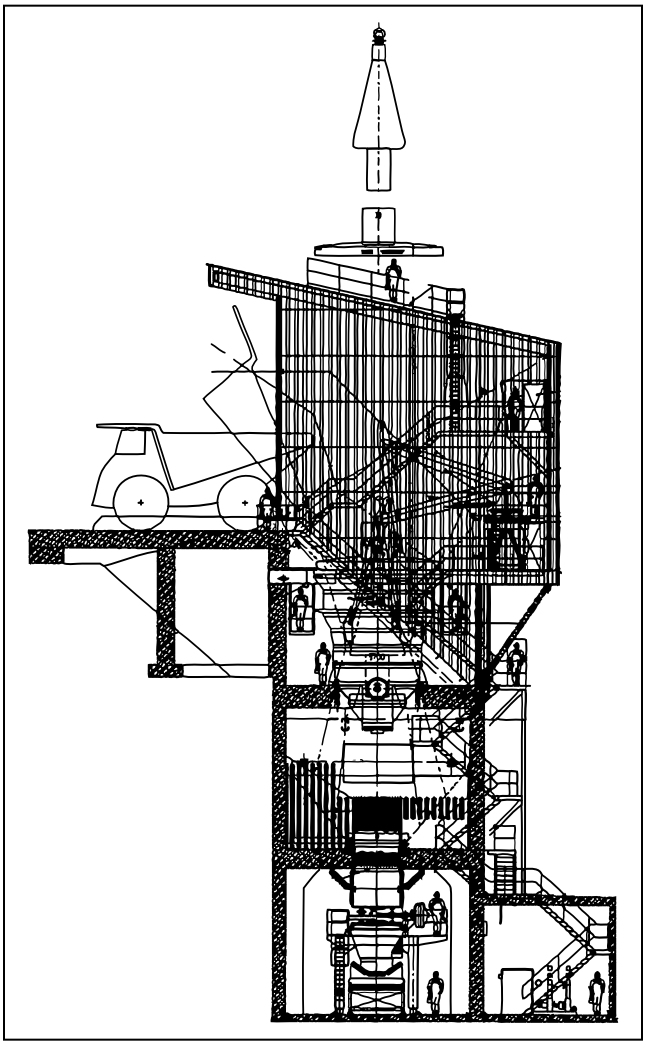

Figure 10.5-7 Rim-mounted structural steel station

TYPES OF IN-PIT CRUSHING SYSTEMS

The in-pit crushing systems developed and operated to date have varying degrees of mobility ranging from fully mobile units to permanently fixed plants, which resemble traditional in-ground crushing plants. The crushing plants can be stationary (mounted on concrete foundations) or semimobile style, supported on steel pontoon feet. As the mining operation progresses, the semimobile crushing plants can be relocated within the mine using multiwheeled trailers or transport crawlers. Typically, shovels load the ROM ore on to heavy-duty haul trucks that transport the ore to the crushing plant, thus relocating the crushing plant as the mine expands and reducing the distance that the large trucks need to haul the ore from the working face. The following terms are presented to help distinguish the range of mobility within the generic term of *in-pit crushing systems*.

Fixed Crushers: Stationary In-Ground or Rim-Mounted Crushing Plants

The stationary in-ground crusher is installed in a concrete structure below grade. The crusher is usually located external to the pit and is never moved.

The stationary rim-mounted crusher is typically installed in a concrete structure, which is part of or attached to the bench wing wall (Figure 10.5-6). A portion or all of the structure may be fabricated steel and could be disassembled and moved (Figure 10.5-7). The stationary rim-mounted crusher is usually installed for 15 or more years.

Semifixed Crushing Plant

The semifixed crusher is mounted on a steel structure that rests on a concrete foundation (Figure 10.5-8). The structure houses some or all of the auxiliary equipment and subsystems to operate the crusher. The crusher is located at or near the edge of the pit. Some degree of disassembly is required to move the structure. The planned frequency of moves for a semifixed crusher is no less than 5 to 10 years.

Semimobile Indirect Feed Crushing Plant

The semimobile indirect feed crushing plant is an all-steel structure (Figure 10.5-9). The plant typically consists of three major modules: the apron feeder, the crushing plant with the crusher, and a separate tower that houses the control room. The control room module is bolted to the crusher module when the plant is moved. The civil work required for retaining walls is relatively simple and offsets the cost of the apron feeder. However, the work is massive because

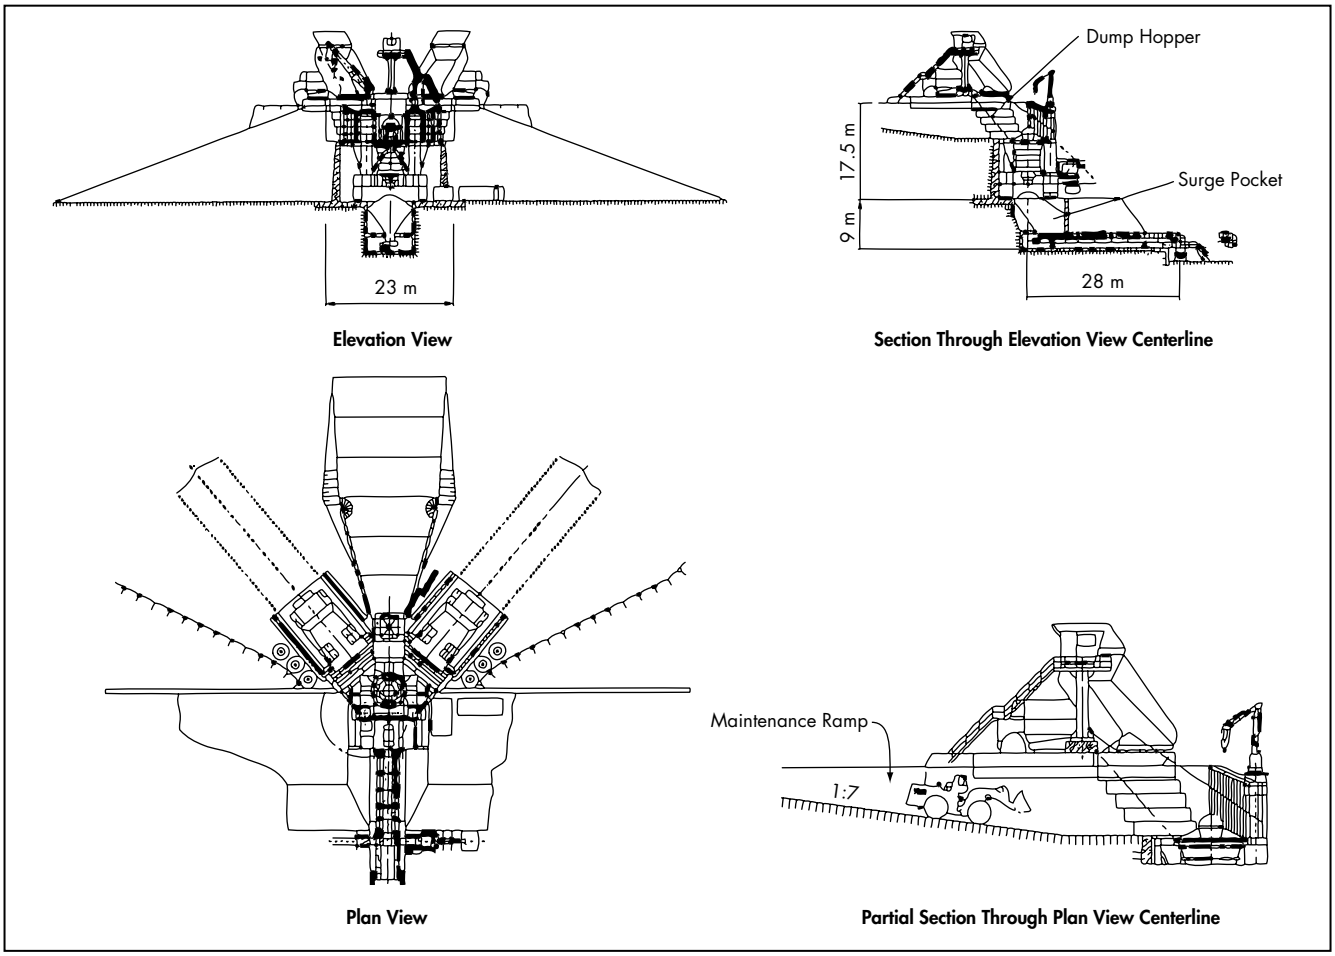

Figure 10.5-8 Semifixed crushing plant

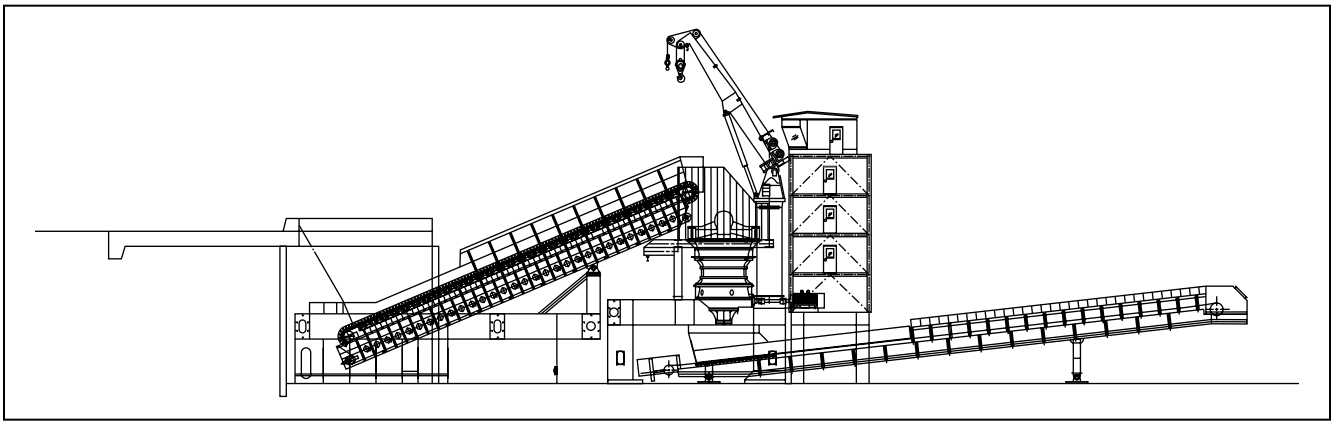

Figure 10.5-9 Semimobile indirect feed crushing plant

the structures, often in excess of 25 m (82 ft) in height, are required to support the load of the 400-ton trucks. The crusher is typically located near the centroid of the working portion of the mine to minimize truck haul distance. To allow for movement of the structure by commercially available transport equipment, bulkheads are built into the structure. The planned frequency of moves for a movable crusher is between 3 and 5 years.

Semimobile Direct-Dump Crushing Plant

The semimobile direct-dump crushing plant is mounted on a steel structure that houses all of the auxiliary equipment and subsystems to operate the crusher (Figure 10.5-10). The structure is self-supporting and rests on the mine floor, either with or without footers. The plant design allows for two or three dump points. To minimize truck haul distance, the crusher is typically located near the centroid of the working portion of

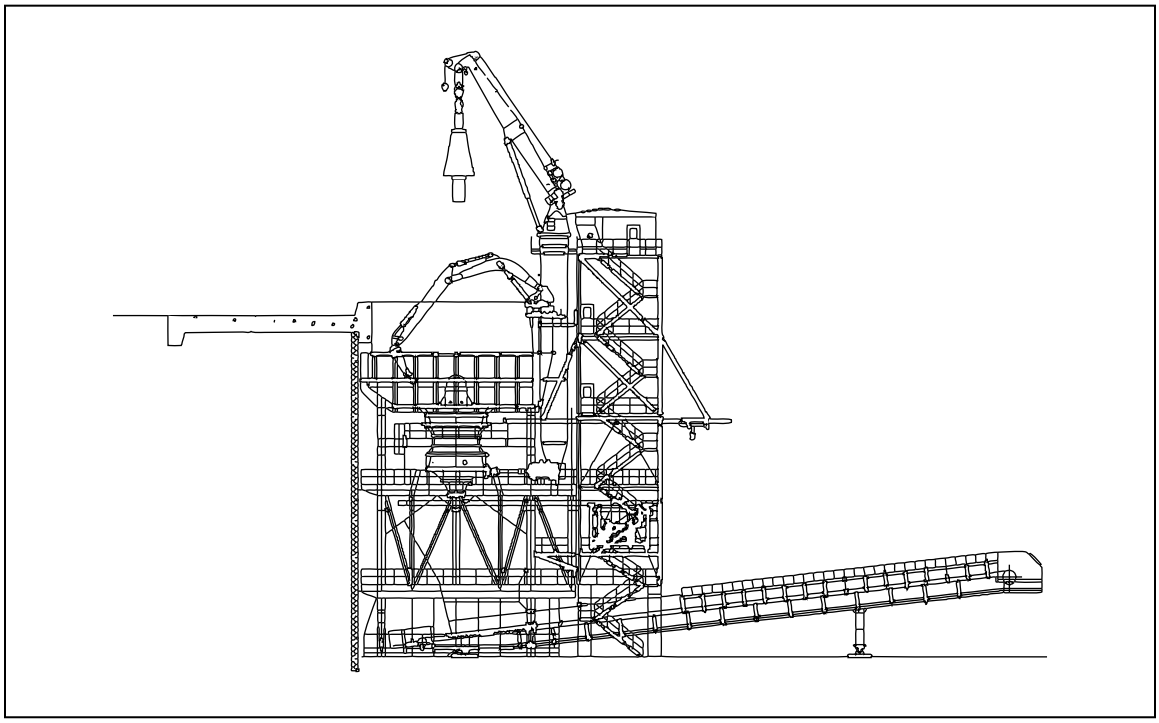

Figure 10.5-10 Semimobile direct-dump crushing plant

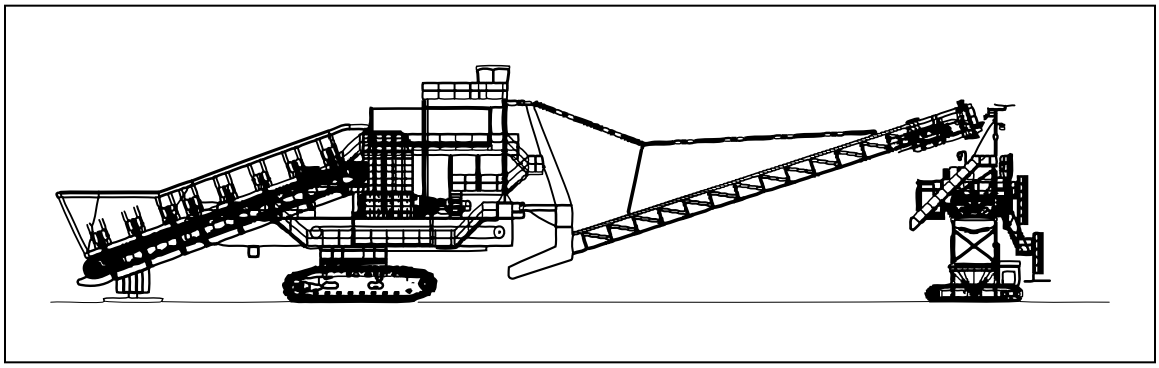

Figure 10.5-11 Fully mobile crushing plant

the mine. Bulkheads are built into the structure to allow for movement of the structure by commercially available transport equipment. The planned frequency of moves for a movable crusher is between 1 and 10 years.

Fully Mobile Crushing Plant

The fully mobile crusher is mounted on a steel platform and is self-propelled (Figure 10.5-11). The platform houses all auxiliary equipment and subsystems to operate the crusher and is self-supported and rests on the mine floor. To minimize truck or front-end loader haulage, the crusher is located at the working face. Wheels, crawlers, or pneumatic pads are integrated into the platform, and drive power to move the equipment is included on board. The planned frequency of moves for a fully mobile crusher is between 1 day and 1 week.

Fully Mobile Continuous Crushing System

The fully mobile in-pit continuous crushing system is mounted on a steel platform and is self-propelled (Figures 10.5-12 and 10.5-13). The platform houses the apron feeder, crusher, discharge conveyor, and all auxiliary equipment and subsystems to operate and propel the crushing plant. The feed hopper needs to accept ROM material that is dumped from shovels and/or draglines. The platform is self-supported and rests on the mine floor. The crusher is located at the working face for direct feed. Crawlers are integrated into the platform, and drive power to move the equipment is included on board. The plant moves in tandem with the shovel. The conveying system moves in tandem with the in-pit continuous crushing system.

OPERATION OF IPCC CRUSHING PLANTS

Fixed Rim-Mounted Crushers

Fixed rim-mounted crushers are increasingly incorporating traditional direct-dump arrangements. With these designs, the hopper above the gyratory crusher is designed to hold 1.5 to 2 times the capacity of the largest truck that will dump into the crusher during operation. Discharge surge bins have

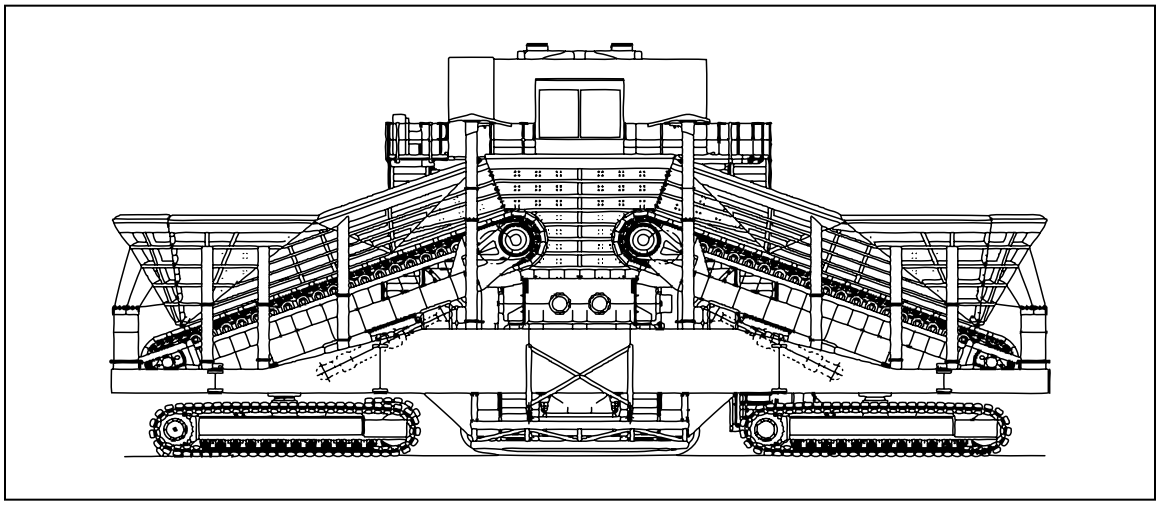

Figure 10.5-12 Fully mobile continuous crushing plant—triple track

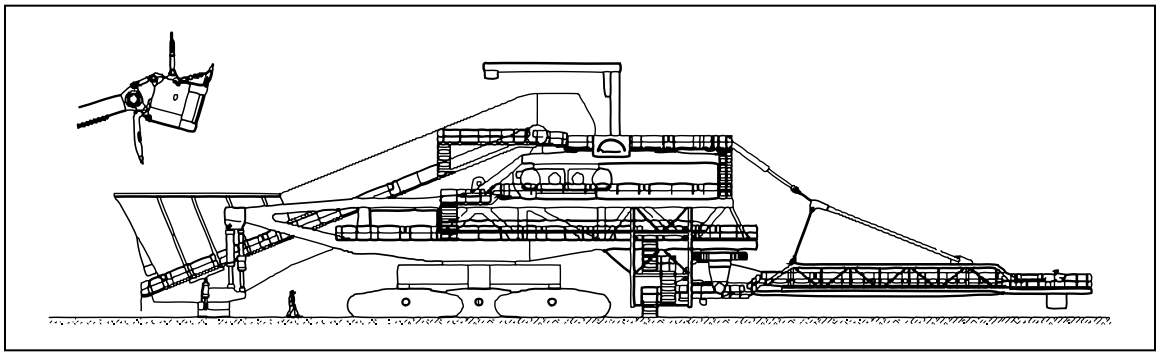

Figure 10.5-13 Fully mobile continuous crushing plant—dual crawler

traditionally been sized slightly larger than the feed hopper to accommodate any unusual fines condition. In order to reduce overall height, and thus capital costs, discharge apron feeders have been replaced by impact-resistant discharge belt conveyors. The trend away from discharge apron feeders to discharge belt conveyors has allowed for wider belts with greater capacity. In conjunction with high-capacity discharge belt conveyors, the typical capacity of the surge bin below the crusher has decreased dramatically.

Even with removing the discharge apron feeder and reducing surge bin capacity, direct-dump arrangements result in tall structures. With rim-mounted in-pit crushers, this tall overall height requires wing walls to support and reinforce the structure. Traditional fixed crushers are installed below grade and fed at grade. Recent in-pit installations such as at the Cripple Creek and Victor gold mine in Colorado (United States), which is an all-concrete structure, and Buxton Lime in Buxton, England, which is an all-steel structure, are partially below and above grade to accommodate a single bench height. The dump pockets can be arranged for one, two, or three dump positions. With a two-position dump pocket design, the two dump points are set 90° apart from each other. The spider orientation is either in-line with the centerline between the two dump positions or at 90° to the centerline between the two dump positions. Either position is mechanically satisfactory to the gyratory crusher. With a three-position dump pocket design, it is universally accepted that the spider is orientated in-line with the centerline of the central dump position.

Advantages of fixed rim-mounted crushers with direct feed arrangements include

- Traditional plants with simple configurations easily adapted for in-pit crushers,
- Reduced maintenance costs due to no longer needing an apron feeder,
- High crushing chamber throughput,
- Reduced capital costs due to limited degree of mobility,
- Reduced maintenance costs due to a greater amount of crushing in the upper portion of the chamber and decreased localized abrasive wear, and
- Greater capacity and finer product size due to the weight of the ore column above the crusher.

Disadvantages of fixed rim-mounted crushers include the following:

- Poured concrete design cannot be moved.
- Structural steel designs are typically not designed to be moved. If the structure were designed to be moved, an extensive substructure is required to support the plant for moving.
- Overall height is greater because of the higher dump point bench level.
- Greater height means extensive retaining wall structures.

Semifixed Crushers

Semifixed crushers are the mining industry's attempt to incorporate the advantages of limited mobility while eliminating the need for an extremely expensive inclined apron feeder. Semifixed plants have incorporated both indirect feed using a horizontal apron feeder as well as various forms of direct-dump arrangements. Due to the high capital and maintenance costs of apron feeders as well as the availability of high payload haulage trucks capable of sustaining high crushing capacities, the majority of semifixed crushing plants installed since about 2000 have incorporated direct-dump arrangements.

In a semifixed crushing plant, a portion of the station is fabricated from steel. The direct-dump feed hopper, crusher support structure, and control rooms are almost always steel fabricated. Differences in design are related to the degree where the lower portion of the plant is concrete or steel.

Typically, only the crusher and part (or all) of the dump hopper are mounted on a steel base, while the remainder of the station is of civil construction. The steel portion is moved by crawler transporter as self-propelled modular transporters (SPMTs). The station is moved to a new civil structure and the old station destroyed.

Advantages of semifixed crushers with direct feed arrangements include

- Traditional plants with simple configurations easily adapted for in-pit crushers;
- Reduced maintenance costs due to no longer needing an apron feeder;
- High crushing chamber throughput;
- Reduced capital costs due to limited degree of mobility;
- Increased long-term flexibility due to the limited mobility, which allows for future changes and modifications;
- Reduced maintenance cost due to greater amount of crushing in the upper portion of the chamber and decreased localized abrasive wear; and
- Greater capacity and finer product size due to the weight of the ore column.

Disadvantages of semifixed crushers with either indirect or direct feed arrangements include

- Only the crusher and part or all of the hopper are mounted on a steel base, and
- The balance of the station is civil construction. Greater overall height is due to the higher dump point bench level.

Semimobile Indirect Feed Crushing Station

The semimobile indirect feed in-pit crushing stations utilize an apron feeder to lift ore into the feed opening of the primary crusher. The use of an apron feeder allows for the crusher station to either operate at grade or to utilize a single low bench. The semimobile indirect feed in-pit crushing station is typically designed and built in three or more modules: apron feeder, primary crusher, and the control room. Some semimobile controlled feed in-pit crushing stations have a separate lubrication and hydraulic system module located adjacent to the main structure. New environmental controls for dust collection and/or dust suppression may add a dust collection module as a separate item. The control room is separate from the crusher structure to reduce crusher-initiated vibration in the control and electrical rooms. The design usually incorporates a feature that allows for the control room to be attached to the crusher module for moving.

Additionally, the use of a truck dump hopper at the apron feeder creates a large surge pocket between the mine and the crusher, making the flow of ore through the crusher more uniform and continuous.

Advantages of indirect feed using an apron feeder include

- Low bench height for dumping ore,
- Reduced truck queue time due to the surge pocket,
- Improved control of oversize material fed to the crusher, and
- Reduced crusher downtime due to bridging of large lumps.

Disadvantages of indirect feed using an apron feeder include

- Increased total capital cost,
- Increased maintenance costs associated with adding an apron feeder, and
- Increased maintenance costs associated with the crusher from using an apron feeder. Due to the nature of the feeder, ore tends to impinge upon small areas within the crushing chamber, causing premature localized wear of the concaves and mantles. The use of alloy steels has mitigated the problem, although the cost of alloy steel components remains higher than manganese steel, and availability is limited.

Semimobile Direct-Dump Crushing Plant

The semimobile direct-dump crushing plant has been the design of choice for IPCC since about 2000. This design incorporates all of the features of the traditional in-ground crushing station. The crushing plant incorporates the feed hopper, the crusher, and the lubrication and hydraulic systems to support the crusher, as well as all maintenance equipment, including a rock breaker and usually a crane with capacity to lift the mainshaft assembly with the oversize mantle. An operator's control room and electrical rooms are also included. Above the traditional gyratory crusher station with two dump points and an apron feeder discharge is the hopper, which can hold two times the capacity of the largest truck that will dump into the crusher during operation. For an operation with 400-ton trucks, this translates into 726-t (800-st) live ore capacity. Traditional design for the surge pocket under the crusher of a gyratory crusher plant would be 2.5 times the largest truck or 907-t (1,000-st) capacity to prevent backup of ore into the crusher chamber in case of an unusual fines condition. In order to reduce overall height, and thus capital costs, discharge apron feeders have been replaced by impact-resistant higher-speed discharge belt conveyors. The trend away from discharge apron feeders to discharge belt conveyors has allowed for wider belts with greater capacity. In conjunction with high-capacity discharge belt conveyors, the typical capacity of the surge bin below the crusher has decreased dramatically. Because the crusher discharge belt has a higher capacity than the haulage belt, a surge bin is usually added to the circuit.

The structure is self-supporting and rests on the mine floor either with or without footers. The plant design allows for two or three dump points. The crusher is typically located near the centroid of the working portion of the mine to minimize truck haul distance. Bulkheads are built into the structure to allow for movement of the structure by commercially available transport equipment. The planned frequency of moves for a movable crusher is between 5 and 10 years.

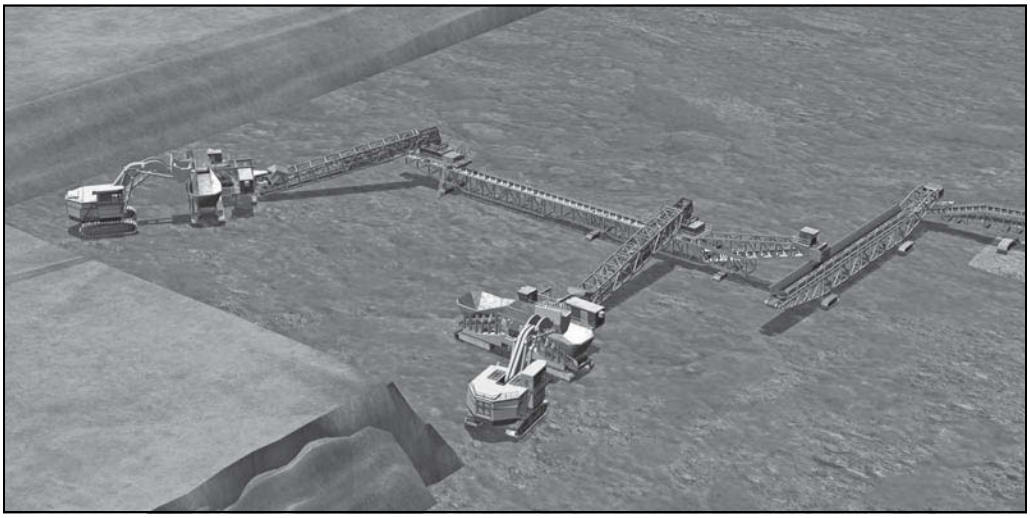

Figure 10.5-14 Fully mobile crushing plant

Advantages of semimobile direct feed arrangements include

- Traditional plant configuration,
- Reduced maintenance costs due to deletion of the apron feeder,
- High crushing chamber throughput,
- Reduced capital costs due to limited degree of mobility,
- Increased long-term flexibility due to the ability to move the complete station intact,
- Reduced maintenance costs due to greater amount of crushing in the upper portion of the chamber and decreased localized abrasive wear when compared to indirect feed designs, and
- Greater capacity and finer product size due to the weight of the ore column.

Disadvantages of semimobile crushers with either indirect or direct feed arrangements include

- Large and heavy structure requiring large transporters for moving; and
- Greater overall height due to the higher dump point bench level, which requires extensive bench-retaining walls.

Fully Mobile Crushers

The fully mobile crusher is mounted on a steel platform and is self-propelled. Wheels, crawlers, or pneumatic pads are integrated into the platform to move the station. The platform, which is self-supported and rests on the mine floor, houses all auxiliary equipment and subsystems to operate the crusher. To minimize truck or front-end-loader haulage, the crusher is located at the working face. The planned frequency of moves for a fully mobile crusher is between 1 day and 1 week.

The majority of fully mobile in-pit crushing stations utilize an apron feeder to lift ore into the feed opening of the primary crusher. The use of an apron feeder allows for the crusher station to operate at grade and move without the need for employing SPMTs. For hard rock, including aggregate and cement, the capacity has been limited to about 2,500 t/h (2,756 stph) with gyratory crushers. The 1,370 × 1,880 mm (54 × 74 in.) gyratory crusher is the largest unit used for this application.

Mobile crushing plants are favorably installed under the following conditions:

- Clear and undisturbed geological situation (almost even and horizontal coal and waste rock layers)
- Straight benches as long as possible for shiftable face conveyor installation
- Long-term mine planning for the design of face conveyors, collection conveyors at bench end (side slopes), and connecting conveyors to waste dumps or processing plants

Advantages of fully mobile crushers include

- Elimination of truck transport,
- Reduced number of personnel,
- Avoidance of high truck maintenance costs,
- Reduction of mine traffic, and
- Increase in overall safety.

Disadvantages of fully mobile crushers include

- Increased total capital costs,
- Increased maintenance costs associated with adding an apron feeder, and
- Increased maintenance costs associated with the crusher from using an apron feeder. Due to the nature of the feeder, ore tends to impinge upon small areas within the crushing chamber, causing premature localized wear of the concaves and mantles. The use of alloy steels has mitigated the problem, although the cost of alloy steel components remains higher than manganese steel, and availability is limited.

Fully Mobile Continuous Crushing Systems

The fully mobile continuous crushing system includes the fully mobile crushing plant as one component of the system (Figure 10.5-14). The components of the system are the shovel or dragline, the fully mobile crushing plant, and the conveying system that transports the crushed material to the next operation in the flow sheet. For fully mobile continuous crushing systems handling overburden, the conveyors take the material to a dump. For coal and oil sands, the material is transported to the processing plant.

The fully mobile crushing plant takes the material directly from the shovel or dragline. The full bucket load is discharged into the hopper of the fully mobile crushing plant. An apron feeder elevates the material and discharges it into the crusher, either a low-speed sizer, a high-speed double-roll crusher, or a hybrid roll sizer. The product from the crusher is transported to the overland conveyor system. All parts of the system are designed to work continuously. This requirement has led to the development of fully mobile crushing plants that have the ability to continue operation while moving. Older systems in oil sands in Canada and coal in Australia had to stop operations, lift the apron feeder off the ground, move to a new location, and set the apron feeder down before resuming operation.

Mobile crushing plants are able to work at one, two, or three benches with only one shiftable bench conveyor (multibench operation). An important design criterion for this effective technology is the transfer equipment to the bench conveyor, which has to bridge not only distances in length but also in height (crusher discharge conveyor, mobile transfer conveyors, and mobile transfer bridges). Ramps in the working face or in the side slope are necessary for equipment relocation from one bench to the other.

IPCC PROCESS CONTROL

Growing recognition exists in the industry of the effect that mining practices have on the efficiency of mineral processing operations. Among numerous variables, size distribution of ore is widely accepted as having a significant effect on the throughput and recovery achieved in mineral processing. Using available digital imaging technology, improved process monitoring and modeling provide the opportunity not only to identify these variables but also to monitor and control them throughout the entire mining process in real time.

The majority of mine designs employ crushers to reduce the size of the material originating from the mine. The primary crusher is the link between the chemical comminution (blasting) and the beginning of the mechanical comminution circuit (crushing and milling). As such, an in-pit crusher is not only a key point in the process to apply a measurement monitor but also a key resource to be optimized.

Feed to the primary crusher from the mine can be measured and monitored to establish blasting performance. Size information associated with each haul truck can be traced back to the location in the mine plan and used to help design future blasting practices. The crusher product is usually the beginning of the mineral processing circuit that involves more energy consumption to further reduce fragment size. In the short term, the crusher's performance is the responsibility of the crusher operator who, through the use of digital imaging, now has a record of the quality of the crusher product size and can make adjustments to the crusher to keep the product in specification, as required by the design, of the remainder of the comminution circuit. In the long term, archives of size trends of crusher feed and product as related to other key performance indicators, such as blast fragmentation, crusher/mill throughput, crusher reduction ratios, Bond work index, and energy consumption and efficiency, optimize management-level decisions. Opportunities for optimization include how to tailor blasting to feed the stationary mechanical comminution circuit, how to load the crusher, and how to establish better proactive maintenance of the crusher, as well as keeping tighter specifications on the feed and products of the various stages of comminution.

By applying digital imagery technology, a technology widely used in numerous other manufacturing industries, new innovative solutions are available to the mining industry. Applying imaging technology can generate volumes of size information, which were not previously possible, for use in long-term studies, as well as in short-term process control to create long-term operating savings as compared to manual sizing methods or, worse yet, no measurement at all. An engineer with more than 30 years of mining experience was quoted about image analysis: "At our mine we utilize digital image analysis systems to provide quality, quantitative fragmentation information on our blasting and integrate the fragmentation information into our operations database as a quality control mechanism within our ongoing continuous improvement program. An important step to controlling costs is controlling your process. Basically, any company that has a product that requires control of particle size and is concerned with profitability needs this valuable information."

CONCLUSION

IPCC systems with primary gyratory crushers have been the answer to escalating energy and labor costs from 1980 to the present and have the potential to continue to substantially increase the profitability of open-pit mining. The type and configuration for virtually any site-specific application have been designed and built by the world's leading manufacturers and have operated for sufficiently long periods of time to prove their viability.

As evidenced by recent installations such as Collahuasi in Chile and Freeport-McMoRan in Iran Jaya, Indonesia, which operate above 8,500 t/h (9,370 stph), there is a definite trend toward increased capacity for large primary gyratory crusher installations. Similarly, there has been a steady increase in the size of widely available haulage trucks during the same period, from 150 to 363 t (165 to 400 st). In contrast, the radial feed opening of the primary gyratory crusher has not increased since the first Traylor 1,500-mm (60-in.) crusher was built in 1919.

In-pit crushing stations have decreased in mobility from the fully mobile and movable designs dating from 1982 to 1985 to the semifixed and fixed rim-mounted stationary designs of 1998–2001. For example, the 1,370-mm (54-in.) movable indirect feed crusher at Minera Escondida in Chile was built in 1990. When the company installed a 1,500-mm (60-in.) crusher in 1995, a semimobile direct-dump design was chosen. Similarly, the 1,500-mm (60-in.) movable indirect crushers at Codelco's Chuquicamata mine in Chile dating from 1984 have been rebuilt, relocated, and reinstalled in new semifixed direct-dump installations.

The 90-yd^3 shovel and 400-ton haulage trucks have created a gross mismatch between feed size and feed opening with the primary gyratory crusher; a single bucket load weighs more than the total volume of ore that can be held within the largest primary gyratory crusher currently in operation. Further, a single truckload weighs three times the total weight of the common 1,065-mm (42-in.) primary gyratory crusher. It is physically possible for a shovel dipper to pick up a single rock 2,540 mm (100 in.) in diameter and deposit it into a crusher with a 1,065-mm (42-in.) radial feed opening.

Change is required in the comminution flow from fragmentation in the pit to size reduction in IPCC. The top size of ROM feed to the IPCC must be controlled, or else the industry needs to consider alternative crushing technologies

to compensate for the lack of top-size control and yet still be in a position to take advantage of the economies of scale with shovels, trucks, and IPCC.

The fully mobile concept can conceivably be utilized in all mining operations, where a shovel can excavate the ore directly at the face, with or without blasting.

For large open-pit ore mines, which because of the deposit characteristics mainly extend downward, potential applications are currently being examined. Compared to coal and oil sand mines, which typically have relatively wide benches, the planning and realization of a fully mobile concept in an iron ore mine is complicated by the chiefly vertical alignment of the deposits. The fully mobile system, however, promises considerable savings in capital and operating costs, and it is likely that a solution can be realized.

THE FUTURE

The standard 400-ton truck of 2011 and beyond will likely continue to feed direct-dump semimobile crushing plants with the standard 1,500-mm (60-in.) gyratory crushers with 1,220-mm (48-in.) feed. There is the ever-present possibility that the ore will be fed to the crushing plants utilizing 1,800-mm (72-in.) primary gyratory crushers or some other types of primary crusher capable of size reduction of ROM material larger than 1,500 mm (60 in.). As ore grade decreases, efficiency will increase. Capacities will increase as a result of the larger crushers, while, at the same time, operators will take advantage of the larger crusher to obtain the economy of scale.

In the period 1980 to 2001, the type of in-pit crushing plant has evolved from fully mobile to semimobile to semifixed and, in many cases, to rim-mounted stationary structures. This progression from fully mobile in the 1970s and early 1980s to less mobility throughout the balance of 1980s and into the 21st century would seem like a step backward, considering that the original premise of in-pit crushing was to reduce the dependence on truck haulage. The evolution of the in-pit crushing plant cannot be considered by itself but must be viewed in relation to other changes in the size reduction of ROM ore in the pit, as well as delivering to the secondary stage of comminution:

- The platform for the development of IPCC in 1980 was the typical multibench mine.
- The premise was that the design of the plant should be one bench high—that is, 13.7 m (45 ft) for slope stability, economy of dump pocket design, and safety.
- Inserting an apron hopper between the dump pocket and the primary crusher could attain the dump height.
- In 1980, the perceived wisdom was that the crushing plant would be moved every time the pit became deeper by one or two benches.
- The typical mine would be in a position to move the crushing plant in less than 5 years.
- The plant move could be accomplished in as few as 3 days.
- The truck size in 1980 was 150 t (165 tons).

The development of the 240-ton, 300-ton, 350-ton truck, and now 400-ton haul truck has had a profound effect on the in-pit crushing plant designer and operation of in-pit crushing systems:

- With the larger trucks, the dump pocket was no longer a simple structure.
- The economies of scale and efficiencies of the new larger haul trucks negated the original parameters for moving the plant for every one or two benches of depth, or every few years of operation.
- The operational advantages for the use of apron feeders to elevate the ROM ore largely disappeared because of the cost of the dump pocket and the limited number of moves required in the life of the mine.
- Maintenance costs showed that the operating costs of the inclined apron feeder was equal to or more than the maintenance cost for the gyrator crusher.
- The capacity of the gyratory crusher was actually less when operating with an apron feeder than when directly dumped into the crusher.
- The product from the gyratory crusher is finer when directly dumped than when the apron feeder is fed.
- Concave and mantle costs are higher when the crusher is fed with the apron feeder.
- Average capacities increased from 3,000 to 9,000 t/h (3,300 to 9,920 stph).

The net effect of these changes was the progression that evolved into semimobile direct-dump crushing plant designs:

- Plant designs that make use of the slope topography of the pit
- Plant relocation of 3 to 5 years or more
- Capacities to 9,000 t/h (9,920 stph)
- Direct-dump formats
- 1,500-mm (60-in.) primary gyratory crushers

This mismatch in shovel size, truck size, and crusher size will likely manifest itself in fundamental changes to the primary crusher and/or improved and innovative crushing plant designs rather than the installation of the larger and heavier gyratory crushers.

Four of the nine types of primary crushers have achieved capacities of 10,000 t/h (11,000 stph):

1. Gyratory crushers have been operating at or near these capacities on copper oxide ores in Chile. A 10% increase in capacity would be achieved with the next size of primary crusher, ensuring continuous operation at the 10,000-t/h (11,000-stph) level. The question for mine planners: Is the 10% increase in capacity and in feed size from 1,220 × 0 to 1,500 × 0 mm (48 × 0 to 60 × 0 in.) economically justifiable? Gyratory crushers can crush material with compressive strengths as hard as 600 MPa (90,000 psi).
2. Low-speed sizers have attained capacities of 14,000 t/h (15,432 stph) operating in oil sands projects in Canada as well as in coalfields in Australia. Low-speed sizers are crushing material with compressive strengths of 200 MPa (27,500 psi) on a continuous basis.
3. Double-roll crushers have also attained capacities of 14,000 t/h (15,432 stph) operating in oil sands projects in Canada. The giant double-roll crushers are currently limited to compressive strengths of 100 MPa (14,500 psi).
4. Hybrid roll sizers are rated at capacities of 14,000 t/h (15,432 stph) and compressive strengths of 100 MPa (14,500 psi).

The designers of the IPCC crushing plants are constantly working toward shorter, more cost-effective facilities. The low-speed sizer, with its inherent low-profile design and proven

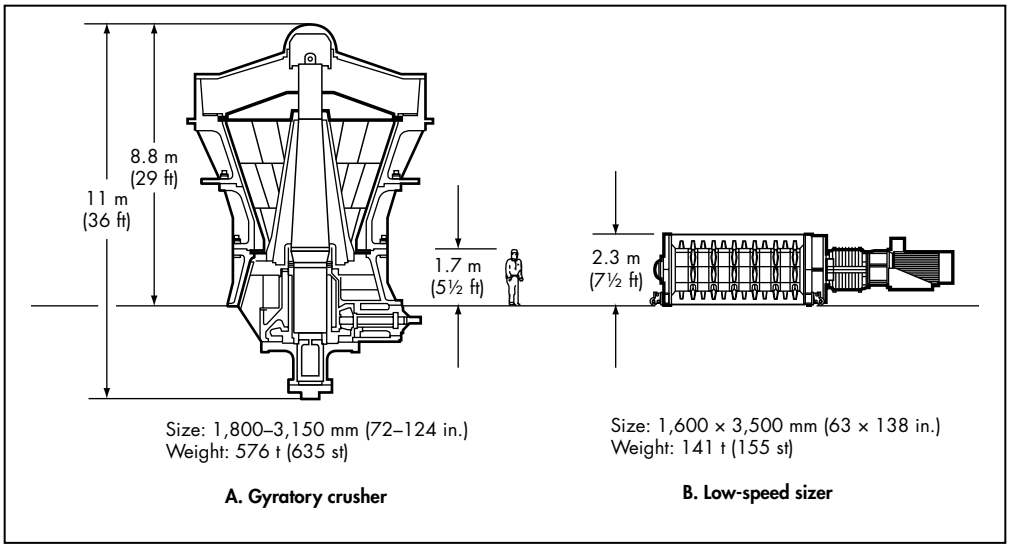

Figure 10.5-15 Comparison of gyratory crusher and low-speed sizer

high-capacity in crushing materials with characteristics similar to copper oxide, appears to provide the most realistic prospect of transfer of technology for future mining IPCC facilities.

A comparison of the next larger size gyratory with a low-speed sizer follows (Figure 10.5-15):

- ROM: 10,000 t/h (11,000 stph)
- Top size: 1,500 mm (60 in.)
- Product: 80% –23 cm (–9 in.)

There is an emerging market for high production, more than 9,000-t/h (9,920-stph) IPCC systems, especially for the removal of overburden. It no longer makes sense to use large volumes of assets such as trucks, tires, and labor to move a waste product that has no value. The ability to process high tonnages of soft overburden is made possible with the use of high-capacity crushers developed for soft material, usually less than 125 MPa (18,000 psi). These crushers have a more compact design and significantly lower capital cost than the typical hard-rock crusher. These soft-rock crushers, such as feeder breakers or sizers, make them perfect for overburden IPCC systems.

In the not too distant future, sizers will be crushing harder materials. Sizers are already crushing limestone with compressive strengths of 150 to 160 MPa (22,000 to 23,000 psi). The Lihir gold mine ore in Papua New Guinea is between 250 and 300 MPa (36,250 and 43,500 psi) and is crushed with a gyratory crusher. In addition to the hard ore, the mine also has wet, sticky volcanic ore that is crushed with a sizer. When the gyratory crusher is being maintained, the hard ore is run through the sizer. A bauxite mine in Australia crushes bauxite at the rate of 2,500 t/h (2,755 stph) with 100-MPa (14,500-psi) ore and 400-MPa (58,000-psi) dolerite inclusions. The history learned from these and other installations provides evidence that sizers will be able to handle overburden and ore with 50% of the feed 150–200 MPa (21,750–29,000 psi) material at rates of 16,000 t/h (17,640 stph).

CHAPTER 10.6

Design, Construction, and Maintenance of Haul Roads

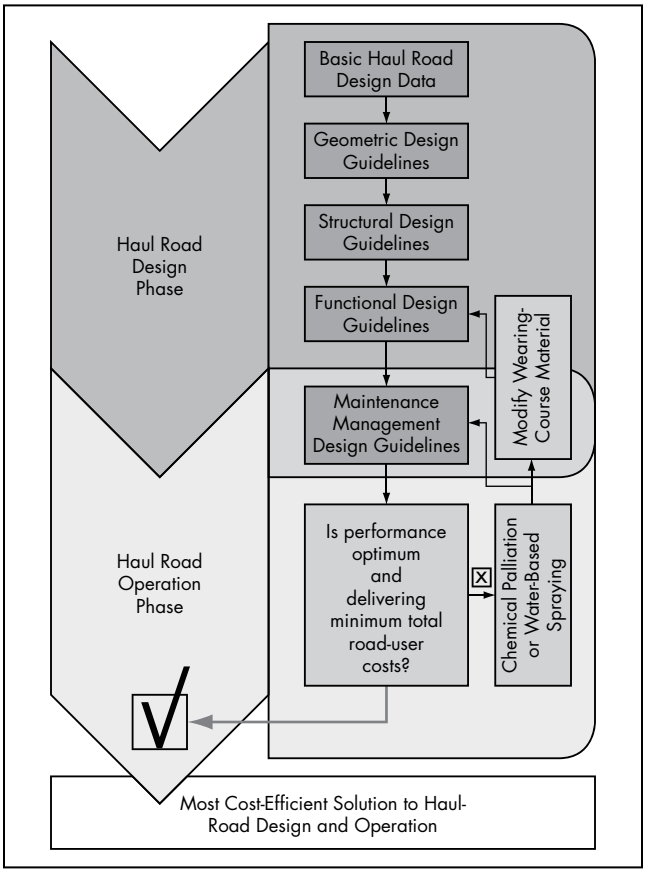
Roger J. Thompson

INTRODUCTION

In truck-based hauling systems, the mine haul road network is a critical and vital component of the production process. As such, underperformance of a haul road will have an immediate impact on mine productivity and costs. Operations safety, productivity, and equipment longevity are all dependent on well-designed, well-constructed, and well-maintained haul roads (Thompson and Visser 1999). The mine haul road is an asset and should, in conjunction with the haul trucks using the road, be optimally designed and its routine maintenance managed accordingly. An ad-hoc or empirical approach to haul-road design is generally unsatisfactory because it has the potential for overexpenditure, both on construction and operating costs, arising as the result of the overdesign and over-specification of short-term, low-traffic volume roads; and the underdesign, leading to excessive operating and road maintenance costs, and premature failure of longer-term, higher-volume roads.

Economies of scale and the increase in haul truck payload have led the ultra-class truck (220 t [metric tons] and larger) population to rise to more than 40% of all mine trucks used (Gilewicz 2006). With this increasing size, haul road performance can be compromised, resulting in excessive total road-user costs, translating to an increase in cost per ton hauled but also indirectly to reduced production rates and vehicle and component service life. Truck haulage costs can account for up to 50% of the total operating costs incurred by a surface mine, and any savings generated from improved road design and management benefit the mining company directly as a reduced cost per metric ton of material hauled.

Central to the cost of truck hauling is the concept of rolling resistance (expressed here as a percentage of gross vehicle mass [GVM]). It is a measure of the extra resistance to motion that a haul truck experiences and is influenced by tire flexing, internal friction, and, most importantly, wheel load and road conditions. Empirical estimations of rolling resistance based on tire penetration specify typically a 0.6% increase in rolling resistance per centimeter tire penetration into the road, over and above the 1.5% (radial and dual wheel assemblies) to 2% (cross-ply or single-wheel assemblies) minimum resistance. In addition to tire penetration, road surface deflection or flexing will also generate similar results, with the truck tire running "up-grade" as the deflection wave pushes ahead of the vehicle. Taking an electric-drive rear-dump ultra-class truck of 376 t (GVM) as an example, on a ramp road with a basic rolling resistance of 2%, an additional 1% rolling resistance will reduce truck speed by 10% to 13%, whereas on a flat surface road, the truck speed will be reduced from 18% to 26%.



Although many concepts from highway engineering can be adapted to the design, construction, and management of mine roads, significant differences in applied loads, traffic volumes, construction material quality and availability, together with design life and road-user cost considerations, mitigate for a tailored design solution for mine haul roads.

COMPONENTS OF AN INTEGRATED MINE HAUL ROAD DESIGN

The operating performance of a mine road can be subdivided into four design components (i.e., geometric, structural, functional, and maintenance management); when designing and constructing a haul road for optimal performance, these design components are best addressed using an integrated approach. If one design component is deficient, the other components may not work to their maximum potential and road performance is often compromised. This will most often be seen as "maintenance intensive" or high rolling resistance roads, translating to increased equipment operating, downtime, and repair costs. The cure, however, is not necessarily just more frequent maintenance; no amount of maintenance will fix a poorly designed road.

Design and management of haul road systems should also be approached holistically, especially with regard to the benefits achieved from various solutions to enhance productivity. Although, for instance, trolley-assist may improve cycle times and reduce cost per metric ton hauled, it is first necessary to evaluate the extent to which an existing haul road network meets optimal design requirements before resorting to solutions that do not directly address the key deficiencies of the existing road system. The recommended approach is therefore to assess the extent to which the asset (the current road network) exhibits scope for improvement and, once optimized,

Roger J. Thompson, Professor of Mining Engineering, Curtin University (Western Australian School of Mines), Kalgoorlie, Western Australia

Figure 10.6-1 Integrated haul road design and management system components

then revert to resource supplementation to leverage these benefits through optimal asset and resource interaction.

Figure 10.6-1 illustrates the approach to mine road design, based on the geometric, structural (layerworks), functional (wearing course), and maintenance management design components, together with a dust palliative evaluation methodology. These design components form the basis for the following sections of the chapter.

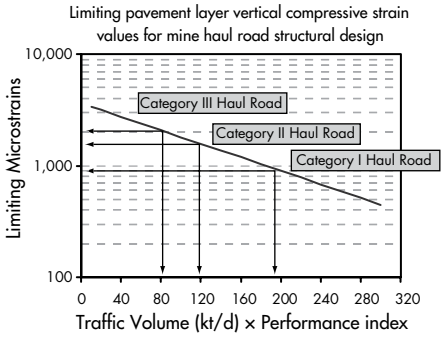
The first component, that of geometric design, is commonly the starting point for any haul road design and refers to the layout and alignment of the road, in both the horizontal and vertical plane. The ultimate aim, to produce an optimally efficient and safe geometric design, can only be achieved when sound geometric design principles are applied in conjunction with the optimal structural, functional, and maintenance management designs.

The aim of a structural design is to provide a haul road that can carry the imposed loads over the design life of the road without the need for excessive maintenance. It is focused on the design of road layerworks and the response of construction materials in and under the road to the truck wheel loads.

The functional design is centered on the selection of wearing course (or surfacing) materials; the most suitable choice, application technique, and maintenance strategy is required. Commonly, the running surface of a mine road is a gravel mix, which lends itself to maintenance (blading or, over the longer term, rehabilitation). To improve performance of the material, palliation and/or stabilization is often considered, primarily to reduce both dust generation and material degeneration, the latter leading to increased rolling resistance and associated road maintenance.

The maintenance aspect of haul road design cannot be considered separate from the geometric, structural, and functional design aspects because they are mutually inclusive. Design and construction costs for the majority of haul roads represent only a small proportion of the total operating and maintenance costs. Although it is possible to construct a mine haul road that requires no maintenance over its service life, construction costs would be prohibitively expensive. The converse, an empirically designed and cheaply constructed road, would also incur excessive costs, in this case related to vehicle operating and road and vehicle maintenance costs. The use of an appropriate road maintenance management strategy will generate significant cost savings by virtue of a better understanding of the relationship between wearing course material degeneration rates (manifest as increasing rolling resistance on the road) and its influence on both cost per metric ton hauled and the cost of road maintenance itself.

A mine road network often comprises various roads, each with a specific function, traffic type (size of truck), traffic volume, service level (performance), and operating life. A road classification system should be developed, according to these parameters, as part of a mine-wide common framework for road design. This can be used as the starting point for design guidelines for construction personnel, to enable them to determine easily what design guideline is appropriate when constructing new roads or evaluating and rehabilitating existing mine roads. Clearly, not all roads are equal and thus the approach to design and management must be tailored to apply more resources to high-volume, long-term, and high-cost-impact road segments across the network. Figure 10.6-2 illustrates typical haul road design categories; the accompanying data forms the basic input to the four design categories previously discussed.



GEOMETRIC DESIGN

The geometric layout of a mine haul road is dictated to a great extent by the mining method used and the geometry of both the mining area and the ore body. Mine planning software enables various haul road geometric options to be considered and the optimal layout selected, both from a road design and economic (lowest cost of provision) perspective (MineMap 2008). Although these techniques often have default design values embedded in the software, it is nevertheless necessary to review the basic concepts of geometric design if any modifications are to be considered in the design of mine roads, either on the basis of economics or, more critically, from a safety perspective.

The road layout or alignment, both horizontally and vertically, is generally the starting point of the geometric design. Practically, it is often necessary to compromise between an ideal layout and what mining geometry and economics will allow. Any departure from the ideal specifications will result in reductions in both road and truck life.

Considerable data already exists pertaining to good engineering practice in geometric design (Kaufman and Ault 1977; USBM 1981; Tannant and Regensburg 2000), and forms the basis of the design criteria developed here. Broadly speaking, safety and good engineering practice require haul road alignment to be designed to suit all vehicle types using the road,

Haul Road Category	Typical Description	Range of Maximum Permissible Vertical Elastic Strains (microstrains)	
		Traffic Volumes >100 kt/d	Traffic Volumes >100 kt/d
Category I	Permanent life-of-mine high traffic volume main hauling roads and ramps in- and ex-pit Operating life >20 years	900	1,500
Category II	Semipermanent medium-to-high traffic volume ramp roads in- and ex-pit Operating life >10 years	1,500	2,000
Category III	Shorter-term medium- to low-volume in-pit bench access, ex-pit dump, or ramp roads Operating life <5 years (at >50 kt/d) or <10 years (at <50 kt/d)	2,000	2,500

Maximum permissible vertical strains can also be determined from (kt/d × performance index) where performance index is defined as

1. Adequate but fairly maintenance intensive,
2. Good with normal maintenance interventions, or
3. Outstanding with low-maintenance requirements.

Figure 10.6-2 Typical haul road design categories and associated design data

operating within the safe performance envelope of the vehicle, or, where this is not possible, at the speed limit applied. Ideally, geometric layout should allow the vehicles to operate at their maximum safe speed, but given that the same road is used for laden and unladen haulage, there is often the need to minimize laden travel times, through appropriate geometric alignment, while accepting compromises (generally in the form of speed limits) on the unladen return haul. The process of geometric design is shown in Figures 10.6-3 and 10.6-4 and discussed in the following sections.

Vertical Alignment

Vertical alignment considers the effect of road elevation changes on both sight and stopping distances of trucks, together with the effect of road grade on safety and performance.

Stopping Distance Limits

The truck manufacturer should confirm the distances required to bring the truck to a stop, following International Organization for Standardization (ISO) 3450:1996 standards or local requirements. The following equation can be used to produce a first estimate:

$$\text{stopping distance (m)} = \frac{v^2}{48 - 2.6 \times \text{grade}} \qquad (10.6\text{-}1)$$

where v is the speed of the truck (kilometers/hour) with GVM > 32 t and *grade* is the downslope (positive in direction of travel) (%).

The ISO 3450:1996 standard gives typically a 114-m stopping distance at 10% downgrade at 50 km/h and a 73-m stopping distance at 40 km/h. Although this satisfies most mine ramp road designs where rear-dump trucks are used, care should be taken when using the ISO approach for articulated dump trucks (ADTs). Steeper ramps are often used where ADTs are employed, because they commonly have better hill-climbing ability. With a ramp steeper than 10%, the ISO stopping distance would not necessarily apply. In general, and including driver reaction times, practical retard unassisted (emergency) distances can be determined from the following equation:

$$\text{stopping distance} = \frac{1}{2}gt^2\sin\theta + v_o t + \left(\frac{(gt\sin\theta + v_o)^2}{2g(U_{\min} - \sin\theta)}\right) \qquad (10.6\text{-}2)$$

where g is the acceleration due to gravity (m/s^2), t is the driver reaction time (s), θ is the grade of road (degrees) positive downgrade, v_o is the vehicle speed (m/s), and $U_{\min}$ is the coefficient of friction between the tire and the road, taken as 0.3. This first estimate for stopping distance is based on "ideal" braking and vehicle conditions (dry road, good skid resistance, etc.). When conditions under braking vary (wet roads, poor and slippery wearing course, spillage, etc.), a longer stopping distance would need to be considered.

Sight Distances

At least 150 m is required based on typical stopping distance requirements. On a curve or bend in the road, this could be difficult to achieve, as shown in Figure 10.6-5. Length of vertical curves (L) can be determined from consideration of the height of the driver above the ground (h_1[m]), an object of height h_2 (m) (usually 0.15 m to represent a prostrate figure in the road), SD as the minimum stopping distance (m), and ΔG as the algebraic difference in grades (%).

Where stopping distance is greater than the length of a vertical curve, then

$$L = 2SD - \left(\frac{200\left(\sqrt{h_1} + \sqrt{h_2}\right)^2}{\Delta G}\right) \qquad (10.6\text{-}3)$$

Where stopping distance is less than the length of the curve, then

$$L = \left(\frac{\Delta G \cdot SD^2}{100\left(\sqrt{h_1} + \sqrt{h_2}\right)^2}\right) \qquad (10.6\text{-}4)$$

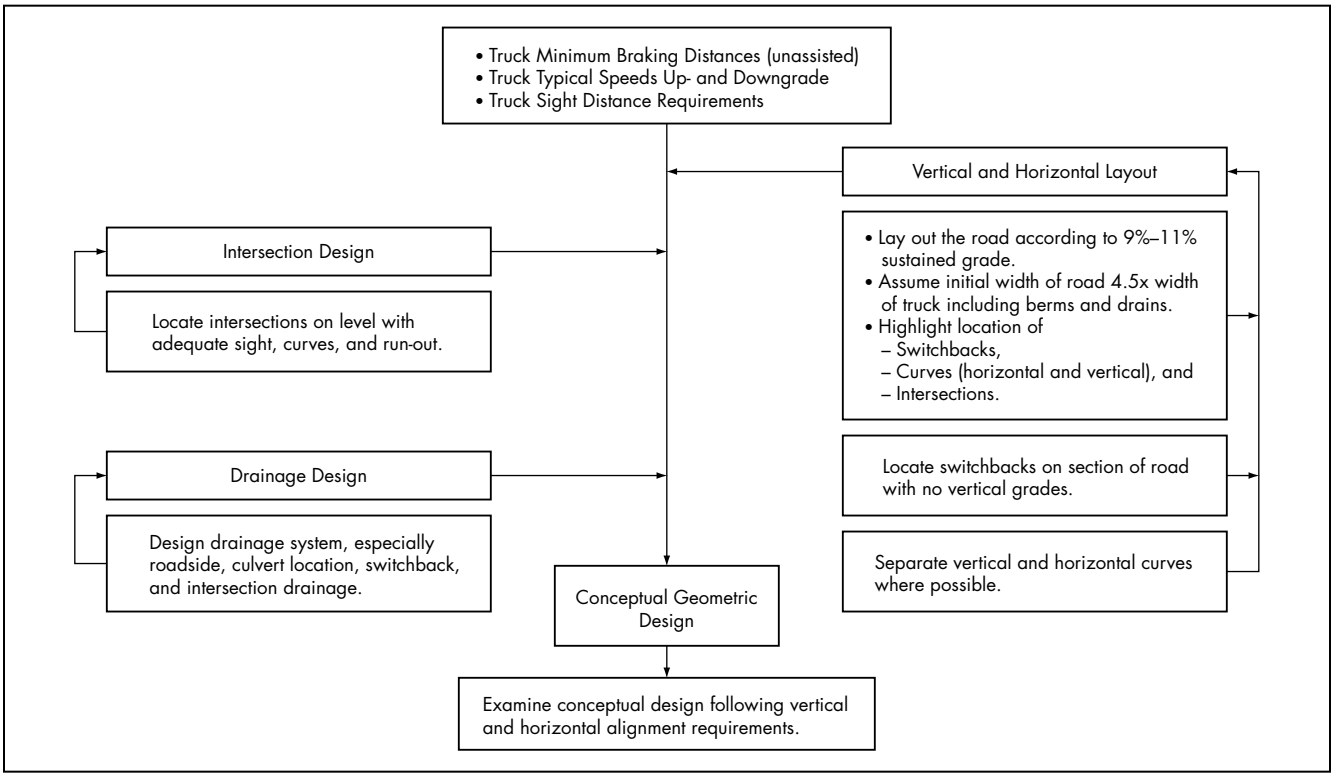


Figure 10.6-3 Conceptual geometric design

When the road curves around a bench edge, to maintain sight distance, a "layback" (LB) is used to keep the road away from the sight obstruction. The layback distance (defined in Figure 10.6-6) is found from consideration of the truck minimum stopping distance and curve radius R [m]):

$$LB = SD\left[1 - \cos\left(\frac{28.65R}{SD}\right)\right] \qquad (10.6\text{-}5)$$

Where sight distance is reduced below the stopping distance, speed limits should be applied or sight distances increased.

Optimal and Maximum Sustained Grades

Although maximum gradients may be limited by local regulations, ideally the gradient should be a smooth, even grade, not a combination of grades. Laden trucks running against the grade work best at total (i.e., grade and rolling resistance) values of between 8% and 11%. However, each truck engine and drive system combination has a characteristic "optimal grade curve" and it is a good geometric design starting point to determine the optimal gradient for the selected truck in use at the mine. Although travel times (laden) are sensitive to grades against the load, care should also be taken when selecting the grade, from the perspective of truck retard limitations on the unladen downward leg of the haul. This aspect becomes critical in the case of downgrade laden hauling when retard capacity would be the limiting design criteria.

Horizontal (Longitudinal) Alignment

Haul road width, curve layout, and associated superelevation and run-out, together with cross-slope or camber and intersection layout, are incorporated under longitudinal geometric design considerations.

Width of Road

The width of the road should allow enough room for the required number of lanes and all the associated safety and drainage features. The widest vehicles proposed determine the roadway width; the dimensions of the safety berms and drainage channels are also added to the roadway width to determine the construction width required. Table 10.6-1 summarizes these design roadway widths.

On single-lane roads, if the sight distance is less than the stopping distance, sufficient space must be provided for moving vehicles to avoid collision with stalled or slow-moving vehicles.

Curvature and Switchbacks

Any curves or switchbacks should be designed with the maximum radius possible and be kept smooth and consistent. Changes in curves radii (compound curves) should be avoided. A larger curve radius allows a higher safe road speed and increased truck stability. Sharp curves or switchbacks will increase truck cycle times and haul cost as a result of rear dual tire wear due to tire slip.

Minimum radius (R [m]) can be initially determined from

$$R = \frac{v_o^2}{127(e + U_{\min})} \qquad (10.6\text{-}6)$$

where v_o is the vehicle speed (km/h); e refers to the superelevation applied (m/m width of road); and $U_{\min}$ is the coefficient of friction between the tire and the road, taken as 0.3 (soft, muddy, rutted road surface) to 0.45 (partially compacted gravel surface). Where the pit layout does not permit these minimum radii, speed limits need to be applied.

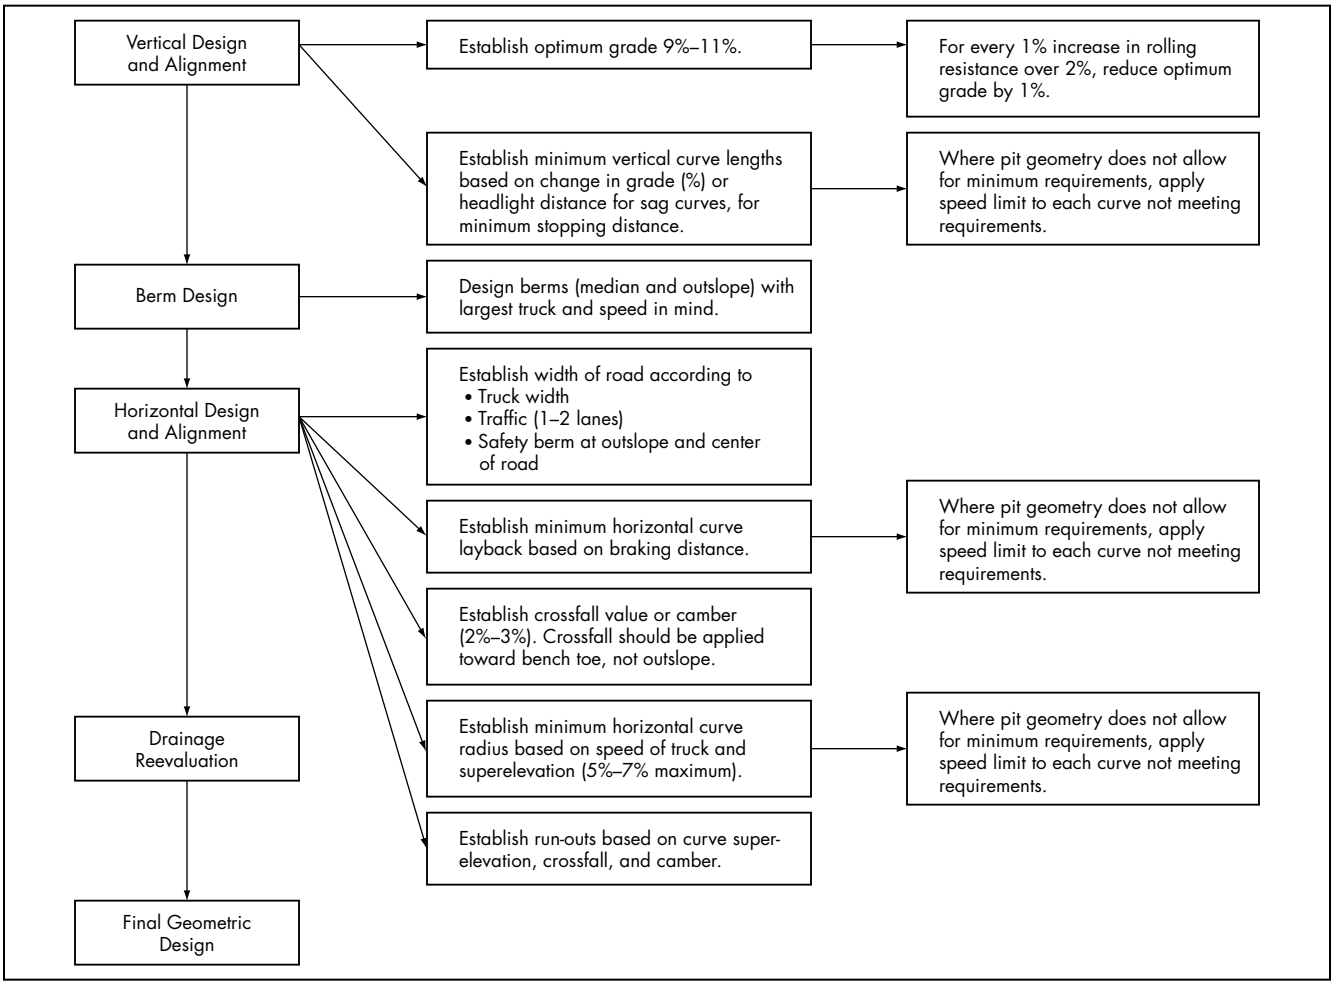

Figure 10.6-4 Final geometric design

Curve Superelevation (Banking)

This is the amount of banking applied on the outside of a curve to allow the truck to run through the curve at speed. Ideally, the outward centrifugal force experienced by the truck should be balanced by the side friction between tires and road. Superelevations should not exceed 5% to 7%, unless high-speed haulage is maintained and the possibility of sliding minimized. Table 10.6-2 shows typical superelevation rates based on speed of vehicle and radius of curve. Where tighter curves are required or truck speed is higher on approach to the curve, a speed limit should be applied.

Cross Slope or Camber

This is critical to the design and successful operation of mine roads. Applying a crossfall or camber ensures that water does not gather on and penetrate into the road surface. Standing water on or in a road will cause rapid deterioration of the road.

Two options exist: either a cross slope from one edge of the road to the other edge or a camber (crown) from the center of the road to both sides of the road. Whatever option is adopted, at the point where the road edge and camber or cross-slope downslopes meet, a drainage ditch must be provided. The two options are illustrated in Figure 10.6-7 (with safety berms omitted, but including drain locations).

A constant camber or cross slope of 2% to 3% is ideal, providing adequate drainage without incurring adverse truck tire and strut loading. A preference may exist for cross slopes because of the envisaged equalized load sharing and tire scrub (i.e., loss of tire tread [rubber]) because of shear contract with the road wearing course. A cross slope should be used with caution, with the slope falling toward the inside of the bench (toe position) as opposed to the outslope side. Where a camber or crown is selected and where this leads to the possibility of trucks sliding in the direction of the bench crest or outslope, or toward a large vertical drop, it is only recommended when large deflection berms are placed at road crest edge.

Special consideration must be given to determining when to use the maximum and minimum rates. Lower cross slopes are applicable to relatively smooth compact road surfaces that can rapidly dissipate surface water without the water penetrating into the road surface. In situations where the surface is relatively rough, a larger cross slope is advisable.

Run-out

Run-out should be used when a section of haul road changes from a cross slope or camber into and out of a superelevated section. The change should be introduced gradually to prevent excessive twisting or racking of the truck chassis. The run-out

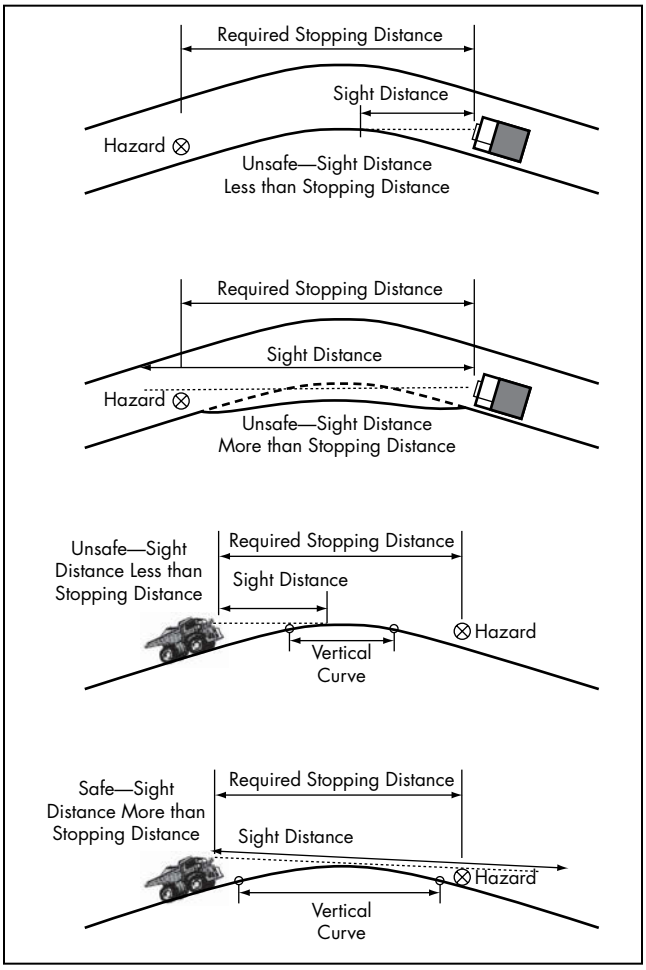

Figure 10.6-5 Horizontal and vertical curve line of sight

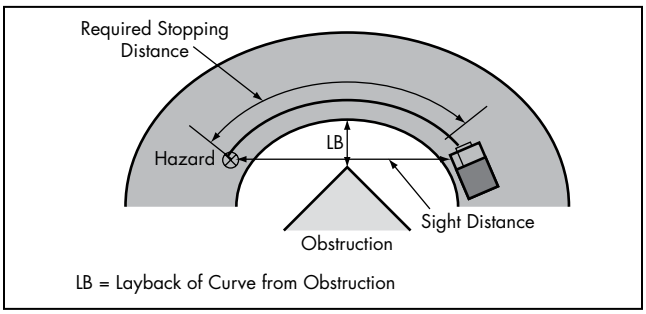

Figure 10.6-6 Layback requirements on obscured horizontal curve

length is typically apportioned 25% to 33% to the curve and 66% to 75% to the tangent or run-up to the curve. Run-out lengths vary with vehicle speed and total crossfall change and can be estimated as

$$CSx = 15.65 - 5.67 \log_{10}(v_o) \qquad (10.6\text{-}7)$$

where CSx is the maximum change (m) in elevation per 30-m tangent road length and v_o is the speed of the truck (km/h). Run-out is best incorporated in a mine road design "by eye" rather than by calculation. Where the run-in or run-out is at 0% (i.e., the road is flat), there should be a slight grade ideally to prevent water ponding on the road at this point.

Table 10.6-1 Minimum haul road width

Number of Lanes	Factor × Width of Largest Truck on Road
1	2
2	3.5
3	5
4	6

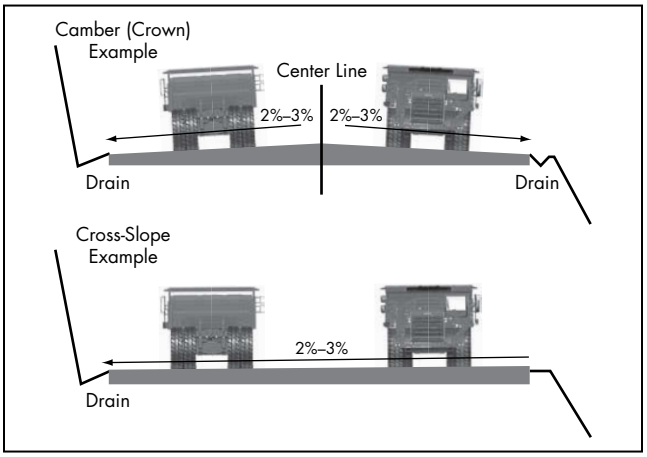
Note: For switchbacks or other sharp curves and/or roads with high traffic volumes or limited visibility, a safe roadway width would be designed with an additional 0.5 times the vehicle width. A four-lane road is recommended where trolley-assist systems are in use.

Intersection Layout

This often entails smaller curve radii than that required for maintaining high-speed hauling. Junction priorities should be maximized for nonyield traffic flows. The design of the intersection run-in and run-out should be a smooth spiral progression from one cross slope or camber to the curve superelevation and out again, as shown in Figure 10.6-8. Drainage at the side of each intersection leg must be adequate to keep water from ponding at the roadside and, where possible, intersection segments—or at least nonyield segments—must be placed on flat (not inclined) areas.

Where feasible and safe to do so, junctions can be designed on a herringbone layout, with traffic flow in the direction of the primary destination (i.e., the largest radius of curvature out of the junction), which will facilitate higher-speed hauling and reduce tire scrub, but consideration should be given to maintaining sight distances in all four quadrants.

Combined Alignment



When laying out a haul road, some additional considerations arise with combined alignment:

- Sharp horizontal curves at or near the top of a grade section should be avoided. If a horizontal curve is necessary, it should start well in advance of the vertical curve.
- Switchbacks should be avoided where possible, but if mine plan dictates their use, the radius should be as large as possible and should not be placed on grade.
- Sharp horizontal curves requiring a (further) speed reduction following a long sustained downgrade where haul trucks are normally at their highest speed should be avoided.
- Short tangents and varying grades should be avoided, especially on multilane roads. Grades should be smooth and of consistent grade percentages.
- Intersections should be avoided near the crest of vertical curves or sharp horizontal curves. Intersections should be as flat as possible with sight distances being considered in all four quadrants. Where an intersection lies at the top of a ramp, 100–200 m of flat road should be considered before the intersection, and stopping and starting a laden haul truck on grade should be avoided.
- Drainage design at intersections should stop any ponding of water against intersection superelevated curves.
- Sections of road with no camber or cross fall should be avoided. Often encountered at curve superelevation run-in or run-out, these flat sections should preferably be at a 1% to 2% vertical grade to assist drainage.

Table 10.6-2 Superelevation rates*

	Speed and Superelevation, m/m Width of Road								
Curve Radius, m	15 km/h	20 km/h	25 km/h	30 km/h	35 km/h	40 km/h	45 km/h	50 km/h	55 km/h
50	0.035	0.060	0.090						
75	0.025	0.045	0.070	0.090					
100	0.020	0.035	0.050	0.075	0.090				
150	0.020	0.025	0.035	0.050	0.065	0.085			
200	0.020	0.020	0.025	0.035	0.050	0.065	0.080		
300	0.020	0.020	0.020	0.025	0.035	0.045	0.055	0.065	0.080
400	0.020	0.020	0.020	0.020	0.025	0.035	0.040	0.050	0.060
500	0.020	0.020	0.020	0.020	0.020	0.025	0.030	0.040	0.050

*Elevation rates in the shaded blocks should only be applied as a combined superelevation with a road (center) splitter berm used to separate slow and fast lanes of the road (each with its own speed-related superelevation), because of the possible instability of slow-moving vehicles negotiating higher rates of superelevation.

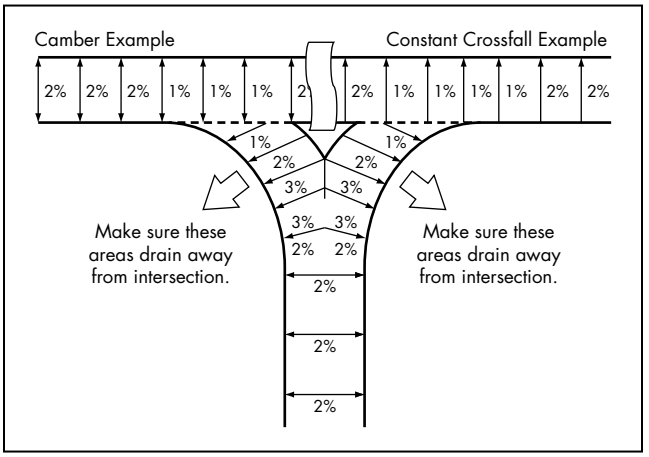

Figure 10.6-8 Junction layout and drainage details

Safety Berms

A crest (outslope) or road-edge berm (windrow) will not effectively stop trucks (especially high-speed laden or unladen trucks) from leaving the road. At best, they will provide limited deflection and warning to the driver that the truck path needs correcting. For large haul trucks, the berm height should be at least 66% of the truck wheel diameter. The slope of the sides of the safety berm should be preferably 3H:1V to ensure stability and maintenance of height.

Truck GVM has a significant deformation effect on the berm, which is typically constructed from unconsolidated material; as the truck climbs the berm, the high center of gravity in combination with a narrow width of the wheel track make trucks susceptible to overturn. Furthermore, large tire sizes and noncentering steering mechanisms reduce the tendency of the truck to redirect itself when encountering a berm. With 4×6- and 6×6-wheel drive ADTs, berm dimensions in excess of 66% wheel diameter are recommended, because of the truck's ability to climb smaller berms. Other factors such as inertial characteristics, sprung mass ratio, and suspension characteristics indicate significantly different response patterns for haul vehicles when encountering berms.

To arrest runaway trucks, median (center or arrestor) berms are often used. They are placed in the center of the roadway and a camber (crown) is required so that water drains to the edges of the road. To enable the driver to steer the truck onto the berm, the front edge is sloped at a 4H:1V run-in, up to the height required. This height is generally 2.5 times the truck ground clearance. Length of the berm is a minimum of 50 m, subject to spacing requirements. To allow the truck to run up, spacing between the berms is required. The berm spacing (Equation 10.6-8) is a function of maximum safe vehicle speed at entry to the berm (v_{max}, m/s), speed at point of brake failure or other hazard (v_{fail}, m/s), and θ, the grade of road (degrees) positive downgrade with a mean coefficient of rolling resistance of 0.05 applied. Figure 10.6-9 illustrates the typical median (arrestor) berm layout.

$$\text{berm spacing} = \left(\frac{v_{max}^2 - v_{fail}^2}{2g \sin(\theta - 0.027)} \right) \tag{10.6-8}$$

Ditches and Drainage

A well-designed drainage system is critical for effective operation and safety; water on the road or in the road layers will quickly lead to poor road conditions. As part of the haul road geometric design process, contours in the vicinity of the proposed road should be examined prior to construction to identify areas of potential ponding, locations of culverts, and so forth.

Drains at the edge of the road should be designed to lead the water off the road without causing erosion. Drains should not be cut into the base layer and should preferably be lined

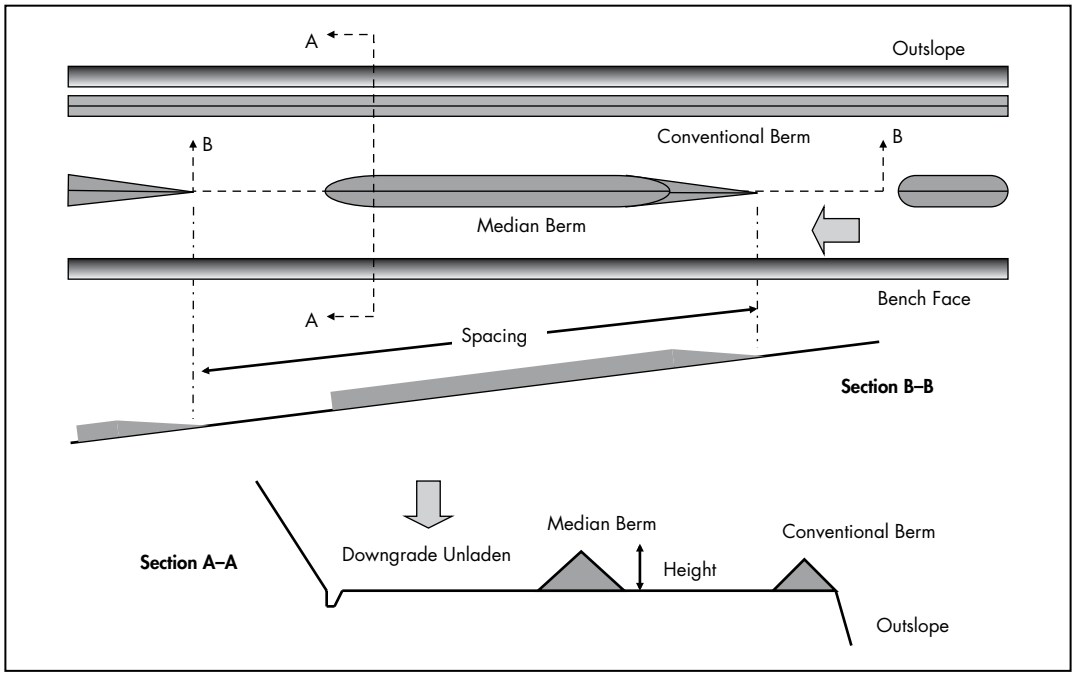

Figure 10.6-9 Median (arrestor) berm design

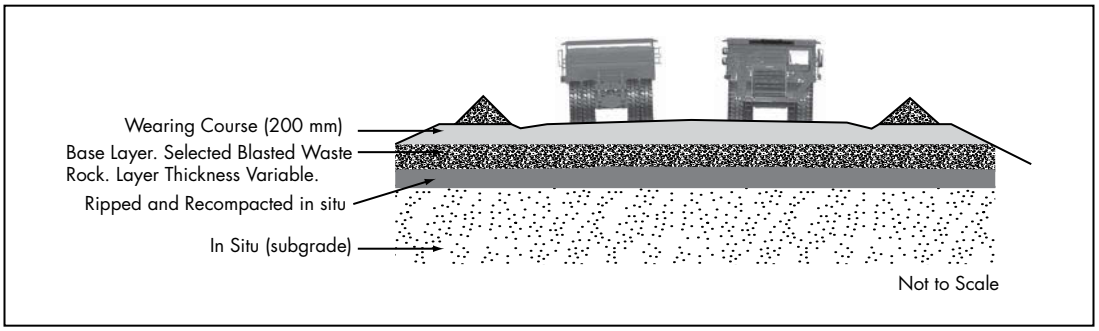
with compacted wearing course, thereby preventing water from seeping into the underlying layers.

V-ditches are recommended for nearly all applications, owing to their relative ease of design, construction, and maintenance. The ditch cross slope adjacent to the haul road should be 4H:1V or flatter except in extreme restrictive conditions. In no case should it exceed a 2H:1V slope. The outside ditch slope will vary with the material encountered. In rock, it may approach a vertical slope; in less consolidated material, it may be a 2H:1V slope or flatter.

In a cut/fill section, a cross slope toward the cut side should be used and drainage should run in a single ditch. In a total cut or total fill section, drainage should be carried on both sides with crown or camber from the road center line. Ditch lining is a function of road grade and in-situ material characteristics: between 0% and 4% grade, the ditch may be constructed without benefit of a liner except in extremely erodible material such as sand or easily weathered shale and silts; at grades greater than 5%, the lining should consist of coarse crushed waste rock placed evenly on both sides to a height no less than 0.3 m above the maximum depth.

Ditches must be designed to handle expected runoff flows adequately under various slope conditions. The primary consideration is the amount of water that will be intercepted by the ditch during a rainstorm. Typically, a 10-year, 24-hour storm chart should govern the design.



Culvert sections are used to conduct runoff water from drainage ditches under the haul road. If buried piping is used, they should be set at 3% to 4% fall and smooth-wall concrete pipes should be used in conjunction with a drop-box culvert of a size that will allow it to be cleaned with a small backhoe excavator. At all culvert inlets, a protective encasement or "headwall" consisting of a stable nonerodible material should be provided.

Typical culvert units are either portal and rectangular precast concrete culvert units or precast concrete pipe culvert units. Depth of cover after the culvert pipe is determined by the type of culvert in relation to the vehicles that will use the road. A minimum cover of 1,000 mm over the pipe is required in most cases. All prefabricated culverts should be constructed under trenched conditions after the road has been constructed. Concrete pipe culverts are laid on a layer of fine granular material, 75 mm thick, after the bottom of the excavation has been shaped to conform to the lower part of the pipe. Where rock, shale, or other hard material is encountered on the bottom of excavations, culverts should be placed on an equalizing bed of sand or gravel. After placement, the culvert trench is backfilled and compacted.

STRUCTURAL DESIGN

Structural design concerns the ability of a haul road to carry the imposed loads without the need for excessive maintenance or rehabilitation. Haul roads deteriorate with time because of the interactive effort of traffic load and specific subgrade and in-situ material strengths and structural thicknesses. The California bearing ratio (CBR) method (Kaufman and Ault 1977) has been widely applied to the design of mine haul roads in which untreated materials are used. However, when multilayered roads are considered in conjunction with a base layer of selected blasted waste rock, a mechanistic approach is more appropriate. When a selected waste rock layer is located under the wearing course, road performance is significantly improved, primarily because of the load-carrying capacity of the waste rock layer, which reduces the susceptibility of the soft subgrade and in-situ material to the effects of high axle loads. It also has the added advantage of reduced construction costs (by virtue of reduced volumetric and compaction requirements) compared with the CBR cover-curve design approach (Morgan et al. 1994; Thompson and Visser 1996).

A mechanistic design is based on a theoretical linear–elastic multilayer system model of the road. A limiting design criteria of vertical compressive strains in the subgrade or

Courtesy of Caterpillar, Inc.

Figure 10.6-10 Typical haul road structure and layer terminology

in-situ material is then used to assess the haul road under the specific loading conditions, thereby determining the adequacy of the structural design.

Vertical compressive strains induced in a road by heavy wheel loads decrease with increasing depth, which permits the use of a gradation of materials and preparation techniques, with stronger materials being used in the upper regions of the pavement. The road as a whole must limit the strains in the subgrade (in-situ) materials to an acceptable level, and the upper layers must in a similar manner protect the layers below. Using this premise, the road structure should theoretically provide adequate service over its design life. Figure 10.6-10 illustrates a mechanistically derived haul road structure.

In general terms, applied load, subgrade strength, and the pavement structural thickness and layer strength factors predominantly control the structural performance of a haul road. An upper limit of 2,000 microstrains is generally placed on subgrade or in-situ layer strain values. Strain values exceeding 2,500 microstrains are associated with unacceptable structural performance in all but the most lightly trafficked and short-term roads. Data from Figure 10.6-2 can be used to assist in selecting a limiting strain value, according to the category of road to be built and the associated operating life and traffic volumes. In addition, to prevent excessive damage to the wearing course, deformation at the top of this layer must be limited to no more than 3 mm.

As for trolley-assist roads, haul roads in general have a much higher degree of traffic channeling (in which trucks follow the same wheel paths), so structurally, no difference in the approach to structural design is warranted. Critical to the success of trolley-assist is the height of the road surface under the trolley lines; with a good structural design, slight loss of running surface or compaction of the road structure will generally be within the limits of the truck pantograph system. To prevent trucks being rejected from the trolley line, grade changes under trolley should be avoided as far as possible. However, in the case of wearing course material management, because of the high shear forces developed at the wheel–road surface interface as trucks are "accepted" under trolley and accelerate, severe wearing course raveling is often seen in these local areas. This can be ameliorated to some extent by the use of well-specified wearing course material and the use of dust palliatives, which assist in binding the wearing course material.

Mechanistic Structural Design Procedure

To determine the layer response to an applied load, a layered elastic model can be used to represent the various haul road layers in the design. Software is available that can be used to solve multilayer problems in road design, including ELSYM5A (FHWA 1985) and CIRCLY (MinCad 2008). Irrespective of the solution software used, the approach is similar.

The effective elastic (resilient) modulus (E_{eff}) and Poisson's ratio (μ, typically 0.35) define the layerworks material properties required for computing the vertical strains (ε_v) in a road. In addition to the material properties, a layer thickness (200 mm) is also specified for the wearing course (discussed later in the "Functional (Wearing Course) Design" section). By varying the thickness of the waste rock-layer, a solution for maximum strain in any pavement layer that is below the limiting strain criteria for that class of road is found. Generally, a three-layer model is sufficient where the road is built directly on subgrade fill (in-pit blasted rock) or in-situ material (ex-pit softs or weathered overburden). If the construction incorporates ripped and compacted in-situ material, this may also be added as another layer. For computational purposes, the layers are assumed to extend infinitely in the horizontal direction and the lowest pavement layer is assumed to be infinite in depth.

The applied load is calculated according to the mass of the vehicle and the rear dual wheel axle load distributions, from which the maximum single wheel load is found. The load application is determined from dual wheel geometry and, together with tire pressure, the contact stress is calculated. Figure 10.6-11 summarizes the layered elastic model.

The strains induced in a pavement are a function of the effective elastic (resilient) modulus values assigned to each layer in the structure. In order to facilitate a mechanistic design, some indication of applicable modulus values is required. Figure 10.6-12 gives recommended modulus value correlations to the Unified Soil Classification System (USCS) and (American Association of State Highway and Transportation Officials (AASHTO) classification system. To select suitable modulus values for in-situ materials, the associated range of CBR values (alternatively derived in the field from dynamic cone penetrometer probing, Tayabji and Lukanen 2000) are also given. Other values are published by Thompson and Visser (1996) and the South African Roads Board (SARB) (1994). Equation 10.6-9 can also be used in conjunction with layer CBR values to determine modulus values (E_{eff}, MPa), but in each case, care should be taken to ensure that the general correlations presented here are consistent with soil properties not directly assessed in the derivation of the equation.

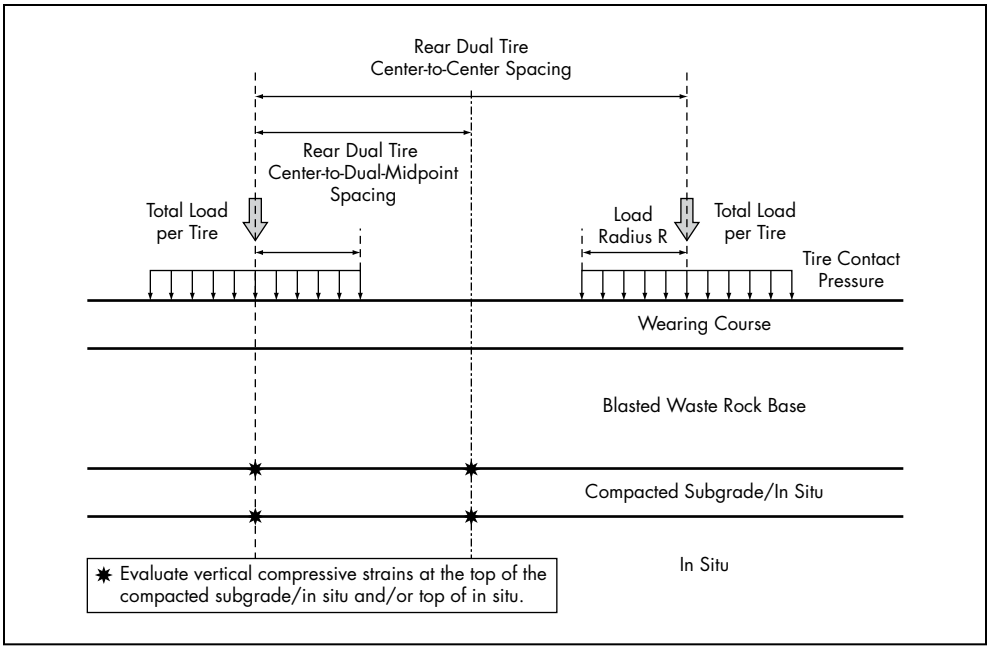


Figure 10.6-11 Multilayer model for structural design evaluation

$$E_{\text{eff}} = 17.63\text{CBR}^{0.46} \quad (10.6\text{-}9)$$

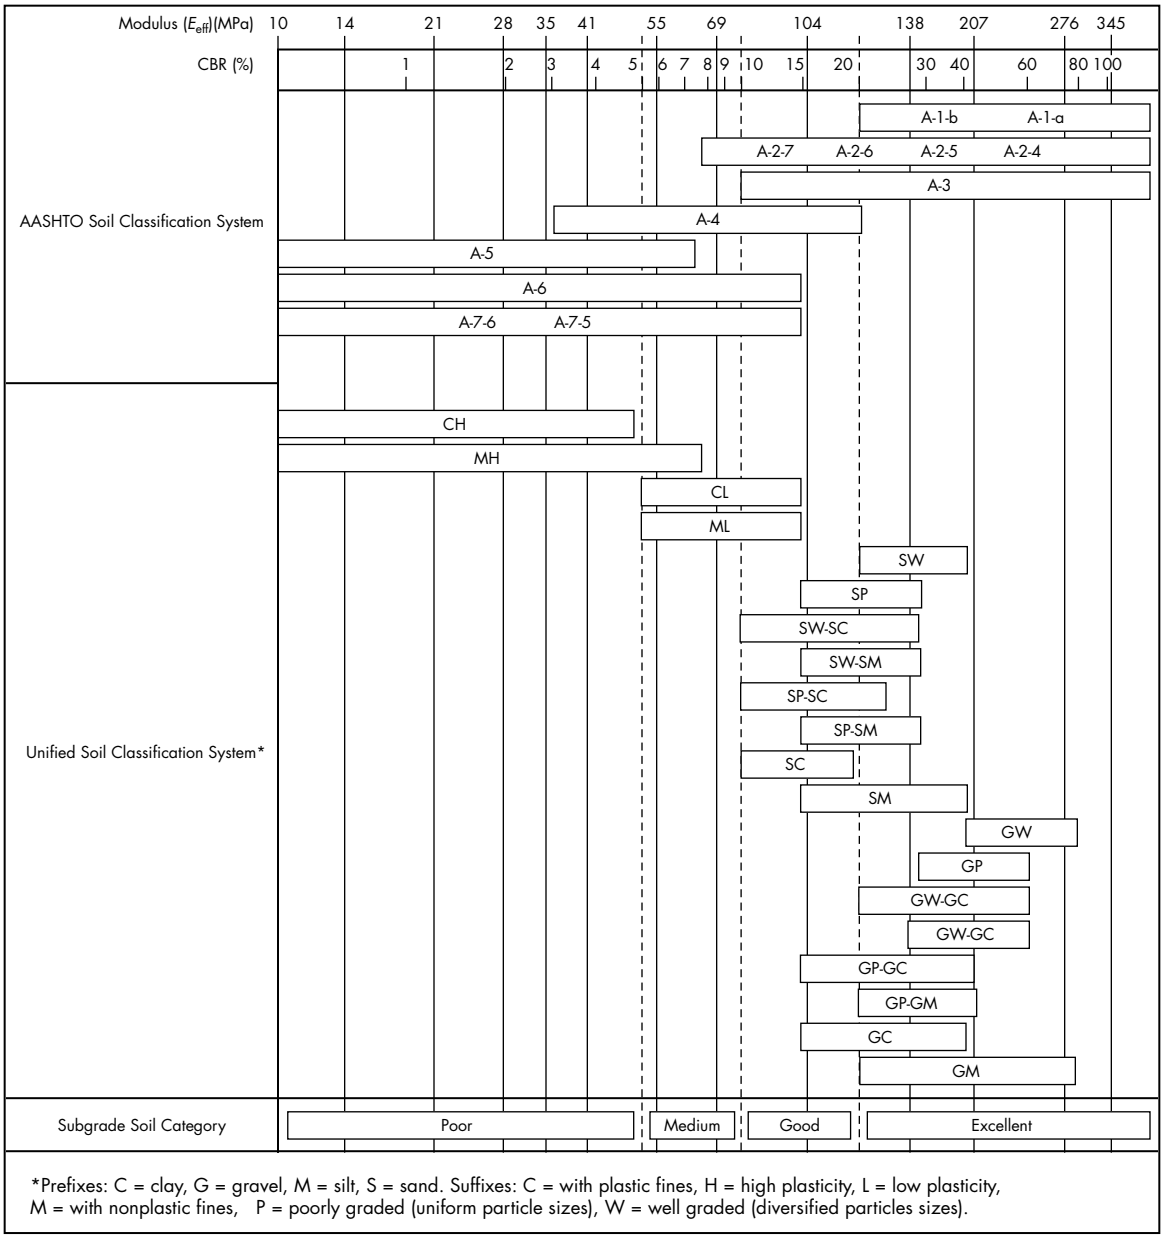
The modulus value adopted for the selected blasted waste rock layer is typically 3,000 MPa. This value is derived from consideration of a cement-stabilized layer in its precracked (large intact blocks with some shrinkage cracks) state, which corresponds closely to a well-compacted waste rock layer.

Method Specification Notes for Structural Design

The structural design is based on the use of selected blasted waste rock. This is subject to the material selected being blocky (maximum block size <50% layer thickness) and not containing excessive (minus-25-mm sieve) fines or clay contamination. Care should be taken when selecting blasted waste; rock from weathered overburden will contain excessive softs. To satisfy the layer specifications, either the blast burden and spacing can be reduced or powder factor increased to produce a finer fragmentation than a conventional production blast. Alternatively, a grizzly sizer can be used to remove the oversize material before placing in the road.

When constructing the various rock layers, the blasted selected rock should be placed in a single lift (if using impact roller compaction), or 300-mm lifts (if using vibratory roller compaction). By running haul trucks over the road during construction (end tipping) and dozing to profile, compaction of the layerworks will be improved and structural capacity increased. In addition, to improve compaction, all excessively large boulders (>50% of layer thickness) should be removed (if not scalped at the grizzly) from the upper portion of the compacted rock layer. The rock layer should be compacted (dry) by impact or vibratory roller compaction until no movement under the roller is visible. This improves the structural response of the road to the applied loads and provides an anvil for improved wearing course layer compaction. Following compaction, a final pass of a grid roller can be used to assist in creating a correction layer of crushed or blasted overburden rock, or similar can be placed if longitudinal or cross-alignment needs correction. Fines should not be used for this purpose.

Finally, a gravel wearing course layer of 200 mm is placed onto the selected rock layer. Design of this layer is discussed in the following section.



FUNCTIONAL (WEARING COURSE) DESIGN

Equally important as the structural strength of the design is the functional trafficability of the haul road. This is dictated to a large degree through the selection, application, and maintenance of the wearing course (or road surfacing) materials. Poor functional performance is manifest as poor ride quality, excessive dust, increased tire wear and damage, and an accompanying loss of productivity. The result of these effects is seen as an increase in overall vehicle operating and maintenance costs.

The functional design of a haul road is the process of selecting the most appropriate wearing course material or mix of materials, typically natural gravel or crushed stone and gravel mixtures that are commensurate with safety, operational, environmental, and economic considerations. The most common wearing course material for haul roads remains compacted gravel or gravel and crushed stone mixtures. In addition to their low rolling resistance and high coefficient of adhesion, their greatest advantage over other wearing course materials is that roadway surfaces can be constructed rapidly and at relatively low cost. As with structural designs, if local mine material can be used for construction, the costs are all the more favorable. This cost advantage is, however, not apparent in the long term if the characteristics of the wearing course material result in suboptimal functional performance.

An ideal wearing course for mine haul road construction should exhibit

- The ability to provide a safe and vehicle-friendly ride without the need for excessive road maintenance,
- Adequate trafficability under wet and dry conditions,
- The ability to shed water without excessive erosion,
- Resistance to the abrasive action of traffic,

Source: Adapted from NAPA 1994.

Figure 10.6-12 Typical elastic modulus correlations to empirical soil properties and classification categories

- Freedom from excessive dust in dry weather,
- Freedom from excessive slipperiness in wet weather, and
- Low cost and ease of maintenance (McInnes 1982; Thompson and Visser 2000a).

The defects most commonly associated with mine haul roads, in order of decreasing impact on hauling operational performance, are typically as follows:

- Skid resistance—wet
- Skid resistance—dry
- Dustiness
- Loose material
- Corrugations
- Stoniness—loose
- Potholes
- Rutting
- Stoniness—fixed
- Cracks—slip, longitudinal, and crocodile. "Crocodile cracks" are cracks in a road caused by high plasticity/high clay content material shrinking when drying. This is a well-known phrase among the pavement design fraternity.

By examining which wearing course material property parameters lead to these defects, a specification has been developed for wearing-course materials selection. The specifications are based on an assessment of wearing-course material shrinkage product (*Sp*) and grading coefficient (*Gc*), defined in Equations 10.6-10 and 10.6-11:

$$Sp = \text{LS} \times \text{P425} \tag{10.6-10}$$

$$Gc = \frac{(P265 - P2) \times P475}{100} \quad (10.6\text{-}11)$$

where

LS = bar linear shrinkage
P425 = percent wearing course sample passing 0.425-mm sieve
P265 = percent wearing course sample passing 26.5-mm sieve
P2 = percent wearing course sample passing 2-mm sieve
P475 = percent wearing course sample passing 4.75-mm sieve

A suitable wearing course material can be determined from the selection chart (Figure 10.6-13) in terms of two parameters that describe the material: the grading coefficient (*Gc*) and shrinkage product (*Sp*). If the three most critical haul road defects are considered, it appears that mine road-user preference is for much reduced skid resistance and dust defects. This defines the focus point of the specifications to an area bounded by a grading coefficient of between 25 and 32 and a shrinkage product of between 95 and 130 in which the overall and individual defects are minimized (Area 1). Extending this region to encompass poorer (but nevertheless operable) performance enables an additional area (Area 2) to be defined.

The specification stipulates individual parameter limits but also has predictive capabilities that contribute to an understanding of the consequences when materials outside the specified ranges are used as wearing course materials. If the only materials available for wearing course selection lie outside the parameter limits, a mixture of those materials can be evaluated using the preceding guidelines. The proposed mix ratio can be used to define a new "mixed" material specification proportional to the mix ratio, from which *Gc* and *Sp* can be derived. In a similar fashion, an existing haul road wearing course can be successfully rehabilitated by adding an appropriate material to restore the mix to specification.

The specifications should also be evaluated in the light of other material property limits identified as important in functional performance but not directly assessed in Figure 10.6-13. Table 10.6-3 presents a summary of these property limits, together with the type of road defects most often associated with departures from the recommended parameter ranges.

Method Specification Notes for Functional Design

The method specification for placement of the wearing course depends on whether the haul road is being built from new or being rehabilitated (where material is mixed with the existing wearing course to bring it back to specification). For rehabilitation, the existing wearing course layer should be ripped and scarified and any large lumps of compacted material broken down to a maximum size of one-third of the compacted layer thickness. During the processing, the scarified layer should be ploughed or bladed to bring large lumps to the surface. An offset disc harrow can be used for this purpose. Material to be mixed should be dumped, opened, and mixed with the existing wearing course. Placement of the wearing course should proceed in two lifts of 100 mm, each compacted to 98% maximum dry density to give a minimum CBR of 80% using a large vibratory roller and with moisture content at or slightly dry of optimum. Material volumetric requirements must be determined such that the final thickness of the wearing course does not exceed 200 mm.

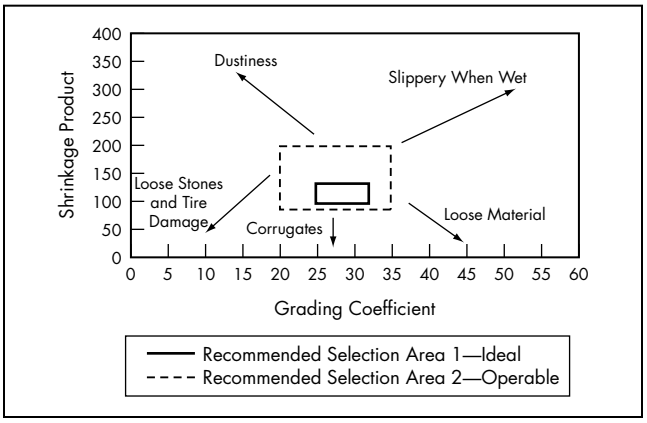


Figure 10.6-13 Haul road wearing course material selection

Estimating Haul Road Rolling Resistance

The rolling resistance of a haul road is primarily related to the wearing course material used, its engineering properties, and traffic speed and volume. These dictate to a large degree the rate of increase in rolling resistance. Ideally, road rolling resistance should not increase rapidly, which implies that those road defects (roughness defects) leading to rolling resistance should also be minimized. This can be achieved through careful selection of the wearing course material, which will minimize, but not totally eliminate, rolling resistance increases over time (or traffic volume).

To estimate rolling resistance at a point in time, an estimate of the roughness defect score (RDS) is required, and this can be determined from an initial estimate of the minimum and maximum roughness defect scores (RDSMIN, RDSMAX), together with the rate of increase (RDSI). Rolling resistance is then estimated from a minimum value (RRMIN) and the associated rate of increase (RRI). Equations 10.6-12 to 10.6-18 apply, together with the parameters and variables defined in Table 10.6-4. When using these equations, care should be taken to ensure the parameters limits are comparable to the values used in the original research (Thompson 1996).

$$RDS = RDSMIN + \left[\frac{RDSMAX - RDSMIN}{1 + \exp^{(RDSI)}}\right] \quad (10.6\text{-}12)$$

where

$$RDSMIN = 31.1919 - 0.05354 \cdot Sp - 0.0152 \cdot CBR \quad (10.6\text{-}13)$$

$$RDSMAX = 7.6415 + 0.4214 \cdot KT + 0.3133 \cdot Gc + 0.4952 \cdot RDSMIN \quad (10.6\text{-}14)$$

$$RDSI = 1.768 + 0.001 \cdot D(2.69 \cdot KT - 72.75 \cdot PI - 2.59 \cdot CBR - 9.35 \cdot Gc + 1.67 \cdot Sp) \quad (10.6\text{-}15)$$

$$RR = RRMIN + RDS \cdot \exp^{(RRI)} \quad (10.6\text{-}16)$$

where

$$RRMIN = \exp^{(-1.8166 + 0.0028 \cdot V)} \quad (10.6\text{-}17)$$

$$RRI = 6.068 - 0.00385 \cdot RDS + 0.0061 \cdot V) \quad (10.6\text{-}18)$$

Table 10.6-3 Recommended parameter ranges for mine haul road wearing course material selection

Impact on Functionality Below Recommended Range	Material Parameter	Range		Impact on Functionality Above Recommended Range
		Minimum	Maximum	
Reduced slipperiness but prone to raveling and corrugation	Shrinkage product	85	200	Increased dustiness and poor wet-skid resistance
Increased loose stones, corrugations, and potential tire damage	Grading coefficient	20	35	Increased raveling and poor dry-skid resistance
Reduced dustiness but loose material will ravel	Dust ratio	0.4	0.6	Increased dust generation
Increased loose stoniness	Liquid limit, %	17	24	Prone to dustiness, reduced raveling
Increased loose stoniness	Plastic limit, %	12	17	Prone to dustiness, reduced raveling
Increased tendency to ravel, loose stoniness	Plasticity index	4	8	Prone to dustiness and poor wet-skid resistance
Poor wet weather trafficability, churning, excessive deformation, and cross-erosion; maintenance intensive	Soaked CBR at 98% Modified AASHTO	80		Increased resistance to erosion, rutting, and improved trafficability
Ease of maintenance, vehicle-friendly ride, and no tire damage	Maximum particle size, mm		40	Poor surface finish following maintenance; potholing and potential tire damage

Table 10.6-4 Definition of parameters and independent variables used in the defect score progression model

Parameter	Description
RDS	Roughness defect score
RDSMIN	Minimum roughness defect score immediately following last maintenance cycle
RDSMAX	Maximum roughness defect score
RDSI	Rate of roughness defect score increase
RR	Rolling resistance, newtons/kilogram
RRMIN	Minimum rolling resistance at RDS = 0
RRI	Rate of increase in rolling resistance from RRMIN
Variable	**Description**
V	Vehicle speed, kilometers/hour
D	Days since last road maintenance
KT	Average daily tonnage hauled, kilotons
PI	Plasticity index
CBR	California bearing ratio of wearing course at 100% modified AASHTO compaction

Haul Road Dust Palliation

Dust generation is the process by which fine wearing course material becomes airborne. Such generation is termed a *fugitive* (or open) dust source. The amount of dust that will be emitted is a function of two basic factors:

1. The wind-erodibility of the material involved; and
2. The erosivity of the actions to which the material is subjected.

In broad terms, the effectiveness of any dust suppression system is dependant on changing material wind-erodibility or erosivity. The wearing course silt and fine sand fractions (i.e., between 2 and 75 μm) are a good indication of its erodibility.

The motivation for the use of some additional agent to reduce a material's inherent erodibility is based on increasing particle binding. The finer fraction, although contributing to cohesiveness, also generates much of the dust, particularly when the material is dry. The presence of larger fractions in the material will help reduce erodibility of the finer fractions, as will the presence of moisture but only at the interface between the surface and the mechanical eroding action. This forms the basis of the water-based dust suppression techniques used most commonly on mine haul roads.

The consequences of dust generation include

- Loss and degradation of the road pavement material, the finer particles being lost as dust and the coarser aggregates being swept from the surface or generating a dry skid-resistance defect;
- Decreased safety and increased accident potential for road users, because of reduced or obscured vision and reduced local air quality; and
- Higher vehicle operating costs (VOCs), with dust penetrating the engine and other components resulting in increased rates of wear and more frequent maintenance.

Many products available are claimed to reduce both dust and road maintenance requirements for mine roads. Often, however, no comprehensive, comparable, and controlled performance trials have been published. Additionally, incorrect application techniques and construction methods often result, which leads to considerable skepticism about such products and their overall cost-effectiveness.

From a mining perspective, the following parameters would define an acceptable dust palliative:

- Spray-on application with deep penetration (the ability to penetrate compacted materials) or, though less preferable, mix-in applications with minimal site preparation (rip, mix-in, and recompact)
- Straightforward applications requiring minimal supervision, not sensitive nor requiring excessive maintenance or closely controlled reapplications
- The road trafficable within a maximum of 24 hours (short product curing period)
- Availability in sufficient quantity at reasonable prices
- Adequate proven or guaranteed durability, efficiency, and resistance to deterioration by leaching, evaporation, ultraviolet light, and chemical reaction with wearing course or spillage on road
- Effective over both wet and dry seasons
- Evaluated against local and international safety standards and environmentally acceptable

Table 10.6-5 Dust palliative products and application parameters

	Hygroscopic Salts	Lignosulphonates	Petroleum-Based Products	Others (sulphonated petroleum, ionic products, polymers, and enzymes)
Climatic limitations	Salts lose effectiveness in continual dry periods with low relative humidity. Selection dependent on relative humidity and potential to water road surface.	Retains effectiveness during long, dry periods with low humidity.	Generally effective regardless of climate but will pothole (small diameter) in wet weather where fines content of wearing course is high.	Generally effective regardless of climate.
Wearing course material limitations	Recommended for use with moderate surface fines (maximum 10%–20% <0.075 mm). Not suitable for low fines materials or high shrinkage product/PI*, low CBR†, or slippery materials.	Recommended for use where high (<30% <0.075 mm) fines exist in a dense graded gravel with no loose material.	Performs best with low fines content (<10% <0.075 mm). Use low-viscosity products on dense fine-grained material, more viscous products on looser, open-textured material.	PI range 8–35. Fines limit 15%–55% < 0.075 mm. Minimum 98% maximum dry density. Performance may be dependent on clay mineralogy (enzymes).
Treatment maintenance and self-repair capability	Reblade under moist conditions. $CaCl_2$ is more amenable to spray-on application. Low-shrinkage product materials may shear and corrugate with high-speed trucks. Shear can self-repair.	Best applied as an initial mix-in and quality of construction important. Low-shrinkage product materials may shear and corrugate with high-speed trucks. Tendency to shear or form "biscuit" layer in dry weather—not self-repairing.	Requires sound base and attention to compaction moisture content. Slow speed, tight radius turning will cause shearing—not self-repairing but amenable to spot repairs.	Mix-in application—sensitive to construction quality. Difficult to maintain—rework. Generally no problem once cured.
Tendency to leach out or accumulate	Leaches down or out of pavement. Repeated applications accumulate.	Leaches in rain if not sufficiently cured. Gradually oxidizes and leaches out. Repeated applications accumulate.	Does not leach. Repeated applications accumulate.	Efficacy depends on the cation exchange capacity of the host material. Repeated applications accumulate.
Comments	A high fines content may become slippery when wet. Corrosion problems may result.	Generally ineffective if wearing course contains little fine material or there is excessive loose gravel on the road.	Long lasting—more effective in dry climates.	Generally ineffective if material is low in fines content or where loose gravel exists on surface. Curing period required.

*Plasticity index.
†California bearing ratio (%).

The broad classes of products available are described in Table 10.6-5.

The selection matrix in Table 10.6-6 can additionally be used to identify classes of palliative that would suit a certain application. However, the data does not specify the level of performance that could be expected, nor the average degree of palliation or degeneration rate expressed in terms of time from initial establishment and reapplication rates. This information would be required as a precursor to an economic assessment of the selected palliative benchmarked against the base case of water-based spraying.

A poor wearing course material cannot be improved to deliver an adequate performance solely through the addition of a dust palliative. The haul road wearing course material should ideally meet the minimum specifications presented earlier. If not, the inherent functional deficiencies of the material will negate any benefit gained from using dust palliatives. In road surfaces with too much gravel, dust palliatives do not appear to work effectively, more especially where a spray-on technique is used as opposed to a mix-in. The palliatives do not aid compaction of the surface because of the poor size gradation nor form a new stable surface. New surface area is created from exposed untreated material while, with a mix-in application, poor compaction leads to damage and raveling of the wearing course, traffic-inducing breakdown of the material, and eventual dust generation. With regard to water-soluble palliatives, rapid leaching may be problematic in some climates.

In compact sandy soils, tar and bituminous-based emulsion products appear effective where leaching of water-soluble products may be problematic. However, in loose medium and fine sands, bearing capacity will not be adequate for the tar/bitumen products to maintain a new surface, and degeneration can rapidly occur. In road surfaces with too much silt, it is unlikely that a dust suppression program will be effective. Excessive silt or sand fractions may lead to a slippery road, while poor bearing capacity leads to rutting and the need for road rehabilitation or maintenance, which destroys most products. Small-scale potholing has been observed on a number of pavements following spray-on application or reapplication, as a result of trafficking lifting fine cohesive material from the road. Again, where no depth of treatment has built up, this will lead to the creation of new untreated surfaces.

In general, spray-on applications do not appear appropriate for establishment of dust treatments, especially with regard to depth of treatment required. A spray-on reapplication or rejuvenation may be more appropriate, but only if penetration of the product into the road can be ensured; otherwise, it will only serve to treat loose material or spillage buildup, which will rapidly break down and create new untreated surfaces. A spray-on treatment is however useful

Table 10.6-6 Preliminary palliative selection matrix

	High PI (>10)	Medium PI (>5)	Sand	Wet Weather Trafficability	Ramp Roads	Heavy Traffic	Short Term	Long Term	Spray-On	Mix-In	Maintainable
Wetting agents		✓			✓		✓		✓I/R		
Hygroscopic salts		✓				✓	✓		✓R	✓I	✓M
Ligno-sulfonates	✓	✓	✓				✓	✓		✓I/R	✓SO
Petroleum emulsions	✓	✓	✓	✓	✓	✓	✓		✓I	✓I	
Polymer emulsions	✓	✓		✓	✓	✓		✓		✓I	✓SO
Tar/bitumen emulsions		✓		✓	✓	✓		✓	✓R	✓I	✓SR

Note: I = initial establishment application, R = follow-on rejuvenation applications, M = maintain when moist or lightly watered, SO = maintain with spray-on reapplication, SR = maintain with spot repairs.

to suppress dust emissions from the untrafficked roadsides, because it would be easier (and less expensive) to apply and, with the material typically being uncompacted, would provide some depth of penetration and a reduction in dust emissions because of truck-induced air turbulence.

When chemical-based dust suppressants are applied to an appropriate wearing course, the average degree of dust palliation and the period over which it is applied is often seen to be considerably better than that achievable by water-based spraying alone (Thompson and Visser 2002). However, in terms of cost-effectiveness, an evaluation is required with which to determine the extent of the cost benefits attributable to chemical-based dust suppression, together with an indication of those factors likely to alter the trade-off between water- and chemical-based dust palliation. A typical approach is illustrated in Figure 10.6-14.

Finally, it is worth noting that although tire chains are mostly limited to loading equipment, when dust palliatives are used, to maintain (treated) wearing course integrity, all tracked and tire-chained equipment should be kept off the road and either run along the road edge or be transported by low-bed trailers.

MAINTENANCE MANAGEMENT DESIGN

Design and construction costs for the majority of haul roads represent only a small proportion of the total operating and road maintenance costs; in particular, the use of an appropriate road maintenance management strategy has the potential to generate significant cost savings, particularly in the light of increases in rolling resistance because of the interactive effects of traffic volume and wearing course deterioration (Thompson and Visser 2003).

The management and scheduling of mine haul road maintenance has not been widely reported in the literature, primarily because of the subjective and localized nature of operator experience and required road functionality levels. In most cases, comment is restricted to the various functions comprising maintenance, as opposed to the management of maintenance to minimize total costs. Long (1968) suggests that adequate serviceability (functionality) can be achieved by the use of one motor grader (and water car) for every 45,000 tkm (metric ton–kilometers) of daily haulage. The U.S. Bureau of Mines' Minerals Health and Safety Technology Division (USBM 1981) in their report on mine haul road safety hazards confirm these specifications but without a clear statement as to what activities comprise road maintenance.

In addition to the lack of unanimous objectives in applying maintenance, the definition of maintenance as applied to mine haul roads varies from mine to mine. Table 10.6-7 summarizes these maintenance activities, modified for application to mine haul roads. The routine maintenance category is adopted here to describe the various activities envisaged for haul road routine maintenance. Table 10.6-8 summarizes the various routine maintenance systems that mines typically apply.

Routine maintenance is carried out on mine haul roads almost daily, depending on the functionality of the road and the traffic volume. The principal goals are to restore the road functionality to a level adequate for efficient vehicle travel with the aim of augmenting productivity and minimizing total road-user costs, and to conserve the integrity of the road wearing course by returning or redistributing the gravel surface.

Ad-hoc or scheduled blading is an inefficient means of road maintenance, with the potential to generate excessive costs due to overmaintenance or undermaintenance of the road. Ideally, an optimized approach is required with which to minimize total road-user costs. A maintenance management system (MMS) for mine haul roads is described here, following Thompson and Visser (2006) to address these needs.

Maintenance Management Systems

The ideal maintenance strategy for mine haul roads should be the one that results in the minimum total road-user cost because, in the case of mine haul roads, the agency maintaining the haul road network is directly affected by road-user operating costs. Two elements form the basis of road-user costs, namely road maintenance costs and VOCs. Both these cost elements are directly related to road condition or, more specifically, rolling resistance. The selection of a maintenance program for mine haul roads should be based on the optimization of these individual costs, such that total vehicle operating and road maintenance costs are minimized, as shown schematically in Figure 10.6-15.

Mine haul road maintenance intervals are closely associated with traffic volumes, with operators electing to forgo maintenance on some sections of a road network in favor of others. This implies an implicit recognition of the need to optimize limited road maintenance resources to provide the greatest overall benefit. This optimization approach is inherent in the structure of the MMS for mine haul roads. Two elements form the basis of the economic evaluation, namely

1. Haul road functional performance—rolling resistance increases with time/traffic, and
2. Vehicle operating and road maintenance cost increase with time/traffic.

The approach is suited to a network of mine haul road segments, as opposed to a single road analysis. For a number

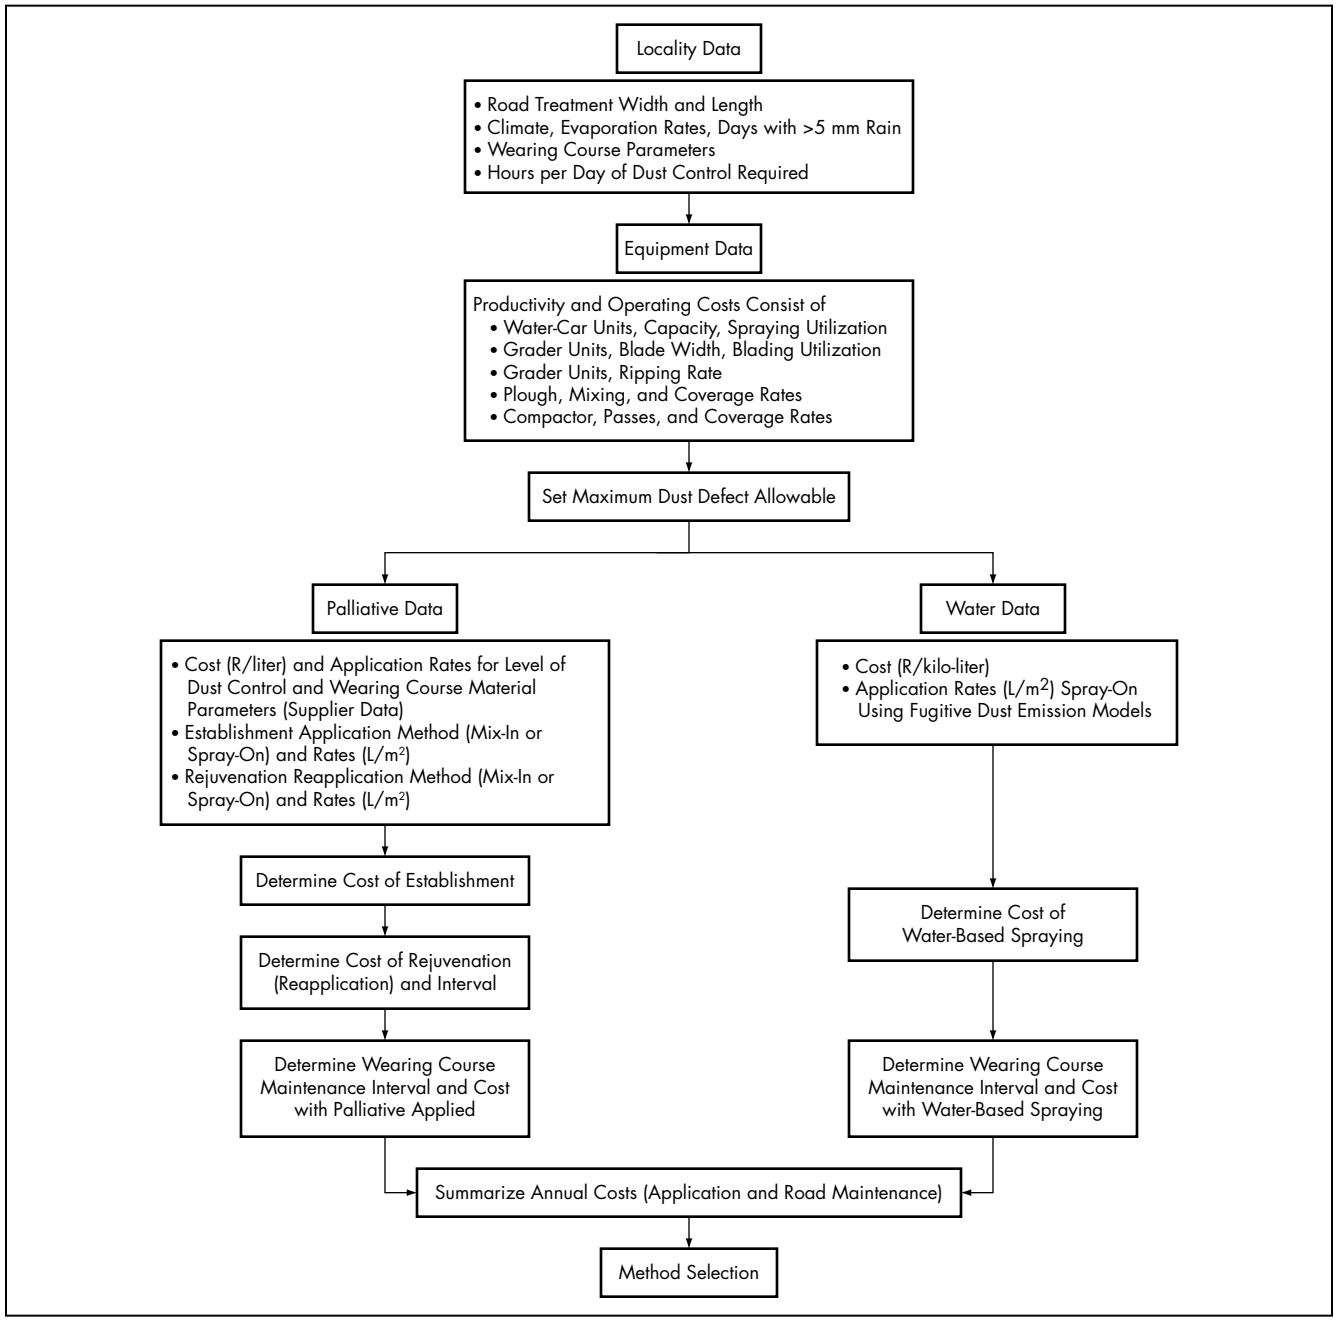

Figure 10.6-14 Basis of dust palliative cost–benefit evaluation

of road segments of differing functional and traffic volume characteristics, together with user-specified road maintenance and VOC unit costs, the model assesses

- Traffic volumes over network segments during the analysis period (as specified),
- The change in road as rolling resistance by modeling or on-site assessment,
- The maintenance quantities as required by the particular strategy,
- The VOCs (by modeling),
- Total costs and quantities, and
- The optimal maintenance frequency for specified segments of the network such that total road-user costs are minimized.

Figure 10.6-16 illustrates the MMS flow chart used to determine optimum maintenance interval for a mine road consisting of a number of road segments. Cost savings associated with the adoption of an MMS approach are dependant on the particular hauling operation, vehicle types, road geometry, tonnages hauled, and so forth.

The first element of an MMS for mine haul roads is based on modeling the variation of VOCs with rolling resistance. When combined with a road maintenance cost model, the

Table 10.6-7 Maintenance categories and activities for mine haul roads

Mode	Activity	Effect
Routine maintenance	Shallow blading Spot regraveling Drainage and shoulder maintenance	Fill minor depressions, reduce rolling resistance, exclude water. Reduce erosion and material loss, improve roadside drainage. Redistribute surface gravel.
Resurfacingt	Full regraveling Deep blading	Restore thickness of wearing course. Reprofile road and reduce rate of increase in rolling resistance. Remix wearing course material.
Rehabilitation	Rip, regravel, recompact	Improve, strengthen or salvage deficient wearing course.
Betterment	Rehabilitation and geometric improvement	Improve geometric alignment and structural strength.

Table 10.6-8 Routine mine haul road maintenance systems

System	Description
Ad-hoc blading	Reactionary maintenance management in response to poor haul road functionality. Typically managed by daily inspection of the road network and a subjective assessment of road segment functionality and maintenance priorities.
Scheduled blading	Road network is maintained according to a fixed schedule or frequency, irrespective of the actual functionality of the road segment being worked.
Maintenance management system	Road network is analyzed to determine rate of functional deterioration of individual segments, based on rolling resistance deterioration, traffic volumes, and so forth, and segment blading frequency is determined to minimize segment and network total road-user costs.

optimal maintenance strategy for a specific mine haul road commensurate with lowest overall vehicle and road maintenance costs may be identified.

Vehicle Operating Cost Model

The VOC model refers to the incremental cost of truck operation with changes in road rolling resistance. The cost model should consider the effect of increased rolling resistance on fuel consumption, tires, and vehicle maintenance. However, a reasonable approximation can be determined from fuel consumption alone. The prediction of fuel consumption variation with rolling resistance involves simulation with specific haul trucks to generate a speed model for various road grades. The speed model forms the basis of the fuel consumption model, derived from vehicle simulations coupled with vehicle torque/fuel consumption maps.

Road Maintenance Cost Model

The road maintenance operating cost per kilometer comprises both grader and water-car operating costs. Although not contributing directly to a reduction in rolling resistance, the incorporation of the watering costs in the maintenance costs model reflects (the ideal) operating practice in which, immediately before blading, the section of road is watered to reduce dust and erosion and to aid blading and recompaction.

Grader and water-car productivities of 0.75 and 6.25 km maintained road per operating hour for each machine, respectively, are typical and correlate with published figures of between 8 and 18 km of maintained road per 16-hour day. However, as the condition of the haul road deteriorates, maintenance becomes more time-consuming and the number of blade passes required to achieve an acceptable finish when the RDS exceeds 45 (equivalent to approximately 3% rolling resistance) increases. A maintenance productivity curve, shown in Figure 10.6-17, incorporates this reduction in grader productivity associated with excessively rough roads. RDS can be converted to rolling resistance through Equations 10.6-16 to 10.6-18. The road maintenance cost model is thus constructed from consideration of the average blade width per pass, road width, RDS before blading, motor-grader productivity curve, and hourly cost from which the motor-grader cost per kilometer is found. This cost is then combined with the cost per kilometer of the water-car and workshop costs to produce a total cost per kilometer for road maintenance.

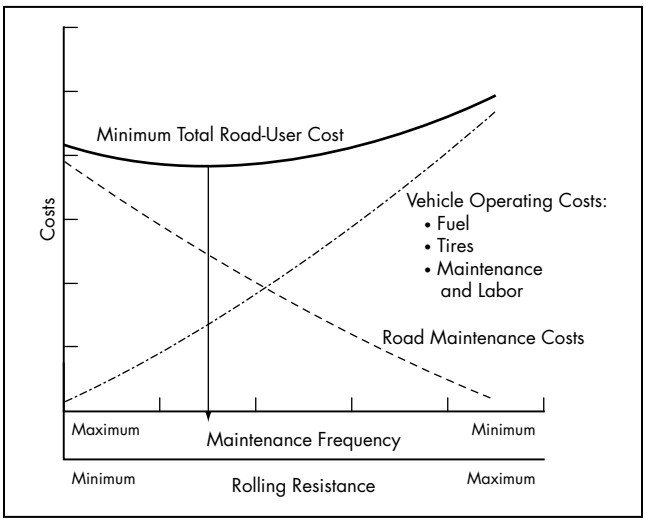

Figure 10.6-15 Minimum total cost solution and required road maintenance frequency from VOCs and road maintenance cost considerations for one segment of haul road network

Estimating Rolling Resistance from Road Visual Assessments

In addition to the estimation techniques for rolling resistance progression presented earlier in the chapter, rolling resistance can also be estimated from qualitative visual evaluation. A road defect classification system can be applied in which the key defects influencing rolling resistance are identified and the product of defect degree (measured from 1–5) and extent (measured

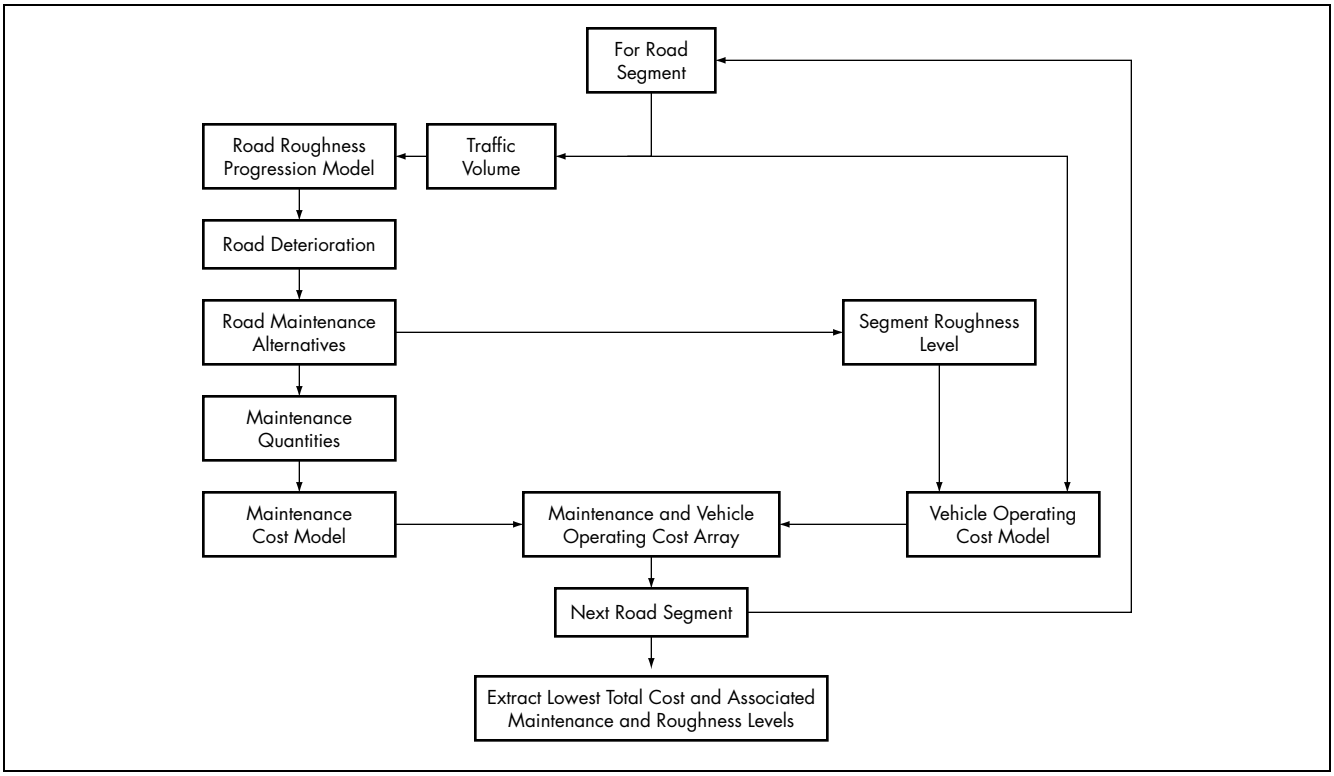

Figure 10.6-16 Flow diagram of MMS for mine haul roads (for a single maintenance strategy iteration)

from 1–5) are scored (following Table 10.6-9). The sum of the individual defect scores thus rated (equivalent to the RDS discussed previously) can be converted using Figures 10.6-18 and 10.6-19 to give a rolling resistance for the segment of haul road under consideration. More details of the approach and aids to visual evaluation of defects are given by Thompson and Visser (2006).

CONCLUSIONS

To design and operate optimally efficient and safe mine roads requires an integrated road design and management strategy. Specifically, through addressing the requirements of each aspect of road design (geometric, structural, functional, and maintenance management), rolling resistance can be optimized and total road-user costs minimized across a network. Implicit in the approach is the need to evaluate the contribution of various segments of the road network to the total cost of haulage, and prioritize resources to where they deliver the most benefit in terms of reducing cost per metric ton hauled.

Targeting haul road improvement strategies should be based on recognizing the root cause of underperformance. When geometric design is optimized and potential problems are identified and corrected, the structural design methodology can be used to reduce rolling resistance by minimizing deflection and deformation of the road structure beneath the vehicle wheels. Improving functionality of a haul road is based on the optimum wearing course material selection parameters. To achieve this optimum, an operation should evaluate its current or proposed wearing course and recognize what material deficiencies exist, as a route to determining which additional or new materials or palliative products should be added to bring the wearing course to specification.

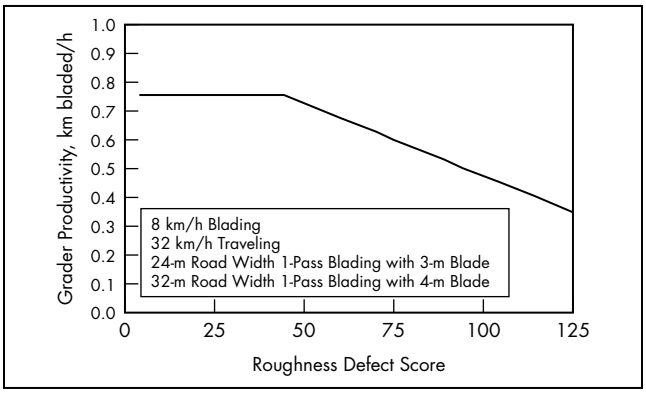

Figure 10.6-17 Productivity of a motor-grader during routine haul road maintenance operations

By using a modeling or visual evaluation system, both as a basis for rolling resistance evaluations and maintenance interventions, mines will be able to recognize recurring defects on the road and target improvement strategies, because the root cause for underperformance can be recognized. In the longer term, the approach can be used as a basis for planning strategic improvements by identifying the specification parameter and performance deficiencies across the network of roads. Segments of the network can then be selected for upgrade based on the costs of repair measured against the benefits derived from total road-user cost reduction over the operating life of the segment.

Table 10.6-9 Defect degree and extent scores for rolling resistance evaluation

	Description of Defect Extent or Degree				
Extent Score	**1**	**2**	**3**	**4**	**5**
Extent	Isolated occurrence, less than 5% of road affected	Intermittent occurrence, from 5% to 15% of road affected	Regular occurrence, from 16% to 30% of road affected	Frequent occurrence, from 31% to 60% of road affected	Extensive occurrence, more than 60% of the road affected
Defect Degree Score	**1**	**2**	**3**	**4**	**5**
Potholes	Surface pock marked, holes are <50 mm diameter	Potholes 50–100 mm in diameter	Potholes 100–400 mm in diameter and influence riding quality	Potholes 400–800 mm in diameter, influence riding quality, and obviously avoided by most vehicles	Potholes >800 mm in diameter, influence riding quality, and require speed reduction or total avoidance
Corrugations	Slight corrugation, difficult to feel in light vehicle	Corrugation present and noticeable in light vehicle	Corrugation very visible and reduces riding quality noticeably	Corrugation noticeable in haul truck and causing driver to reduce speed	Corrugation noticeable in haul truck and causing driver to reduce speed significantly
Rutting	Difficult to discern unaided, <20 mm	Just discernable with eye, 20–50 mm	Discernable, 50–80 mm	Obvious from moving vehicle, >80 mm	Severe; affects direction stability of vehicle
Loose material	Very little loose material on road, <5 mm depth	Small amount of loose material on road to a depth of 5–10 mm	Loose material present on road to a depth of 10–20 mm	Significant loose material on road to a depth of 20–40 mm	Loose material, depth >40 mm
Stoniness—fixed in wearing course	Some protruding stones, but barely felt or heard when traveling in light vehicle	Protruding stones felt and heard in light vehicle	Protruding stones influence riding quality in light vehicle but still acceptable	Protruding stones occasionally require evasive action of light vehicle	Protruding stones require evasive action of haul truck

CHAPTER 10.7

Surface Ore Movement, Storage, and Recovery Systems

Sergio Zamorano

INTRODUCTION

After the mineral products are extracted from an underground or surface operation, they need to be moved, stored, and recovered before being treated further or sold to external clients.

Traditional and small operations are based on small-scale discontinuous movement of materials that are labor intensive. The trend of the industry is toward larger continuous systems with increased automation levels. While in the first part of the 20th century a 1,000-t/h (metric tons per hour; 1,100-stph [short tons per hour]) operation could have been classified as large, volumes of 10,000 t/h (11,023 stph) are quite common today. Some continuous operations reach 40,000 t/h (45,000 stph), and several mining operations reach levels close to 1 Mt/d (million metric tons per day [1.1 million stpd]) between ore and overburden removal. In most open-pit mines, the volumes of overburden and waste rock required to be moved are much larger than the ore volume. Ratios between waste and ore of 2 to 6 are quite common; they can get as high as 30 before an underground operation becomes a better option. The old paradigm of abundant and cheap labor in third-world countries is disappearing: Globalization brings common standards for environmental and safety requirements at the same time that economic development reduces the income gap between First and Third World countries. Thus, regardless of its location in the world, any operation needs higher productivity and continuous improvements to remain competitive.

This chapter will discuss the most common methods to move, store, and recover ore used in mineral operations, including newer developments and developments foreseen for the near future. The intent is to give a general overview in the limited space available, keeping in mind that a comprehensive and in-depth discussion goes beyond the intent of this handbook.

ORE MOVEMENT

This section reviews transport systems in which the payload is motionless in relation to the transporting media (truck haulage; rail, marine, and multimodal transportation); and belt conveyors and stationary systems in which the material is in motion during transport.

Truck Haulage

The loading and transportation of mined products by truck within the mine and to the processing plant are discussed in detail in other sections of this handbook that deal with surface mining and underground mining. Mine operations use underground or off-road-type trucks, for which design and size evolve continuously.

Large off-road trucks have reached capacities of up to 364 t (400 st) with gross machine weights around 625 t (688 st; Caterpillar, n.d.). In the past, large off-road trucks were mostly diesel-electric, with direct-current (DC) wheel drives; however, the newer, larger trucks have mechanical transmissions or alternate-current (AC) wheel drives. Recent developments include autonomous trucks for both underground and surface operations (Komatsu 2008) that are aimed at increasing reliability and safety while reducing labor requirements.

Trolley-assisted trucks have been in operation in southern Africa since the 1980s. A pantograph is used to connect an overhead trolley line, which feeds energy directly to the truck's electric wheel motors (Figure 10.7-1) while the diesel engine runs idle. Used on inclined ramps, the system allows savings in fuel consumption while the truck can climb faster and thus operate with higher efficiency (Alvarado 2009). The advantages of a trolley line are linked to the availability of cheap electrical energy and to high fuel costs. Initial designs had DC electrical feed; the advent of AC trucks has allowed the use of simpler and lower-cost AC distribution lines.

Off-road trucks are intended not for long-distance haulage, but for operations with complex deposits and multiple loading points. It is not unusual to find them operating on routes several kilometers long.

Long hauls are also common for overburden handling, where more effective transportation methods such as conveyors require the sizing of the mined material, as opposed to the trucks than can handle run-of-mine material without any further size reduction beyond blasting. As pits grow and become deeper, overburden has to be lifted more and more and deposited at ever-increasing distances as waste dumps are filled.

Transportation of mined products to market by road is less significant on a volume and distance basis than other

methods (e.g., rail or marine transportation). However, trucking is often involved at some stage of the transport chain between producer and final customer. The flexibility of trucks is diminished by the high cost per metric ton per kilometer, or per ton per mile, over longer distances.

Trucks designed for the movement of bulk minerals on standard roads are divided into three general classifications. The first and most common is the end-dump design. A variation of the standard design is the frameless trailer, in which the dump body is self-supporting. The objective with this custom design is to gain more payload while staying within the load limitations imposed by traffic authorities. Another alternative to increase payload is the use of aluminum construction in the trailer, normally employing extruded sections. The second classification is that of bottom-dump design. A special unloading facility is required, normally a long grated hopper over feeders and conveyors; the truck drives over the hopper to discharge the load. This design offers a fast unloading cycle, but at the expense of custom-designed truck bodies and significant civil works associated with underground structures. The third classification is the side-dump design (Figure 10.7-2). The advantage here is a faster unloading

Figure 10.7-3 Truck load-out station

cycle, although larger receiving hoppers are required than for the end-dump design.

The typical bulk-handling truck is composed of a tractor unit and a trailer or semitrailer attached to it. On long distances it is quite common to use longer combination vehicles that allow trucks to haul more on a single trip. They usually have a tractor unit that pulls two or three trailers. This type of truck is allowed in some states in the United States, mostly in the western part of it. They are also used in Canada, Argentina, and other countries, mostly in remote areas and where access roads are relatively flat. Australia allows the use of even longer vehicles; some Australian states allow the use of triple and AB-quad road trains that are up to 53 m (174 ft) long and weigh up to 170 t (187 st). The use of powered trailers allows for even larger combinations, with long-distance haulage systems reaching payloads up to 350 t (386 st).

The transport of small-size and dusty bulk materials is normally done using pneumatic trailers. Air pressure is used to discharge and transport the material through hose or piping directly into the storage container. The truck body is divided internally, so the bulk cargo can be gravity fed to the discharge ports. Airflow allows the material to move through the discharge pipe to its destination. Typical trailer capacity is 28 m^3 (1,000 ft^3). These trailers normally are used to transport fine and free-flowing material (e.g., cement and limestone) used as a reactive in mineral concentrators.

Dump trucks are loaded most of the time using front-end loaders or similar equipment. However, on high-capacity applications, loading bins are used at times (Figure 10.7-3), enabling 300-t (331-ton) trucks to be loaded in 60 seconds. Crushed material is loaded onto trucks to be placed on a heap and leached.

Rail Transportation

In smaller operations, common carriers generally handle rail transport, which is therefore outside the scope of the mining

company. However, the mine retains control of loading and unloading the trains and can influence the decision of the type of trucks to be used.

In a small to medium-size operation, partial train load can be used. The normal procedure is for the common carrier to drop off the required empty cars. Since the loading time is not a critical factor, the plant operator moves the empty cars to position them under a loading point with a car puller or a shifting locomotive. Most carriers charge per car, not per ton, of material transported; however, they do penalize the plant if the cars are overloaded. Therefore, controlling the loading accurately makes economic sense as it minimizes transport cost. This is accomplished by using weigh belt conveyors or track scales.

For throughputs ranging up to several million metric tons per year, it is normal to use unit trains. A unit train is a freight train composed of cars carrying a single type of commodity to the same destination, running nonstop between the loading and unloading points. This results in reduced transit time and lower transport cost. American railway companies introduced the unit train concept in the 1950s for the transportation of coal from mines to power plants. By the late 20th century, about 50% of the coal shipped in the United States was carried by these types of trains, typically in convoys of 100 cars. Other bulk cargoes transported by unit trains are cement and minerals such as iron ore. The largest train ever run in the world was a unit train carrying iron ore in Western Australia. The train consisted of 8 locomotives and 682 loaded wagons, carrying more than 80,000 t (88,185 st) of ore over a distance of 275 km (171 mi) to the port. The train was more than 7 km (4 mi) long. Today, trains with more than 200 cars and over 25,000-t (27,558-st) capacity transport iron ore daily in northwestern Australia, with more than one train per hour per line. Some of these trains are fully autonomous. Trains of comparable size are operated for iron ore transport in South Africa and Brazil as well as other countries. It is quite common in larger operations to have a dedicated railway and port owned and operated by the mine owner or a consortium of mine owners that handle the same commodity.

The need to load larger trains in an efficient and accurate way led to the development of specialized loading stations (Fletcher 1997). To load a train efficiently, it is necessary to ensure that the full unit train can be loaded—that is, that sufficient storage is required. A reliable, accurate, and fast loading system and a device to move the train through the load station are also required. The most common type of high-capacity train-loading plant is the flood loading system, in which the height of the material in the wagon is controlled by a profile chute while the discharge gate is controlled by photocells that monitor the position of the wagon. Two in-motion scales are installed, one before the loading system and one after, so the amount of material loaded in the wagon can be measured. Material loaded into the wagon is measured after the operation. The accuracy of the amount loaded depends on the dimensional and suspension consistency of the wagons.

The need to maximize the loading of each wagon without exceeding the maximum gross weight allowed on the tracks led to the development of the flask loading system in the 1970s in South Africa. In this system, the material is loaded onto a weigh flask first. When the required load is achieved, the gate from the storage bin is closed and the gate to the profile chute is opened, and the wagon is loaded with a predetermined load. Train load can be controlled accurately up to capacities of 8,000 t/h (8,818 stph).

In some installations, a silo with a capacity comparable to the train capacity is used. Lower-capacity systems fill the silo before the train arrives so that train-loading time is minimized. Typical silos have a capacity up to 12,000 t (13,228 st). Another option would be to use a smaller silo linked to a large storage system, such as a stockpile. In this instance, a larger loading system (operating at a capacity equal to the load-out rate) is required. This option is preferred when loading large unit trains having more than 100 wagons.

Losses of material due to wind can be reduced by applying crusting agents to the mineral surface. On fine and environmentally sensitive materials, such as mineral concentrates, railcars are covered.

When high tonnage rates are not required and capital expenditure needs to be minimized, the use of bottom-dump hopper cars is the logical choice. Normally, car movers are used to position the car over a hopper, and the bottom gates are opened manually to discharge the contents to the hopper. Feeders and conveyors or elevators are used to take the material to its final destination.

One way to obtain higher discharge rates is to use a trestle structure over a storage area. The loaded cars are tripped open by a device alongside the truck and are emptied while in motion. The disadvantages of this method are the additional capital and maintenance costs of the cars with special quick-opening doors and potential environmental dust problems when the material is dumped from the top of the trestle to the ground. At an installation recently built in Germany, the railcars are discharged over a 6.4-m- (21-ft-) wide belt that transfers the material at a rate of 17,000 t/h (18,739 stph). Of course, in this case, a higher discharge rate justifies the high capital and operational costs.

Extreme cold weather can cause the material to freeze if the cars are left to sit idle or the traveling time is long. This can cause serious operating problems when attempting to unload the cars. If this is a normal situation, a car-thawing system is required. Even then, large frozen lumps might form and will have to be broken up before going into the receiving system.

It can also be hard to unload fine materials after a long trip. This is particularly true with some mineral concentrates having a high moisture content that are loaded into the trains. Vibration and heat during the trip causes the material to consolidate, making car unloading very difficult. On relatively short distances and low throughputs, round "pots" are placed over flat cars, and the cars are overturned with the help of a crane during unloading. Vibrators or "beaters" are used to loosen up material stuck to the pot. When transporting mineral concentrates over long distances (several hundred kilometers), it becomes harder to unload the cars. One method that is used successfully is to place a backhoe excavator on a platform over the cars and excavate the material out. Throughputs up to 700 t/h (772 stph) are achievable in this fashion.

Unit trains are normally discharged using a rotary car dumper to achieve a high unloading rate. Each car is turned upside down and the contents discharged into a large hopper that feeds a conveying system leading to the storage location. Traditionally, it was necessary to uncouple each car so that it entered the dumper unattached. Newer, higher-capacity systems use rotary couplers that permit dumping without separating the cars. Also, high-capacity systems have twin dumpers that allow the discharge of two cars at the same time.

A high unloading rate is linked to the ability to move the cars in and out of the dumper quickly. To this effect it

is common to use a shifting locomotive with local or remote control. These units can handle a group of cars or an entire unit train. An alternative is the employment of a remotely controlled train positioner that can handle a full unit train. The device uses a pickup arm or arms to push the train one or two car lengths (depending on whether it is a single or twin dumper arrangement). While the cars are unloaded, the arm moves to the next car or cars. This type of operation requires the use of rotary couplers to prevent uncoupling of the cars.

Environmental regulations now require effective dust control by means of dust suppression or dust extraction systems. In most cases today, the installation for car dumping is entirely enclosed.

Marine Transportation

The vast majority of long-distance transportation of bulk minerals is done using marine transportation, coupled in most cases with some degree of overland transport. The capital and operational costs of loading and unloading equipment are outweighed by the low cost of water transport. The continuous growth of international trade has resulted in the transport of increasingly large amounts of bulk minerals down rivers and across the oceans. The largest transport volumes are associated with coal (steam and metallurgical) and iron ore, each representing about 800 Mt (882 million st) transported by sea every year (VK 2005; WSA 2009).

Inland marine transportation allows large amounts of low-cost minerals to be moved to final destinations at a cost per metric ton per kilometer (or per ton per mile) that is among the lowest for this process. In the United States, the Mississippi River system is used to transport about 50 Mt (55 million st) per year of coal—approximately 10% of the coal transported within the country. Barges are also used extensively in Europe for the inland transport of iron ore and coal. Barges can be self-propelled or towed by tugboats, or they can be pushed by towboats in a series of several barges at the same time. For example, a 10,000-hp towboat can push up to 30 barges down the open-river section of the Mississippi River to the Gulf Coast. Barge dimensions are limited by lock sizes in the area in which they operate. A typical barge is about 60 m (197 ft) long and 10 m (33 ft) wide with a loading capacity of approximately 1,350 t (1,488 st).

Ship Loading

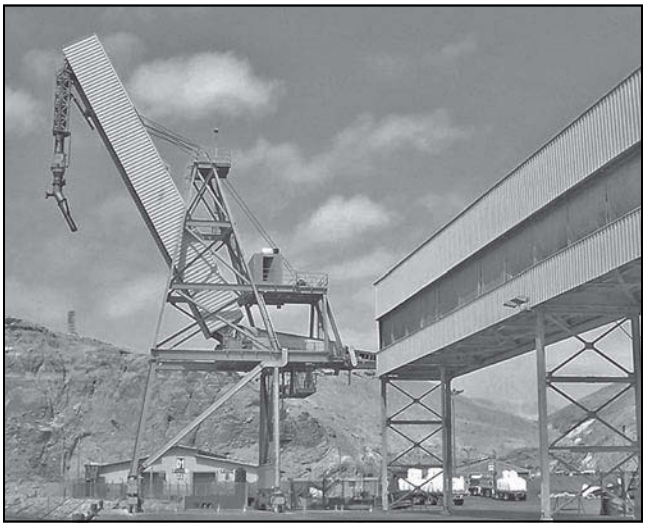
Typical barge-loading systems include a fixed loading conveyor that discharges directly onto the barge. The barge is moved as necessary by a barge puller that is basically a system of winches and cables.

Various methods are employed to unload barges. The traditional method is the clamshell-type unloader. Other designs include continuous unloading systems with bucket-chain unloaders or bucket-wheel unloaders. In coal and iron ore applications, these systems can achieve capacities up to 5,000 t/h (5,511 stph).

For fine materials, pneumatic unloaders are used. They can be stationary, mobile within the dock area, barge mounted, or fully mobile (mounted on a truck). Materials such as cement are normally handled using pressure conveying; coarse and abrasive materials such as lime, alumina, and petroleum coke are handled using vacuum systems.

In locations without proper infrastructure, load from barges is transferred directly to ocean vessels. In relatively low-tonnage operations, this is done using the ship's cranes. Larger operations use custom-made ships to transfer the load using clamshell or continuous systems.

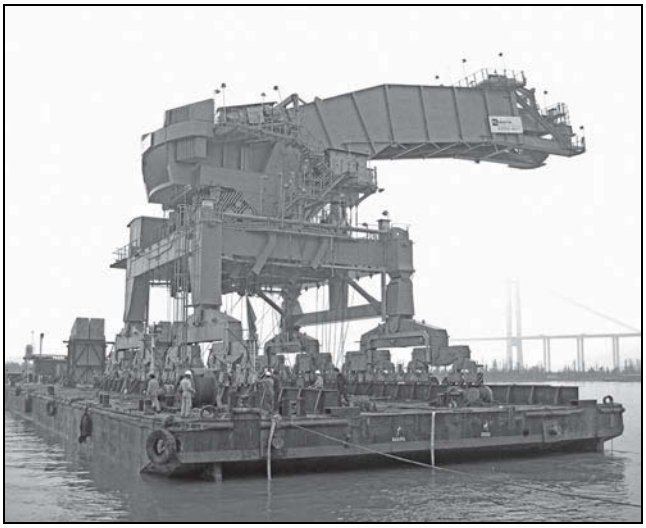
Ocean transport of minerals involves four main types of ships, namely Handy, Handymax, Panamax, and Capesize. Handy and Handymax sizes are the most common, with deadweight (dwt) ranging from 10,000 to 39,000 t (11,023 to 42,990 st) for the Handy type and between 40,000 and 59,000 t (44,092 and 65,036 st) for the Handymax type. They are used for multiple cargoes, either broken or bulk. In bulk materials they are limited to either short-distance transportation or the transport of low-volume, high-value cargoes such as copper concentrate. Panamax-size vessels are the largest ships that can go through the Panama Canal, and their deadweight fluctuates between 60,000 and 80,000 t (66,139 and 88,185 st). Their maximum draft is 14 m (45 ft), and they have less than 36 m (118 ft) beam. They are the most common type of vessel used for moderate and large volumes of bulk solids transported over long distances. Capesize vessels are not limited in size other than by port capacities. The most common sizes vary between 130,000 and 180,000 dwt. Some of the largest bulk carriers exceed 300,000 dwt, being as long as 340 m (1,115 ft) with a draft of 28 m (92 ft) and a beam of 60 m (197 ft).



As volumes transported grow steadily, the tendency is toward using larger ships. In this way, both operating costs and carbon emissions are reduced.

There are several ways of loading bulk materials onto a ship. On low-capacity operations, fixed single-point loaders are used, and the ship is moved to load the different hatches. This is by far the simplest and cheapest way to load a ship. Telescopic heads, tilting telescopic chutes, and/or loading spouts are used to distribute the material inside the ship hull. On berths used for multiple purposes, mobile conveyors and loaders are also used. When loading is completed, the conveyors and loaders are removed to leave the area open for other uses.

As transported volumes increase, so do ship size and the number of hatches to be loaded. In these cases, the low efficiency of a single loading point doesn't make economic sense since the loading operation has to be stopped frequently to reposition the ship. Moving a large ship generally involves a tugboat or a large crew to operate the ship's winches. It is possible to reduce ship movement and loading interruptions by using a radial stacker that can rotate from the hatch.



A traveling ship loader moves along a wharf, normally on rails, so it can move from one hatch to another, making it unnecessary to move the ship. The ship loader is normally fed by a conveyor parallel to the wharf and a tripper car. In most installations, the feed conveyor is installed inside an enclosed gallery (Figure 10.7-4). In this case, the boom conveyor can lift its boom, so it can move easily from hatch to hatch. This type of loader is relatively inexpensive; most operational costs are related to the civil cost of the continuous wharf and the structure of the elevated gallery. The loader depicted has a tilting telescopic chute and a rotating loading spout that allow for better trimming of the load in the ship.

Another type of traveling ship loader has a slewing boom. In some cases the boom is of fixed length; in others it is telescopic, which allows for an optimum distribution of the load on the ship. This factor is quite relevant with low-density materials such as coal, for which trimming the material is more complex, than with high-density materials such as copper concentrate and iron ore. In the case of a slewing boom, the machine needs to have an intermediate feed conveyor

Courtesy of FLSmidth Spokane, Inc.

Figure 10.7-4 Traveling and luffing ship loader

Courtesy of FLSmidth Spokane, Inc.

Figure 10.7-5 Traveling, slewing, luffing, and telescopic ship loader being transported to operating location

that connects the feed and the boom conveyors. Another variation uses a ground-level conveyor with a large tripper car that feeds a luffing, slewing, and telescopic loader that is parallel to the ship. This type of unit can load ships on either side of a dedicated wharf. Figure 10.7-5 shows a 14,000-t/h (15,432-stph) ship loader being transported fully assembled to its final destination. It is a common practice to assemble large port equipment on a barge while traveling and then move the equipment directly into its working position.

When the port is dedicated exclusively to the loading of bulk materials, the cost of the wharf can be minimized by using mooring dolphins to support the ship-loading system. A design that allows the loading of multiple hatches with a minimal civil cost is the so-called quadrant ship loader. It is formed by a fixed-span bridge that turns around a fixed point on the land side while traveling over a curved runway on the water side. A shuttle boom assembly travels over the bridge. The radial movement of the boom and the slewing bridge combine to provide access to the ship hatches. This type of loader can load ships from Handy to Panamax sizes without requiring movement of the ship during loading operations. The cost saving in civil structures is offset by the higher cost of the machine.

A variation of the quadrant ship loader is the linear loader, in which the runway is straight and the bridge moves back and forth over an inverted carriage mounted at the pivot point, thereby changing its span. A further development is the dual linear ship loader, in which a slew bearing and an inverted carriage are mounted on the carriage traveling on a runway parallel to the ship. The loading point is mounted over a fixed pivot and a shuttle boom is mounted over the bridge.

For larger ships (e.g., Capesize vessels), dual arrangements of quadrant or linear ship loaders are sometimes used (Dibben 2006).

Ship Unloading

Unloading ships is a significant part of the transport cost of minerals. The most common system used to unload ships is the clamshell bucket. In Handy- and Panamax-type vessels, it is quite common to use the ship's own deck crane to unload the material at smaller rates up to 300 t/h (331 stph). This type of ship is referred to as a geared vessel.

Dock-mounted clamshell unloaders can be classified into two main categories: crane and portal. Normally the unloaders are used in a fixed position and operate at capacities up to 700 t/h (772 stph). Some units are capable of moving along the wharf, but it is more common to use two cranes simultaneously to unload a Handy or Panamax ship. For larger capacities and ships (e.g., Capesize vessels with capacities up to 2,500–3,000 t/h [2,756–3,307 stph]), portal clamshell unloaders are frequently used. Again, using two unloaders simultaneously is quite common. The efficiency—or the actual average unloading rate achieved from start to finish divided by the free digging rate—is normally 50% or less. The ship's hold is cleaned by small earthmoving equipment that is lowered into the hold area. The need for extensive cleaning associated with clamshells is larger for smaller ships that have smaller holds, reducing the efficiency accordingly.

The need to improve efficiency and reduce ship turnaround times has prompted the development of continuous ship unloaders. A relatively lightweight continuous-unloading solution is the vertical screw system, which draws the material from the ship's hold and transfers it to a transfer conveyor belt. Fine materials can be handled at relatively low capacities in this fashion.

Higher capacities can be achieved using a bucket-chain continuous unloader. The lower demurrage cost and higher utilization of this type of unloader balance the higher cost when compared with the clamshell unloader. There are several variations to this design that include steel buckets on steel chains and steel buckets on rubber belting. Rubber pocket belts or sandwich belts loaded by bucket wheels are also used. Once the material is elevated above the ship's deck it is transferred to a belt conveyor, which transfers the material to a dock conveyor and port storage.

When fine and dusty materials are involved, pneumatic unloaders, either stationary or mobile, are normally used. Gantry-type unloaders can unload vessels up to 50,000 dwt.

Great Lakes, coastal, and Gulf of Mexico transport comprise a significant part of the mineral transportation market in North America. The basic differences between the ships used

in these environments and in oceangoing applications are size and draft. Although some self-unloading ships are used in ocean bulk transport, the majority of these vessels are found in the Great Lakes and the Gulf of Mexico. However, they are also used in Northern Europe and East Asia (OSC 2002) for transport distances up to 5,000 km (3,107 mi).

In most cases, the ship cargo holds have a W-shaped bottom with several hydraulically operated gates that discharge the material onto a belt-conveyor arrangement. The material is carried to deck level using sandwich-type belts or rubber pocket belts. A boom conveyor transfers the material to a hopper and conveying system on the dock or, in some cases, directly onto the ground. High unloading rates can be achieved with free-flowing materials.

The relatively short transport time and shorter unloading time offset the machinery cost and lost payload capacity on lake and coastal applications. Short travel time also reduces the probability of material consolidation and arching caused by long marine trips. Another alternative is the use of hybrid vessels that add a system of hoppers and conveyors to a conventionally outfitted ship. Most of the advantages of the self-unloading ship are obtained for a limited cost, but discharge rates are limited because of crane capacity.

Multimodal Transportation

Conventional transportation involves the use of a separate contractor or operator for each type of transport (i.e., trucks, railway, and marine). Multimodal transportation covers "door-to-door" delivery by a single transport operator, even when transport through several countries is involved. This method of delivery was developed during the container revolution of the 1960s and 1970s. Today, most multimodal cargo is containerized; however, it is different than typical container transport.

Most minerals are transported in bulk rather than in packaged or break-bulk shipments. However, some sophisticated or friable bulk minerals can be loaded in standardized marine containers or packed in flexible intermediate bulk containers (FIBCs) also known as Big Bags, Bulk Bags, or Super Sacks. The FIBCs have capacities from 500 kg (1,102 lb) up to 2 t (2.2 st), with volumes up to 3 m^3 (106 ft^3). FIBCs are normally made out of polypropylene or canvas fabric.

Regardless of transport method—container, bulk, or FIBC—it can be handled in a multimodal fashion.

Belt Conveyors

Since their introduction in the first half of the 20th century, belt conveyors, due to their simplicity, universality, and reliability, have become indispensable in the layout of facilities that store or process bulk solids. Belt conveyors allow optimal use of floor space and maximum flexibility in the design of the material flow scheme. While capital cost comparisons between conveyor and truck haulage are dependent on the application, operating costs of a conveyor system are far lower. In general, the larger the throughput of the system, the greater the operational savings when compared with an equivalent truck operation. Current technology allows single-flight belts with lengths up to 20 to 30 km (12.4 to 18.6 mi); the longest system in use is 100 km (62 mi) long and has been in operation since the 1970s.

Although most conveyors use 35-degree troughing idlers and three equal rolls, different troughing angles and idler configurations are employed in some operations. Speeds vary from less than 1 m/s (3.3 ft/s) on some short conveyors up to 8.5 m/s (28 ft/s) on selected overland conveyor applications, and even up to 15 m/s (49 ft/s) on spreading conveyors that handle up to 40,000 t/h (44,092 stph). Maximum belt width is limited to 3.2 m (10.5 ft) using conventional manufacturing techniques, although belts can be spliced along their axes to produce even wider belts. Belt width is normally determined by belt capacity, operating speed, and maximum lump size.

Conventional wisdom says that short conveyors handling large lumps are operated at low speed, whereas longer conveyors can be operated faster without compromising belt life and system availability. Belt width must be more than three to five times the maximum lump size of material to be handled. The higher the proportion of large lumps, the closer to five the factor should be. Lump size is defined as the maximum dimension of one side of a piece of material. It should not be confused with crusher opening or dimension of the screen mesh that the material passes through. On slab-like materials, the longest dimension can be up to five times the other dimensions or the opening that the lump has passed through.

The advent of bulk flow simulation techniques such as DEM (discrete element modeling) has made it possible to design transfers that reduce belt wear and tear from the beginning of a project and, therefore, limit the trial and error used in the past. That said, it is important to note that properties of bulk solids can vary widely, so proper testing is required. Even then, modeling can have limitations. Poor transfer design can lead to premature belt wear, poor tracking, material degradation, and dust generation.

There are several published guides for conveyor design. The Conveyor Equipment Manufacturers Association (CEMA) handbook is widely used both in North America and abroad to design conveyors (CEMA 2007). The CEMA book contains recommended practices from the North American conveyor equipment manufacturers and considers a simple calculation method for regular installations that has changed very little since the 1960s. The sixth edition, published in 2007, incorporated a universal calculation method in line with modern research and experience in large systems. Other publications such as DIN (Deutsche Institut für Normung) standards contain regulations about belt rating, component testing, and other aspects of conveyor design.

In long conveying systems, the aim is to reduce the number of transfers to the minimum possible; of course, this is limited by available technology and economic factors. With longer conveyors, vertical and horizontal curves are used to follow the terrain and bypass natural obstacles along the desired route (Figure 10.7-6). Currently, most long conveyors use steel-cord belts. In shorter conveyors, polyester/nylon fabrics (known as EP fabric) have replaced nylon/nylon and cotton fabrics used in the past.

Downhill conveyor applications offer the advantage of regeneration. The potential energy of the material is converted to usable energy as the conveyor drives generate electricity during operation. In many cases, the value of the energy generated is greater than the operating cost of the conveyor, resulting in an operating profit.

An alternative technology to conventional conveyor belts is the cable belt, which was developed more or less simultaneously with steel-cord belting during the 1970s. In this type of system, the belt is supported between two steel cables that transfer the driving forces and carry the belt and material. However, a limited number of installations use cable belts, whereas literally thousands use steel-cord belts. Most likely

Courtesy of FLSmidth Spokane, Inc.

Figure 10.7-7 Pipe conveyor with carry and return transport installed underground

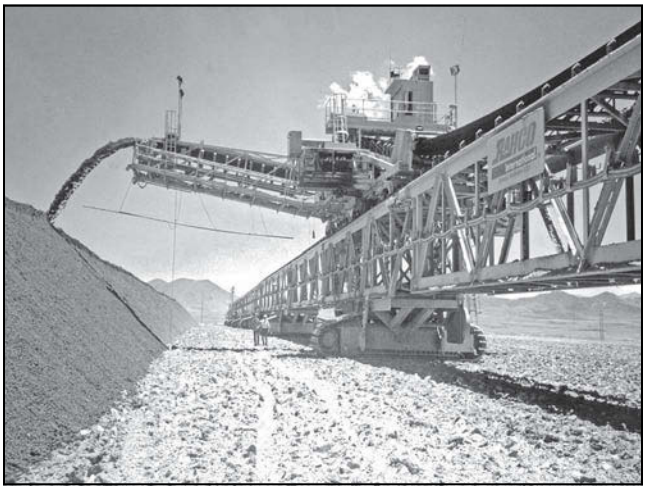
the reason for this is that cable belts are available through one source only, and their capital and operating costs appear higher than costs for conventional belts (Maton 2009).

Another variation of the conventional conveyor design is the pipe conveyor, in which the belt is forced into a pipe shape and encloses the material completely. Since the material is enclosed, spillage is eliminated. Pipe conveyors, therefore, have a lower environmental impact than conventional systems. The belt configuration allows for tighter vertical and horizontal curves in the design as compared with conventional belts; this reduces the civil works necessary with overland conveyors and makes the implementation of new conveyors easier in existing plants. Also, since the material is contained by the belt, pipe conveyors can operate on inclines approximately 50% greater than trough belt conveyors. In addition, the return side can easily be adapted to transport material simultaneously in the opposite direction of the main feed.

Another advantage of the pipe conveyor is its reduced space requirements as compared with a conventional belt. A dramatic example is given in Figure 10.7-7, which shows part of an 8.5-km (5.3-mi) pipe conveyor that transports cement on the carry side and clinker and coal on the return. Six kilometers (3.7 mi) of this conveyor is located in a tunnel beneath the city. A conventional conveyor would have required a wider tunnel and would have had serious difficulty following the complicated conveyor path, which involved dozens of tight vertical and horizontal curves.

Conveyors can negotiate steeper inclines than haul trucks, so the required ramps to go up or downhill are shorter. A pipe conveyor requires an even shorter distance to negotiate a slope since they can operate on steeper ramps. High, steep conveyors, such as the flexible sidewall belts, can go up to 90°. Flexible wall conveyors are quite popular and handle mostly free-flowing, low-abrasion materials. They are used sometimes on difficult applications, mainly when layout constraints do not allow the use of more conventional alternatives; however, their maintenance cost tends to be quite high. System cost is directly related to capacity in an exponential sense, with the belt being the driving factor. Most of these systems that are in operation have capacities less than 1,000 t/h (1,102 stph).

Another type of steep-angle system is the sandwich belt. In this design, a second belt rides above the carry belt in the steep section, holding the material in place with the assistance of inverted pressing idlers.



In a system that combines a flexible wall belt with cableway technology, a belt with sidewalls and integrated sets of wheels travels over carrier cables guided over supports. Long, unsupported spans are feasible, and environmental impact is reduced since civil works are minimal. This type of conveyor is appropriate in irregular terrain with great differences in elevation along the conveyor.

Traveling trippers are used to discharge material from any point along a conveyor belt. They offer great flexibility for storage layouts. Trippers can be mounted on tires, crawlers, or rails at ground level, and they can feed a traveling stacker to form a wedge-shaped longitudinal pile. Trippers can also be mounted on elevated structures and discharge the material to a pile below.

Shiftable conveyors can be used to follow an excavator or to feed a stacker that moves along the length of the conveyor. When the excavator or stacker needs to move to a new position, the shiftable belt is relocated. The individual conveyor tables are not connected to one another and are mounted on skids. Rails connect the skids longitudinally. When the time comes to shift the conveyor, belt tension is slackened and a bulldozer with a roller hook travels along the conveyor, pulling it sideways. The belt tables move snakelike in the direction of the pull 50–100 cm (1.6–3.3 ft) with each completed pass. Passes are repeated until the conveyor is shifted to its new location.

The mobile conveyor is also used in combination with excavators or stackers, or with its own hopper or cross conveyor, depending on whether the machine is used in a stacking or excavating/reclaiming operation. The conveyor is composed of a series of steel truss sections mounted on crawlers. A single conveyor belt moves along the top chord of the truss sections. The whole system moves as a unit because of a control system that monitors the movement and alignment of each section (Figure 10.7-8).

It is important that belt conveyors are designed so that material is not blown from the belt during operation. Covers

Courtesy of FLSmidth Spokane, Inc.
Figure 10.7-8 Mobile stacking conveyor

eliminate this concern and protect both the material and the belt and idlers from the elements. Vertical sideboards are often sufficient for wind problems; complete full covers, usually made from corrugated metal, enclose the entire troughed belt and components. Variations include three-quarter and doghouse covers that leave one side open so the belt can be inspected without having to remove the cover. Fully enclosed galleries are used when handling environmentally sensitive materials, a variation being large culvert-style steel tubes in which the conveyor is located inside the tube. Functionally, this is quite similar to the pipe conveyor discussed previously. Choosing one over the other depends on operational and cost factors.

Pipe Transport

Unlike the systems discussed to this point, pipe transport systems are stationary and the material is in motion. In truck, rail, marine, and conveying systems, the hardware is in motion and the payload is motionless relative to the transporting media.

Conveying solids in a pipe involves transporting solids using the drag resistance and pressure of a flowing medium, such as gas or liquid, to move the material. Pneumatic and hydraulic systems must be considered separately, as the characteristics of the carrier fluids are completely different. Drag resistance is proportional to the fluid density, the cross-sectional area of the solid particle, the square of the relative flow speed of the solid, and the Reynolds number.

Pneumatic conveying systems use a gas as the carrier medium. The low density of the gas (in the range of 1 kg/m^3 [0.062 lb/ft^3]) makes buoyancy nonexistent for practical purposes. The difference in density between solids and media must be compensated with high speeds to obtain the required carrying force, which results in high power consumption. High speeds create wear and attrition (degradation), so speed is limited in this regard. Since gases are compressible, the friction loss causes pressure loss. In other words, the gas expands along the conveying length, and unless the diameter is increased along the line, the speed, energy consumption, and wear increase. Therefore, pneumatic transport is generally restricted to distances less than 4 km (2.5 mi) and is used mainly in plant applications for materials that are dry, free flowing, and relatively small in particle size.

When the ratio between the mass of the transported solids and the mass of the gas is lower than 30, the system is said to be a dilute-phase system. In this case, the transport velocity is high, the mix is homogeneous, and the risk of blockage is minimal. When the mass ratio is much higher than 30, the system is called a dense-phase system. Plugs of material are transported at low speed but with high pressure gradient.

Calculating the design parameters of pneumatic systems is dependent on empirical information and varies depending on what materials are to be transported. Although published information about most common materials is available, it is recommended that appropriate laboratory tests be performed when designing a new system.

Hydraulic conveying, as its name implies, uses a liquid such as water as the carrier medium. The density of the mixture of liquid and solids results in significant buoyancy for the solids particles. Transport can be achieved at relatively low speeds. Far less energy is required for hydraulic conveying than for pneumatic conveying and other comparable transport methods, such as trucks. As the liquid is nearly incompressible, long transport distances—up to hundreds of kilometers or miles—are achievable. Typically, depending on the material handled, solids concentrations vary between 40% and 65% by weight.

In systems in which the solids particles are small enough (<30 μm) and can therefore be maintained in suspension at very low speeds, one can consider homogeneous conveying. The homogeneous suspension appears as a liquid with a higher density and viscosity than the carrier fluid and, in this case, the system can be designed in a similar fashion as for a pure liquid system.

If turbulence is required to keep the particles in suspension, the solids are no longer distributed homogeneously. However, up to a certain point, normally defined as a Reynolds number value of 2 (Weber 1981), it can still be considered pseudohomogeneous conveying, and conventional fluid formulas can be used for calculations. Also, a mixture with less than 20% variation in density between the pipe axis and the vicinity of the pipe wall can be considered homogeneous for practical purposes (Shou 1990).

With Reynolds numbers above 2, conveying takes place in heterogeneous suspensions in which the velocity of the solids and the liquid are different. The method used to design these types of systems was first proposed by Durand (1953) and is still used today with improvements and variations. The use of empirical data is fundamental to the design of systems having heterogeneous suspensions.

Increasing the density of the mixture will result in lower liquid requirements, but the flow properties of high-density mixtures are non-Newtonian, with a nonlinear relationship between shear forces and shear rate. Once again, empirical determination of the rheological behavior of the mixture is required before design is carried out.

Slurry transportation lines are used to transport diverse materials such as coal, iron ore and copper concentrate, bauxite, and phosphate mineral. They have a high capital cost, but operating costs are low in most cases. Slurry lines are used successfully in South America to transport copper concentrate from the Andes to sea level using the natural gradient and dissipation stations instead of pumps. The energy requirement is nil. They also offer the advantage of having a smaller footprint and lower environmental impact than other transport methods. A buried pipeline has almost zero environmental impact after it is built.

Another application of hydraulic transport is the disposal of tailings from concentrating plants. Because of the low grades involved in most concentrators, the volumes of tailings are several times larger than those of concentrates. Tailings lines involve large pumping systems and pipes up to 1,350 mm (53 in.) in diameter. As with any other hydraulic transport operation, the decision of proper solids-to-liquid ratio is driven by economic factors. A high concentration requires smaller pipes and less water but most likely more energy to operate. The tendency is to produce tailings with higher solids concentrations to the point at which the mixture is a paste, not slurry. In downhill operations, open troughs are sometimes used in lieu of closed pipes.

A hydraulic transport system requires a slurry preparation station, pumping stations (or dissipating stations in downhill applications), and a slurry receiving station. It might also include a dewatering plant to treat or reuse the water contained in the solids–liquid mixture.

ORE STORAGE

Since transport from the mine is not necessarily in sync with the processing, production, and consumption of materials, there is a need to store the ore at various stages. For trucking and marine shipping, ore is typically handled in batches; crushing and milling are continuous operations that do not lend themselves to discontinuity in the flow of material.

Storage Sizing

Traditionally, rules of thumb are used to size a stockpile. Typically, stockpiles are based on storage for one day or one shift, the size of a ship, or the duration of a shutdown. In coarse-ore stockpiles with gravity recuperation, a typical value for live capacity is one shift of production and for total capacity the duration of a long shutdown.

A more accurate way to determine sizing of a stockpile is through a dynamic simulation, which includes factors such as the availability of feed, the process plant, and the output system. For a given live capacity, it is possible to estimate the probable number of hours that auxiliary equipment would be required to reclaim dead material or the number of hours a plant would stand because of lack of process material. The net present value of the operating cost for the auxiliary equipment or production losses throughout the plant life can be compared with the extra capital cost of a system having larger live capacity. Operation below the live-capacity line requires the use of mobile equipment. The savings in operating costs and/or lost production might be enough to pay for the higher capital cost of a larger stockpile.

Dead capacity should be enough to accommodate probable shutdowns such as primary-crusher liner replacements, mobile-crusher relocations, or conveyor splices. This sort of shutdown usually lasts a few days. If space is available, additional dead capacity can be created using a bulldozer to spread the material. This kind of storage, usually known as a strategic stockpile, is often used on a coal-fired power station feed so the power supply is not interrupted due to lack of feed. In ship loading and unloading operations, the high cost of ship demurrage creates the need for large stockpiles.

The key word in sizing a stockpile is *probable*, as opposed to *possible*. A stockpile should be large enough that continuity of operations can be maintained under reasonably probable conditions. No matter how big the stockpile, it cannot accommodate all the possible situations. So when sizing stockpiles, it is important to balance the certain costs of a larger stockpile against the probable cost of an operational shutdown.

Storage Configurations

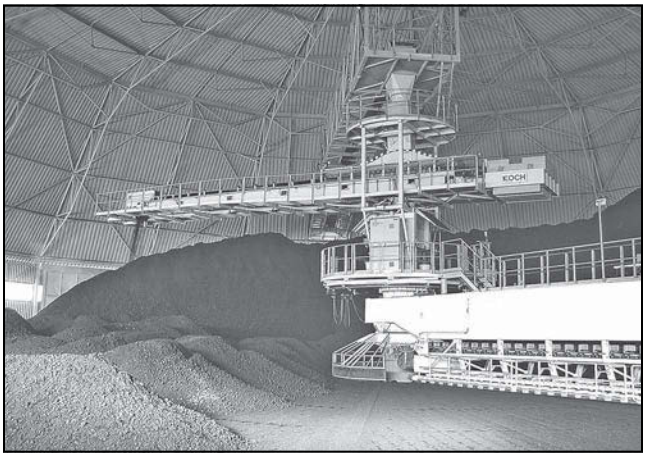
The conical shape is probably the most common configuration for stockpiles. A conveyor feeds material at a single discharge point, creating a cone. Although the natural instinct is to move the discharge point higher to achieve larger capacities, issues such as permissible ground loading, degradation of material when falling from the conveyor, energy cost to lift the material, cost of elevated structures, and reclaim considerations limit the maximum practical height. It is quite common also to use a fixed tripper or a second conveyor to create a dual cone when higher capacities are required. Longitudinal stockpiles can be created if the feed conveyor is elevated and has a tripper with a moving head or it feeds a shuttle conveyor to distribute the material along the axis. The elevated conveyor is supported by steel or concrete columns or by an A-frame structure. Radial stockpiles can be created using a radial stacker or a slewing-type stacker. Various stockpile configurations are discussed by Zamorano (2006).

Another option for forming a longitudinal stockpile is to use a wheel- or track-mounted traveling stacker. If the stacking boom can be raised and lowered (luffed), degradation of material when falling to the ground can be minimized. A boom that can rotate (slew) allows the formation of two parallel piles with one machine. Multiple stackers can be used to form multiple stockpiles in a stockyard operation.

Covered Storage

There are several reasons covered storage may be required; the most common is environmental regulation. However, protecting the material and preventing loss of fines due to wind are also reasons. For small tonnages, steel bins are satisfactory, whereas for larger volumes up to 10,000–12,000 t (11,023–13,228 st), concrete silos are commonly used.

In the case of conical or circular stockpiles, the covers can be conical or dome shaped. The conical shape is suitable for conventional steel structures constructed from steel trusses arranged radially, similar to a tepee. Domes are mostly designed as shell membranes with a variety of alternative designs. Conventional steel structures can be used to create a dome-shaped membrane-type structure that is covered with cladding. Another option is a space truss–type membrane formed with tubes and mechanical connections and covered with cladding. This type of dome is called geodesic and can be manufactured in steel or aluminum.



Other types of domes are made of thin concrete membranes, inflatable membranes (that require a blower in permanent operation), and covers using fabric cladding instead of metal or plastic. Covers for longitudinal stockpiles are usually a variation of the A-frame design. Closely spaced frames are used to support the cladding and the feed conveyor. Geodesic-type frames are suitable for stockpiles with rail-mounted traveling stackers or with a small, light feed conveyor supported by the cover.

ORE RECOVERY

Ore recovery comprises both reclaiming and blending the material.

Figure 10.7-10 Circular blending stockpile

Reclaiming Systems

In enclosed storage facilities, material is recovered via a gravity trough at the bottom of the bin or silo. If the material properties are known, a proper design can be developed and problems like arching and rat-holing can be avoided. Material can be recovered from stockpiles by means of mobile equipment such as front-end loaders and bulldozers that feed a reclaim hopper. Although this option presents the lowest capital cost, the operational cost is quite high, so this option can be justified only in small throughput operations.

Material can also be recovered by gravity using feeders and conveyors located underneath a stockpile. In this case, only a portion of the material—called live capacity—flows unassisted. The rest of the material, called dead capacity, is reclaimed with mobile equipment. In conical stockpiles or where free-flowing materials are involved, 20% to 25% of the storage is considered live. However, in large stockpiles or depending on material properties, rat-holing or arching may appear and the live capacity of the stockpile can be dramatically reduced (Cabrejos and Goodwill 1996) to a point that mobile equipment is required at all times.

A higher percentage of live storage can be attained using longitudinal stockpiles and several withdrawal points or rotary plow feeders. However, in this instance live capacity is 50% at best. Bucket-wheel reclaimers or other types of reclaimers (such as a portal scraper) can put live capacities in reach nearly all the time. These machines remove material placed by stackers when required (i.e., stockpiles, leach pads, etc.).

In some cases these machines are designed to operate as a stacker and a reclaimer; they are called combined machines (Figure 10.7-9). The additional capital expense of mechanized reclaiming systems is generally outweighed by the operational cost savings realized.

Another approach is the use of large, squat silos with assisted feed and reclaim to obtain a 100% live capacity within a small footprint (Nijhof and Ruijgrok 1986).

Blending

Variation of material properties in different areas of a specific mine or from different mines in a single processing facility necessitates blending the material to obtain a homogeneous product. This might involve a chemical component or even particle distribution.

There is a certain amount of natural mixing whenever a bulk material is handled. A crude level of mixing is achieved on stockpiles with the use of front-end loaders or clamshell buckets. The same can be said regarding boom-mounted bucket-wheel reclaimers and scraper reclaimers. Another approach is to use different bins to feed a common conveyor.

The blending effect is defined as the ratio of the standard variation of the control property at the store input and the standard deviation of the same property at the store output. Theoretically, the blending ratio is proportional to the square root of the number of layers reclaimed simultaneously. In reality it is somewhat lower, particularly in coarse materials.

In longitudinal stockpiles, when blending is not required, the preferred stacking method is the cone-shell method, in which the stacker discharges onto a single point. Once the maximum height is reached, the stacker moves a discrete distance and continues to discharge, forming contiguous cones. The chevron stacking method consists of depositing the material while the stacker moves to and fro over the center of the stockpile. To ensure proper blending, the material must be reclaimed from the face of the pile working across the entire cross section. This can be achieved with a bridge-scraper reclaimer that employs a harrow to guide the material into the scraper chain at ground level. The reclaimer recovers material from previously stacked material, while more material is stacked in the area that has been reclaimed.

The chevron method can also be used on a circular blending stockpile, as shown in Figure 10.7-10, where work is done on a continuous basis. A slewing stacker is mounted at a center pile and a bridge scraper reclaimer feeds a discharge point also on the center.

According to the windrow method, material is deposited over several positions across the full width of the stockpile. This method prevents segregation, and the reclaimer can operate on one part of the cross section at a time. A bridge bucket-wheel reclaimer can be used in this type of arrangement.

ENVIRONMENTAL CONSIDERATIONS

Environmental factors become more relevant every day in connection with ore transport and storage operations. Obtaining the relevant local environmental permits has become a key element for most mining operations, and compliance with environmental management standards such as ISO 14000 is

becoming a requirement for international trade. This section addresses concerns directly related to the environment.

The handling of bulk solids generates unwanted airborne dust. During transport by truck or train, it is quite common to use canvas covers to prevent contamination along the transport route. As has been discussed, covers are used along belt conveyors for the same purpose. When fine and troublesome materials are an issue, the entire conveyor is completely enclosed, or closed systems such as pipe conveyors are used. Loading and unloading activities and transfer points generate large amounts of dust, which is controlled by enclosure, suppression, extraction, control of fall speed, or by a combination of these.

Coal storage presents the risk of spontaneous combustion and can produce toxic fumes. Management systems on open stockpiles include the use of large spraying cannons to maintain surface moisture levels. This type of system requires a water management plan to control the acid water percolated from the storage area. Stormwater treatment facilities are required in open storage facilities for coal or other types of contaminating materials.

Enclosures can reduce the fugitive emissions. However, sometimes additional suppression or extraction systems are required. At times, negative-pressure systems are employed on enclosed stockpiles to capture dust.

Dust suppression involves the addition of water at a transfer or drop point to capture airborne particles. Chemical surfactants can also be used to increase the efficiency of a dust suppression system, as they facilitate the coalescence of the water droplets and dust particles. Another approach is the use of "dry fog," in which a special nozzle produces very small droplets. These droplets are approximately the same size as the dust particles and improve the chances of capture. At the same time, this minimizes water consumption and the addition of water to the ore. In open stockpiles, large spraying cannons are used to maintain superficial moisture and reduce dust emissions.

Dust-extraction systems use negative pressure to collect the dust from a transfer point or other dust source. The dust is then removed using a filter, cyclone, or scrubber, depending on the particular application.

Cascade chutes are used to reduce the speed of the material on large drops. The lower the speed, the less dust is generated.

Any water used for dust control or hydraulic transport is treated prior to discharge. However, in dry areas, conflicts can arise between the mine and local communities because water is a scarce resource and residents don't want it to be diverted for mining use. In addition, local communities are concerned that water contamination will result from the mining process.

The issue of noise, including its impact on endangered species, can be another area of conflict between a mine and local communities. If this is an issue, conveyors and pipelines have a clear advantage over trucks.

An aspect of mining that became an issue only recently is carbon emissions. Compared with truck haulage, continuous transport methods such as conveyors and pipelines can reduce the amount of carbon released into the atmosphere. Energy efficiency and the method by which power is generated also greatly influence carbon emissions.

Impacts on the landscape and surrounding communities are also relevant factors to be considered when making decisions about handling systems for bulk materials. Again, continuous methods tend to produce the lowest impact. Planners often neglect to consider the disruption caused by a great many trucks moving through communities.

CHAPTER 10.8

Strip Mining

Gary Dyer and Ken Hill

INTRODUCTION

For minerals that lie within economic reach by surface mining, and when the deposit's specific geometry, either tabular or bedded, allows or dictates, an approach to extraction called open-cast, or strip mining as it is more commonly referred to, can be employed.

Although a range of commodities such as phosphate, bauxite, tar sands, manganese, and even industrial materials from quarries have been recovered in this manner, the most common deposits worked by strip mining are coal deposits, and for this reason this chapter will refer predominantly to coal.

The economic depth for strip mining is dependent on realizing a margin between its unit revenue value and the unit cost to recover, driven by depth and deposit complexity. The lesser-value bulk commodities will typically only be economic to shallower depths, whereas high-value coking coal, such as that found in Australia's Bowen Basin, and where the stripping ratio allows, shows some strip mines currently operating at up to 150 m of depth with potential to progress to more than 300 m. Strip mining is a bulk earth-moving operation making use of large-scale mechanized equipment.

An attractive geometry for strip mining is a tabular deposit with coal subcropping at economic depth and extending laterally, either flat or gently dipping, and constrained vertically within a number of seams. Deposit continuity relatively free of geological structure or intrusions is also attractive but not a prerequisite, although a heavily disturbed and/or intruded deposit and the resulting economies may limit the selection of equipment and operating method.

Strip mining is characterized by its method of waste material, or overburden, movement, which is placed almost entirely in-pit. An initial cut is made on the coal subcrop, called the boxcut, and the overburden is placed on a natural surface updip of the subcrop line. The exposed coal is mined out and successive cuts, or strips, are taken to progress the mining downdip with the overburden from each strip placed inside the previous mining void. Individual strip geometry is typically from 30 to 100 m wide and to the economically recoverable basal coal seam. A strip will extend along the strike until it is constrained by a mining property boundary, limiting surface feature, geological discontinuity, or economic limit with the maximum length of some strips being in the kilometers where conditions allow. A form of strip mining where the strips are aligned downdip instead of along the strike is applied in some instances but is rarer as economics generally favor strike mining. Each strip working area is denoted as a pit with a strip mine consisting of a number of pits.

Strip mining encompasses a number of different mining strategies, each a unique combination of pit configuration, equipment selection, and operating methodology. This chapter begins by outlining a generic strip mining process. It then goes on to discuss alternative pit configurations, equipment selections, and operating methodologies for each of four mining strategies. The strategies have been developed in some detail with a major case study example used to provide comparison and contrast. Additional examples are referred to for variants of note. The chapter closes with some discussion on what drives the selection of one strip mining strategy over another as well as a brief commentary on future trends in strip mining.

GENERIC STRIP MINING

The strip mining process from first workings to final closure can be described generically in six steps:

1. Clearing and topsoil removal
2. Fragmentation
3. Waste removal
4. Waste placement (including soil restoration and initial revegetation)
5. Coal mining
6. Mine restoration, maintenance, and eventual closure

Figure 10.8-1 provides a stylized schematic to show these processes. Each of these process steps will be discussed briefly as a prelude to discussing the four strip-mining strategies.

Some additional operational activities that support the mining process have been covered briefly due to their influence. These include rejects and tailings storage or disposal, river and creek diversions, and water management.

Ken Hill, Managing Director, Xenith Consulting, Brisbane, Queensland, Australia

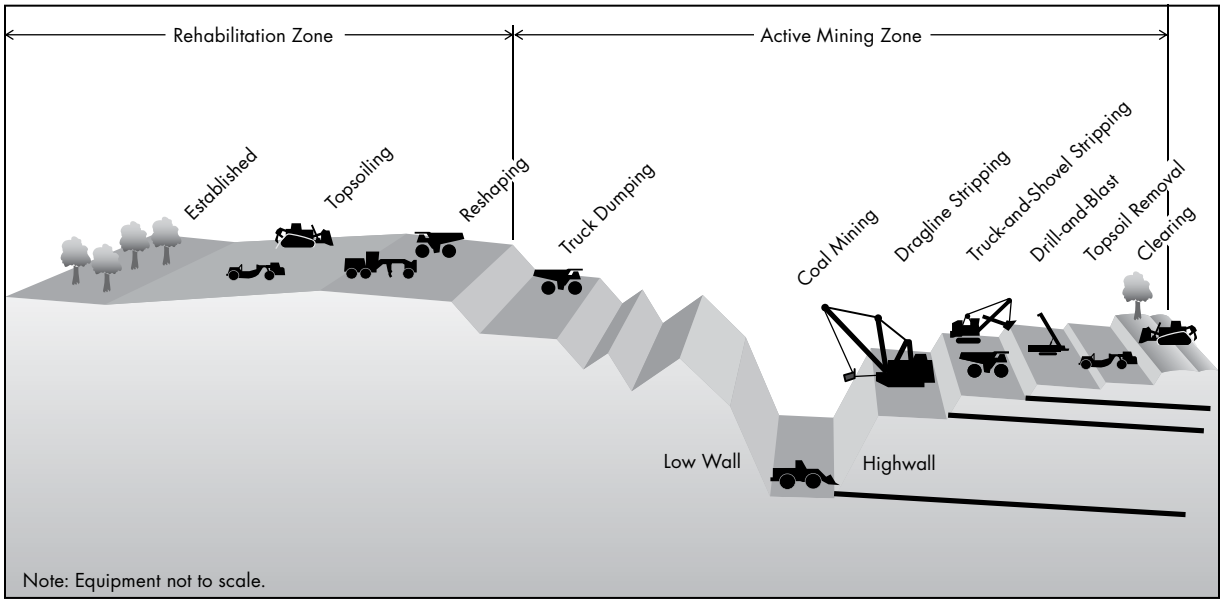

Figure 10.8-1 Strip mining process

Clearing and Topsoil Removal

Prior to first workings, a mining area is typically covered with vegetation and topsoil. The vegetation must be cleared, and the topsoil must be recovered and stockpiled for later use in postmining rehabilitation. Vegetation is cleared by track dozers and pushed into piles and disposed of by burning, shredding for mulch, burying, or a variety of methods dependent on local customs and laws. An examination is made as to the quantity and quality of topsoil, and a target thickness to recover is identified. High-quality soils may need to be separately identified and stored. Topsoil is removed with earthmoving equipment, typically scrapers. However, where thickness allows, dozers assisting excavators to load trucks may also be an efficient operating method. The topsoil is stockpiled in the vicinity of the future mining operation so that it may be recovered for postmining rehabilitation. For a mature mine with ongoing clearing and topsoil removal occurring in parallel to final rehabilitation, it may be possible, and is certainly desirable, to place topsoil directly in its final position without stockpiling. It is important that topsoil stockpiles are not compacted by machinery or excessive thickness as biological activity, and thus their value, will be adversely affected by the exclusion of oxygen and moisture from the topsoil mass.

Fragmentation

Following topsoil removal, there is a relatively small thickness of weathered and/or unconsolidated material overlying much thicker units of competent overburden. However, where there is a substantial thickness of weak material, it may be possible, or even necessary, to progress directly to a waste-removal process. This is the exception, and so fracturing, or fragmentation, of the overburden in advance of mining operations is required so that it may be handled safely and productively. Two main methods of achieving fragmentation are dozer ripping and drill-and-blast, with method selection dependent on the strength of the overburden, its thickness, and the volumetric demand of the mine.

Dozer Ripping

For relatively thin overburden of less than 4 m and where rock strength allows, a dozer-ripping process may be used for fragmentation. Use is made of the track dozer tines and the machine's mass to break the rock into a manageable size. Operational effectiveness is highly sensitive to rock strength, with high-strength rock leading to poor productivity, as well as maintenance downtime, due to adverse wear on the machine.

Drilling and Blasting

Drilling involves the creation of holes in the overburden within which explosives are placed. Drill holes are laid out in a regular pattern, either square or offset, the spacing of which is determined by the diameter of holes being drilled and the desired explosives density per volume of rock to be broken, or powder factor. Drill holes are drilled to either the roof of the target coal seam or to an operational depth to match the waste removal operating methodology. Where the valuable material (i.e., coal) is variable in depth, the driller may drill into the coal to ensure correct hole depth and then put a short length of stemming into the bottom of the hole to protect the relatively soft coal from damage when the overburden is blasted. Otherwise, holes are measured to ensure that the correct depth has been reached, with wet holes being marked and pumped out if the depth of water warrants it. Poor depth control will lead to uneven pit floors and inefficient waste removal. A presplit may also be used where a line of holes at a tighter spacing is drilled along the line of the next strip's highwall and is blasted separately from the main pattern. The intention is to deliver a smooth wall that is productive to excavate the waste back to and safe for personnel and equipment to work under during coal mining.

A blast design is prepared based on the overburden strength characteristics, the wetness of the holes, and the desired direction of movement of the blasted material controlled by placement and duration of hole delays. Bulk explosives are placed in the drill holes by mechanical means with ammonium nitrate and fuel oil (ANFO) being the most

common explosive used. Specialist explosives may be used for stronger overburden with water-resistant emulsions used in wet applications. As each hole is loaded with explosives, an explosive booster tied to a detonating cord is placed within the explosives near the bottom of the hole. The top 5 m or so of the hole is filled with stemming to prevent the blast energy from escaping at the top of the hole and instead direct the blast energy into the rock mass to fracture it (and in some applications to actually move it sideways). The cuttings at the top of the drill hole are often used as stemming material, but some mines import size-graded rock to deliver a superior blast-containment mechanism. After the area to be blasted has been loaded with explosives, the shot firer will connect each hole with detonating cord and time delays. A lead-in detonating cord is run out to a position of safety and, with guards in place and the area confirmed as safe to blast, the shot firer will initiate the blast. Electrically initiated detonators with millisecond delays may be preferred where sensitive vibration control is required. A good blast outcome is typified by an absence of flyrock, no excessive sound and/or vibration, no misfired holes, and good visible fragmentation with the rock mass traveling in the desired direction.

Strip mining is unique in that the drill-and-blast process itself can be employed as an overburden removal process. As the overburden is to be placed into the mined-out void immediately adjacent, certain pit configurations and operating methodologies lend themselves to cast blasting. Cast blasting is where a powder factor and delay design is selected to purposely cause the fractured rock mass to heave in the direction of the mined-out void with large quantities of overburden, up to 30%, resting in final position. It therefore requires no further handling by mining equipment. This is a particularly economical method of overburden removal.

Waste Removal

After blasting, the overburden may then be removed. Each end of the strip is called an endwall. The wall of the strip that is to progress successively downdip and is cut in in-situ material, or prime, is called the highwall. The in-pit overburden, or spoil side, wall is called the low wall because of its flatter slope compared to the highwall. (Refer to Figure 10.8-1.)

Cast–Doze Excavating

At shallow depths of <30 m, a combination of cast blasting and pushing with track dozers will provide the most cost-effective method of waste removal. Cast blasting can place up to 30% or more of the prime overburden into a final position. Track dozers can then push the remaining overburden into final position. If dozer pushes become excessively long or uphill, and therefore less productive, it may be more economical to supplement the operation with an excavator and a short-haul truck operation. The highwall will typically be cut to an angle of 65° with excavator assistance in cutting the batters back to hard material. The low wall will typically be placed at between 37° (the angle of natural repose for fragmented rock) and 45°. Effective rock fragmentation is critical to the success of this method, as blocky oversize overburden has a significant negative impact on the productivity of dozer operations. Poorly cemented overburden may be moved by scrapers.

Dragline Stripping

Where scale and deposit geometries allow (up to 85 m or so in overburden depth, depending on the class of machine being applied), a dragline can provide a more cost-effective method of waste removal. This requires sufficient annual demand for overburden stripping and mine life (in excess of 10 years) to pay back a high-capital, low-operating-cost piece of equipment. Simplistically, the dragline operates by moving overburden, or prime, from the current strip and placing it in the previous mined-out strip as spoil. Figure 10.8-2 shows a diagram of a dragline identifying its main physical features. The dragline needs to be placed at a level from which it can reach the top of the deposit to be exposed. This will either be its dig depth or operating level if less than the machine's maximum dig depth, although the dragline can handle overburden above its operating level via overhand methods. The total thickness of overburden to be allocated to the dragline therefore may consist of a number of passes made up of a combination of overhand and underhand operations and perhaps even repeated for multiple seams.

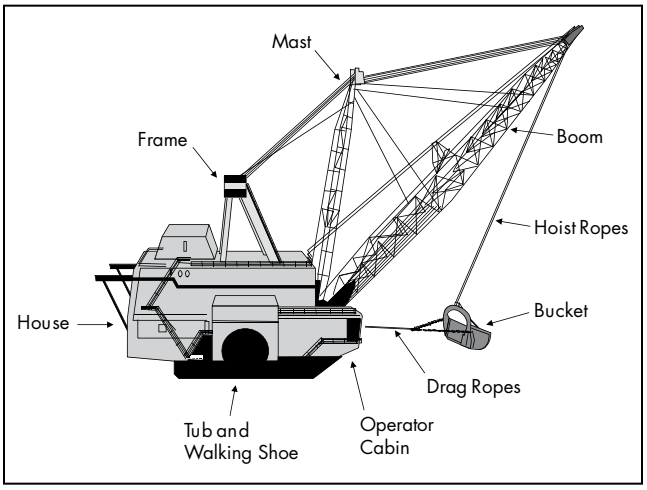

Figure 10.8-2 Dragline

Figure 10.8-3 shows a typical walking dragline operation. Highwall angles range from 45° to 65° and depend on the competency of the material to be excavated, as well as joint orientations. Offset benches in the highwall may be established for reasons of overall wall safety in terms of stability, to reduce risk to subsequent mining operations below the wall, or for operational reasons relating to the maximum reach of the overburden drills. Low-wall angles are typically cut at 45° up to the dragline operating level and then lay back at a 37° angle of repose to the peak of the dragline spoil.

The dragline will advance along the strip, moving by dragging itself on a revolving tub by 1–2-m "steps" delivered by two large feet on an eccentric cam, in regular blocks, typically 30 m in length, but they can be longer or shorter depending on the dragline's operating level and thus its ability to reach the toe of its excavated block. For a narrow strip width, the dragline is often placed directly into a final position, whereas for a wider strip, as is more commonly the case, the dragline builds temporary operating positions out of overburden from which it places waste from the previous block into final position. This is discussed in more detail later. Any overburden that the dragline has to handle a second time is termed *rehandle*. An efficient dragline operation will minimize rehandle, which is achieved by setting the dragline's operating level as low as possible. Unfortunately, the lower the dragline operating level, the lower its direct overall spoiling volume capacity,

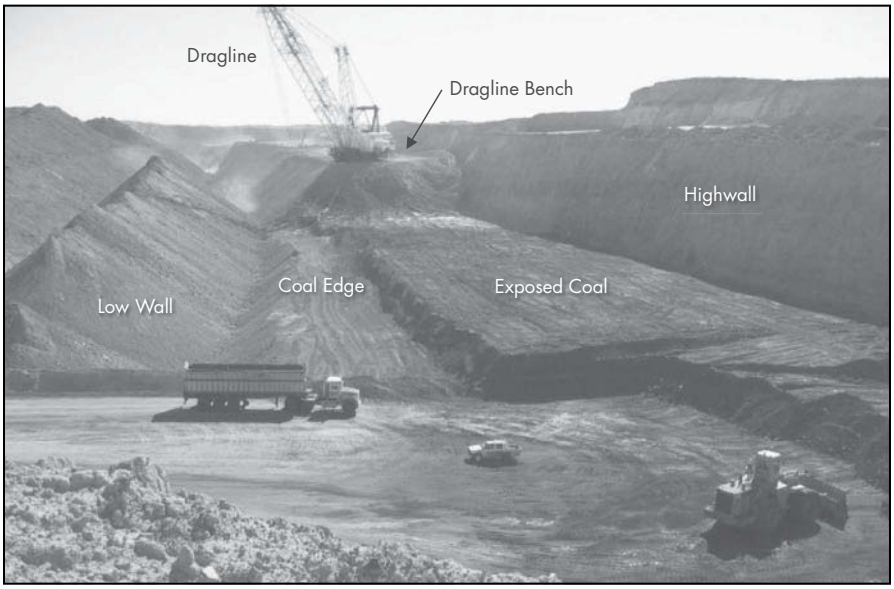

Figure 10.8-3 Typical dragline operation

which will then have to be compensated for, either by employing spoil side rehandle passes or removing material in advance by truck methods. Both of these are expensive, so rehandle is often an outcome of balancing desired coal exposure rates with installed dragline capacity and overburden removal economics.

Dragline operating geometries provide a relatively narrow operating envelope. For the larger class of draglines, their operating parameters are a dig depth of 65 m, a dump height of 55 m, and a dump radius of 95 m with an effective thickness of overburden allocated to the dragline system of around 85 m (Bucyrus 2008). Overburden outside of this envelope will need to be rehandled if the dragline is to deal with it; if it needs to be rehandled twice, it will generally be cheaper to remove by truck methods. Errors in design and unexpected geological impacts such as faults or discovered areas of geotechnical weakness may result in overburden being locally over-allocated to the dragline somewhere along the strip. This may result in the dragline becoming spoil-bound where it can no longer place all of the overburden it has been allocated to a final position using its planned operating methodology. This needs to be rectified either by ramping its bench higher to provide additional spoil room, or, if spoil fit is already maximized, by walking the dragline into the spoil and rehandling overburden even further away, via an elevated bench or pullback operation, to create room for the current strip's waste. This is an expensive exercise and can cause significant unplanned delays in coal exposure rates and so is to be avoided. Mobile, track-mounted draglines are still popular in variable terrain where overburden depths do not exceed the digging capacity of these smaller machines.

The annual operating capacity of a dragline is a product of its rostered time, mechanical and electrical availability, operating use, and productivity. As they are capital intensive (in excess of US$200 million per unit), draglines are typically rostered to operate 24 hours per day, 7 days per week. Their relative simplicity as a predominantly electrical machine leads to high availabilities, typically running in excess of 90%. Apart from geotechnical failures, excessive rainfall, or mine-planning failures (lack of blasted inventory), operating use is also high, running typically in excess of 90% of available time. Productivity will vary depending on the operation, with large swing angles from dig to dump, high spoiling, poor fragmentation, and rework of the excavated face or bench resulting in lower productivities. Total volumes moved per annum will range from 15 Mbm^3/yr (million bank cubic meters per year) for the most common smaller-sized machines to >30 Mbm^3/yr for the larger machines currently deployed. A dragline, depending on its size, will consume the equivalent electricity per annum to supply a small town of 3,000 to 5,000 people. Concentrating so much productive capacity in a single machine and in a pit configuration that requires vertical stripping, however, is a significant risk exposure, and there have been instances of catastrophic failure via machines "falling" into the pit because of bench failures, basic mechanical failure of key structural components (materials failure or operator error), or flooding. For mines relying on a single or a small number of draglines, this results in a significant business impact that is not quickly or inexpensively recovered from. Small efficiencies in dragline use lead to large cost savings, so most large draglines will be fitted with operating monitors. These assist the machine operator to select optimum swing angles, bucket-fill factors, and casting radii.

Dozer-Assisted Dragline Stripping

The dragline can be supplemented by track dozers pushing prime material into the void where, depending on strip width, it can be rehandled to its final position by the dragline. This operation is called production dozing and has the effect of increasing the effective prime waste movement rate, and thus coal exposure rate, of the dragline system, but at the expense of increasing dragline rehandles. Nonetheless, where there is sufficient spoil side room due to the dragline being under-allocated waste in terms of spoil fit for coal exposure rate reasons, it is a low-cost, low-risk way to increase the total thickness of overburden allocated to the dragline system.

Truck and Loader Stripping

For more-restrictive deposit geometries, shorter mine lives, and where a more-variable scale of operation is planned, the superior flexibility of truck-based waste removal methods may be suitable. Truck methods involve the use of trucks and loading equipment to dig overburden and dump it. Loading equipment is selected to match the trucks, whereas the truck and loader package is selected to match the task. Highwall batter angles are 60° for each bench in competent material, with flatter angles for poorer material, but often with 5-m berms between benches leading to much flatter overall highwall angles.

Large bulk thicknesses of overburden, typically >15 m, will be removed by electric rope shovel and ultra-class (>300-t payload) trucks as the most cost-effective operation, provided there is a sufficient annual requirement for waste stripping and mine life (>10 years) to pay back the higher-capital, lower-operating-cost position offered by larger electric shovels compared to smaller hydraulic excavators. For thicknesses >20 m and up to 25 m, overburden can be pushed down with dozers to create a safe working face height. Beyond 25 m of total thickness, multiple benches are often created. These might be separately blasted or through-blasted depending on material competency to allow them to be run over with the trucks. Where ready supplies of electric power are not available or at contract operations, this overburden task will alternatively be handled by large hydraulic tracked excavators, either in shovel or backhoe configuration. Electric rope shovels work most productively on a relatively flat bench, so where the dip of the coal seams exceeds the effective operating grade for the electric shovel, a secondary wedge operation using an excavator and trucks may be needed.

Truck-shovel operations can be used in an advanced-bench mode on upper layers of overburden to prepare a working bench for a large dragline. The truck-shovel operation removes variable topography, leaving a horizontal bench for the dragline. The dragline then is able to operate uniformly and efficiently at its optimum digging depth. Meanwhile, the truck haulage routes are arranged so that a natural-looking final topography is created without the need for spoil rehandle.

For overburden thicknesses <15 m, it will usually be more cost-effective to run with smaller hydraulic tracked excavators loading appropriately sized trucks. As overburden thicknesses reduce, smaller excavators may be selected. Below 2 m of thickness, it may become more effective to have a dozer ripping and pushing overburden up to the excavator, whereas sometimes a pure dozer method is employed where a void is available within a short push distance. Wheel loaders are rarely used to load waste, often due to their inferior economics in overburden operations.

A typical truck and loader fleet will consist of a loading tool, sufficient trucks to match the total cycle time (load, haul, dump, and return) to keep the loading tool running continuously, and various earthworks support gear including dozers, graders, and water carts. When used to remove overburden above the dragline, the truck operation is often termed a *pre-strip operation*. When used to remove waste between coal seams below the dragline operation, the truck operation will often be termed an *interburden operation*, whereas for thin waste bands it may be called a *parting operation*. Where the truck operation uncovers coal in its own right, either above a dragline or in a nondragline mine, it is more commonly termed a *truck and shovel operation*. The width of strip for the truck and loader operation will typically be set to match the dragline strips so that a regular release of dragline strips occurs. This can limit the effectiveness of the loading operation in narrower strips by reducing the operating room, increasing the influence of edge effects, and limiting the opportunity to deploy double-sided loading of the trucks, thereby reducing productivity. Wider strips, however, result in longer truck cycle times and increased work-in-progress in the pit that manifests as a larger invested working capital. Scheduling bottlenecks are also introduced by larger batch sizes via wider truck and loader strips. These effects need to be carefully evaluated depending on local conditions. Figure 10.8-4 shows a typical truck and electric rope shovel operation.

Figure 10.8-4 Electric rope shovel and truck operation

The annual operating capacity of an electric rope shovel is a product of its rostered time, mechanical and electrical availability, operating use, and productivity. As they are capital intensive (in excess of US$20 million per unit), electric rope shovels are typically rostered to operate 24 hours per day, 7 days per week. Their relative simplicity as a predominantly electrical machine leads to high availabilities, typically running in excess of 90%. Apart from geotechnical failures, excessive rainfall, mine planning failures (lack of blasted inventory), or sufficient trucks in the cycle to match the haul duty required, operating use is also high, running typically in excess of 90% of available time. Productivity will generally vary less than a dragline because of the relatively generic nature of electric rope shovel operation most of the time. Productivity will be affected when digging less than optimal bench height, ramping in or out of an area, or when poor fragmentation and difficult materials such as clays result in carry back within the bucket leading to increased truck loading times.

Total volumes for electric rope shovels typically range from 15 Mbm^3/yr to 20 Mbm^3/yr for the larger machines currently deployed with the variability driven by the specific application. Three electric rope shovels will consume approximately the same electricity per annum as a large dragline. Electric rope shovels are inherently flexible but can present some constraints in terms of minimum required working areas, maximum operating cross-grade, and the requirement to manage a cable interacting with blasting operations and a fleet of trucks.

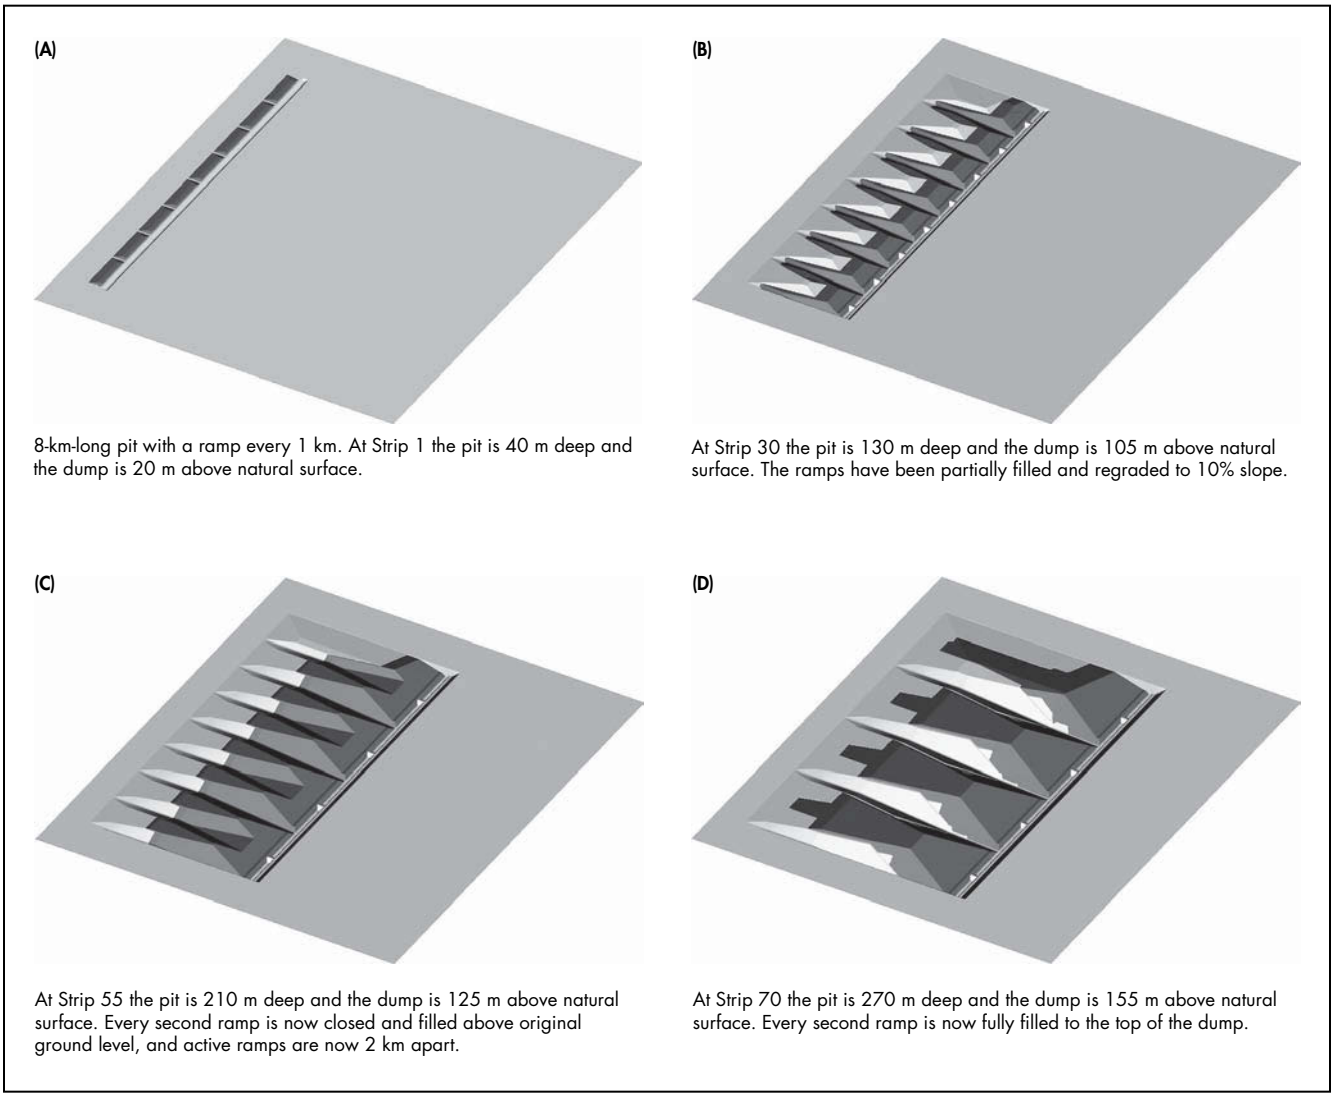
Continuous System Stripping

For pits that require large annual quantities of waste movement (>15 Mm^3/yr) to be placed via long haul cycles (>30-minute return), it may be cost-effective to deploy a continuous or conveyor waste system, either by itself or in conjunction with other waste removal methods. Relatively few of these operate globally, and their successful implementation is highly dependent on developing a specific and robust mine plan that marries overall pit configuration, equipment selection, and operating methodology to the fixed nature of these systems compared to other mobile overburden-moving equipment options. These systems comprise a crusher station at the dig end, a long conveyor (>5 km), and a spreader at the dump end. The crusher may be fed by trucks or directly by track dozer, excavator, shovel, bucket-wheel, or even dragline. These systems are capital intensive, being comparable in capital cost to a dragline with similar annual prime capacity but with an operating cost that sits between a dragline and truck and loader systems. For these reasons, only the longest-equivalent truck hauls provide an effective cost offset; economic payback can take a number of years and depends on achieving large annual volumes, which means minimizing the magnitude and frequency of partial- or full-system relocations. This is a developing mining strategy that will see more potential for economic application as pits deepen, but it is also under competition from emerging technology step-change improvements in truck and loader systems, such as partial or full automation. The environmental advantage of continuous system stripping is the ability to restore spoil in an approximation of the original strata profile.

Waste Placement

The movement of waste is a pure cost to the mining operation and has no direct economic benefit, so the placement of waste will generally be driven by a least-effort approach. For equipment other than trucks and conveyors, this dictates the overburden only be moved a short distance within the practical and economical operating envelope of the equipment in question. This will typically be <200 m in the horizontal from the point of origin with changes in elevation generally <50 m.

Cast–doze excavation, dragline stripping, and dozer-assisted dragline stripping methods generally place the overburden into the void from the previous strip either directly or with some rehandle.



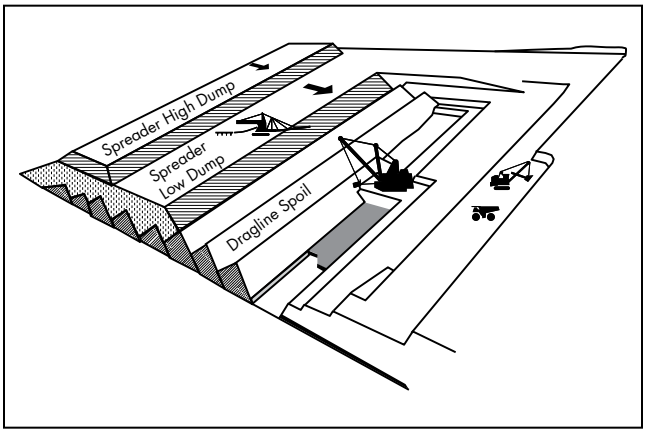
Minor truck stripping operations engaged in either parting or thin interburden operations, and generally at or near the bottom of the strip, will seek to minimize the haul. Overburden is thus placed inside the strip being mined or nearby, perhaps being used to regrade an access ramp that may be running at a flatter grade than that required by the coal mining trucks.

Bulk truck stripping operations, not supporting a dragline stripping method, also place the overburden in the previous void. Least-cost operation is generally achieved when material is hauled on grade, or as flat as possible, and it is desirable to establish the dumping strategy to sustain an average haul. This will ensure that short hauls do not idle spare trucks unduly and long hauls do not create instances where the loading equipment is undertrucked and production is lost. It is vital to have an established road system that allows access to multiple dump levels, and this road system will grow in complexity with pit depth and thus the number of dump lifts being developed.

For bulk truck stripping operations supporting a dragline stripping method, otherwise known as prestrip, the overburden is placed on top of the dragline spoil. The proximity of the truck dump to the active spoil area is determined by the geotechnical competence of the waste material itself and the strip floor; however, a good general rule is two spoil peaks, or prior strips, back. Dump geometry is dictated again by geotechnical competence but also the location of roads to access the dump and the desired intensity of dumping operations that need to be designed for. A typical overall operating angle of 19° for the active dump face is typical for truck dumping, and this profile is the result of a series of dump lifts that batter down at angle of repose interrupted by catch berms and roads. The economic cost of elevating overburden with trucks relative to horizontal haul is approximately 20:1, which is to say a dump will preferentially develop horizontally until economics dictate that an additional dump lift be added. For this reason, the dumps for mature pits will adopt a typical profile with the greatest height in proximity to the active dig area with a trailing back of the dump.

At this point it is worth considering the geometric drivers of dump development as well as economics. Figure 10.8-5 shows how the dumping strategy changes over time as a strip mine deepens. As the pit progresses downdip, batter effects demand greater and greater volumes of overburden to be moved, and this generally reports directly to the truck operation as the dragline is allocated a fixed thickness of overburden for each strip. On the dump side, the dump end batters play a similar role but have the inverse effect: as the dump gets higher, it has a correspondingly lower volumetric capacity due to less pit length available for dumping. The system dynamic is simplistically one of an inverted cone-shaped pit getting deeper, filling a conical stockpile that has a finite capacity for a fixed basal area.

After the dump reaches capacity, only three responses are available. First, any perpendicular ramps to the base of the strips that create large valleys reducing available dump room can be filled with alternative clearance of the mineral to be mined to occur by parallel low-wall ramps or via a high-wall ramp system. Second, the dump can be extended in the direction of the original commencement of mining. This can have grave consequences for any progressive rehabilitation that was undertaken without a final landform design and can lead to redisturbance of previously rehabilitated areas. The same issue might also apply to any infrastructure that was also placed without due consideration of long-term dump designs (e.g., coal haul roads, power lines, stockpile areas). Third, overburden can be placed out of pit or, in other words, beyond the limits of the excavated-to-date pit shell. In some regions, this out-of-pit material is called excess spoil. This can be expensive, involving long hauls or placing overburden on the highwall side of the pit and on top of future resource areas. This may be undesirable unless there are sterile areas due to geological disturbance, intrusions, or underground operations or other factors that may preclude strip mining in that area, or unless the subsequent rehandle of this waste at a future date is still economical. An additional downside to out-of-pit dumping is that it increases the total area of mining disturbance and creates an additional net area to be rehabilitated and maintained after mining ceases. Excess-spoil dumps have created environmental challenges whenever they intrude into established natural drainage channels. The placement of overburden for deep strip mines is an emerging problem and generally starts to manifest at depths of around 150 m. A further uncertainty and risk is the geotechnical stability of large in-pit dumps and is the subject of ongoing research.



Courtesy of BHP Billiton.

Figure 10.8-5 Dumping strategy development with depth

For an integrated truck and dragline method, an additional operational complexity to be resolved is the interaction between the trucks and the dragline with both equipment types often having to operate in close proximity at the same time. The truck operation will seek to minimize its average cycle time by crossing the open strip when it is excavating near the middle of the strip to get to the dump, but the dragline operation seeks to operate long continuous strips for maximum efficiency. One compromise is the use of cross-pit bridges that the trucks travel across. Temporary bridges are constructed from blasted overburden and built to the height of the dragline operating level. When the dragline is a suitable distance away from the temporary bridge, the trucks use it to provide a short-haul access across the pit. They are "rolled" by the dragline on each strip to recover the coal that lies beneath them. The downside of temporary bridges is that the bridge is not always available for use by the trucks, or its use by the trucks becomes a constraint on the mine schedule, and the rolling of bridges has a productivity impact on the dragline. An alternative approach is the use of permanent bridges. These are constructed from in-situ material that is left in place in each successive strip. The coal beneath them is effectively sterilized as the successive mined-out strips are filled with overburden that either buttresses or buries the remnant mineral material. The bridges may be built to any height and may incorporate multiple cross-pit roadways at different levels to further optimize trucking operations. The downsides of permanent bridges are the sterilization of resources, which is magnified for higher bridges due to larger bases from the batter effects, as well as their role in limiting the length of strip the dragline operates with the corresponding productivity impact from end effects and more frequent machine relocations.

The rest of the trucked overburden either travels around the end of the pit or up a highwall ramp system to a natural surface and then around to the dump. A major advantage for endwall road systems is the provision of cost-effective on-grade highwalls, with a detraction being additional stripping demand from access roads cut into sterile ground, which can be substantial at depth, especially for short strips. A major advantage for highwall ramp systems is that they

Courtesy of BHP Billiton.
Figure 10.8-6 Spreader dump

are excavated in material that is part of the ongoing mining operation, and generally already exist if coal seams are present within the prestrip working horizon. A detraction is that productivity impacts the excavation operation from removing and re-creating ramps (if not already in place) as well as the potential need for loaded trucks to haul up to a natural surface and then haul downhill on the dump side, which is inefficient.

Placement of overburden by conveyor systems is most similar to truck operations. A spreader constructs the overburden dump. Depending on the equipment configuration, the overburden dump may be built in benches radially or along the strike. An upper stacked overburden bench of 15-m height may be built simultaneously with a lower filled overburden bench of up to 45-m thick before the whole system is advanced. Because of the immobile nature of continuous waste systems, the conveyor will either travel around the end of the strip or across a central permanent bridge. Figure 10.8-6 shows a diagram of a typical spreader dump.

Landform Strategy—All Placement Methods

The waste dump, or landform, strategy is dependent on a number of key factors including the long-term swell factor, operating pit and progressive and final landform geometries, any mining or dumping constraints, the total static volume balance, and the dynamics of optimal dump construction. The influence of the final pit limit and final pit treatment should also not be underestimated, with impacts for deep pits likely to affect the entire postmining landform constructed early in the mine life, but not manifested until the latter years of the mine life. Variations in the elevation of spoil dumps due to swell factor and the inherent displacement by draglines of contour highs and lows may lead to substantial drainage mismatch between disturbed and undisturbed lands. Surface contouring software can generate plans for final restoration that respect geomorphological principles.

Coal Mining

Although the overburden removal process accounts for the bulk of the operating expenditure for a strip mine, the coal itself is the reason for the stripping and provides the revenue to support overburden removal.

The overburden and coal seams are physically coincident at their boundary, so it is inevitable that imperfect mining processes will result in some unplanned removal of coal with the overburden, or loss, and some unplanned addition of overburden to the coal, or dilution. Typical losses and dilutions by mass can range from 5% to 10% with higher losses incurred for thinner seams and dependent on local practices and conditions.

Loss is directly incurred through blasting that can cast some of the coal into the final spoil position to be lost forever, but also blast-enabled through the disturbance of the overburden–coal interface. By using large-scale earthmoving equipment, driven by the paradigm and key performance indicator (KPI) of minimizing unit operating cost, removing the overburden near the coal can easily be biased toward coal loss. An effective remedy can be to set coal recovery as a KPI or deploy a more selective equipment configuration when approaching the overburden–coal interface in the last 1–2 m. This incurs a higher unit cost for overburden removal, but the affected volume is quite small and the total cost impact minimal. Similarly, the coal mining operation is often biased toward loss over dilution due to the high visibility of overburden within the mined coal.

For high-value coking coal where a processing plant is available to remove dilution and the cost of replacing lost coal is high, it will generally be economical to favor dilution over coal loss. For lower-value coal such as thermal coal, which generally has a lower cost to produce and is often crushed and sold without washing, it is usually more economical to favor coal loss over dilution. Some mines reduce dilution by use of a commercial road sweeper on the coal surface to windrow rocky material away from the coal-loading operation.

Coal mining is commonly by loader and truck systems. For thin seams or soft coal it is dug unblasted or may be ripped and pushed by dozers or even graders as part of the mining process. High-value, thin-seam coals have been excavated by tarmac recovery machines called fine graders or special continuous surface miners whose operation combines the fragmentation and mining process. For thick and/or hard seams a square drill-and-blast pattern is employed to fragment the coal prior to mining. Loading equipment used is either a front-end wheel loader, a diesel excavator in shovel or backhoe configuration, or, more rarely, a smaller electric rope shovel for some mines that have particularly thick coal seams. The choice of loading equipment will be driven by the required mining rate and the thickness of the coal seam and its continuity, with excavators in backhoe configuration being the digging tool of choice for highly faulted or banded coal seams, where selective mining is required. Trucks will either be rear dumps, electric or diesel, or belly dumps. Rear dumps have the advantages of being more maneuverable and faster up the coal access ramps compared to belly dumps, as well as being able to handle ramp grades of up to 10%, whereas they have the disadvantage of being slower on the flat with top speeds of 65 km/h compared to 75 km/h for belly dumps. For very long flat hauls (>20 km), and where ramp grades allow, highway-adapted road trains consisting of multiple self-tipping trailers with up to 300-t capacity are used. Figure 10.8-7 illustrates a typical coal mining operation.

Depending on blending requirements, coal may be direct-mined and fed to the wash plant continuously from a number of strips in different pits at once. Alternatively, it may be mined to stockpile for reclaiming later, either by a mechanical stacker reclaimer system or by manned equipment such as a batch-fed process.

Figure 10.8-7 Coal mining operation

Mine Restoration, Maintenance, and Eventual Closure

The objective of mine closure is to return to the wider community a postmining or final landform that is safe, stable, and sustainable. Safety dictates that the final landform does not present a risk to humans or wildlife. Stability dictates that the final landform is both erosionally and geotechnically stable, with erosional stability more challenging to achieve. Sustainability dictates that the final landform reduces and prevents pollution, enhances biodiversity, and delivers a beneficial use with no ongoing liability to the company that owned and operated the mine.

Strip mining by definition disturbs large areas of land, so the greatest impact, and ultimately closure cost and potential trailing liability, relates to the creation and maintenance of the final landform from the open voids consisting of final strips and ramps. Other aspects of mine closure include the demolition and rehabilitation of mine and fixed plant infrastructure, but these are small contributors compared to the landform. In some jurisdictions the final landform is highly prescribed, whereas in others, legislation provides broad guidance within a set of principles. Final landforms can range from voids whose batters have been regraded to voids that have been fully backfilled to the original topographic levels.

In a strip mine it is worth noting that, by virtue of the operating methodology, mine closure in terms of the delivery of a final landform should be seen as a progressive activity that commences the day the mine opens and occurs more or less continuously until the site is fully rehabilitated. For this reason a strategic landform study should be undertaken as part of the initial development study, or soon after, so that the construction of progressive landforms can be undertaken in a cost-effective manner, maximizing the design of truck dumps to emulate as near as possible the final landform design. This will involve the bulk placement of material to progressively deliver the final landform fill, preferential placement of adverse material types such as acid-forming or highly erosive spoils within the spoil mass, preferential storage with progressive use of materials suitable for controlling erosion of external surfaces, and topsoil to aid in revegetation of the regraded spoil mass to deliver the final landform finish.

The other aspect of the final landform is the treatment of the final voids consisting of access ramps and the last mined strip. Significant costs and liabilities can be incurred if closure is not approached in a planned way. However, there are also significant operating benefits to be accessed from developing a comprehensive operating-to-close strategy and implementing it in the last 5 to 10 years of the mine's life. For deep pits it is likely that any perpendicular coal access ramps will have long been closed for dump room reasons, but for shallower pits approaching closure, and where still in use, they can represent a low-cost dump opportunity. Final strip voids become more valuable as a low-cost dumping opportunity for adjacent pits than as a source of marginally economic coal. A mitigated closure strategy will generally see all ramp voids, and most final strip voids, filled with waste from the remaining operating pits. In time these pits themselves will self-fill as a way to reduce unit operating costs and still yield a positive cash margin, albeit with ever-reducing total mine output. Where sufficient area exists and economics allow, some mines have wheeled their pits around in a large set of 90° offsets so that the last pit is adjacent to the first pit and thereby fills it.

Regulating authorities in some countries demand a final landform design and progressive delivery as a condition for operating a mine, whereas in other countries the approach is less prescriptive. Nonetheless, the final landform is an integral part of operating a strip mine, and it is critical that a strategic landform plan is developed early and followed throughout the mine life.

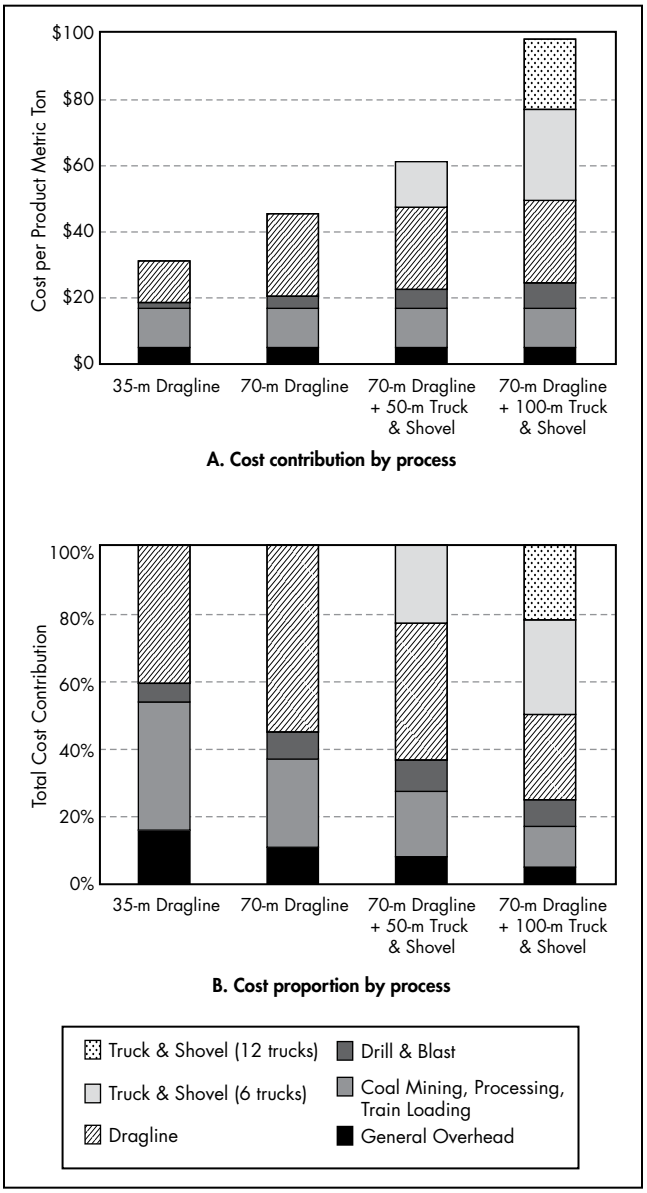

Figure 10.8-8 Relative cost by scenario

Mining companies are able to operate by virtue of the license to operate (LTO) they hold. A company's LTO is a product of its adherence to statutory requirements and the literal permits this provides in combination with figurative permissions provided by meeting the expectations placed on it by the wider community. At its broadest definition, this community can consist of local, regional, national, and international stakeholder groups comprised of individuals, institutions, and organizations. The strength of an open-cast mining company's LTO is directly related to how it manages progressive and final closure and specific mine planning and design aspects such as landform, treatment of final voids, water drainage and quality, and how they ultimately impact postmining land use.

Relative Economics by Business Process and Changes with Depth

Having discussed the key operational tasks that define the strip mining process, it is worthwhile contrasting the relative economics of each, how these relativities change with depth, and the operational implications of these movements. Four scenarios were developed based on a single 10-m coal seam, increasing waste depths, and differential waste allocation by waste-stripping process. Costs include both capital and operating components.

Figure 10.8-8 highlights the contribution waste removal makes to total mine gate cost for the four scenarios—dragline operating productively at shallow depth (35 m), dragline operating at its effective limit (70 m), 50 m of truck and shovel prestrip introduced with relatively short haul (6 trucks), and 100 m of truck and shovel prestrip introduced with relatively long haul (12 trucks). Some key points become clear. For shallow deposits (35 m), coal-related processes make up a significant proportion of total cost, and the operation will be oriented around minimizing coal mining cost. This suggests frequent coal access ramps with coal haul roads optimized for haulage to the processing plant with management focus on the coal mining process. As the seams progress deeper (70 m), drill-and-blast makes up a more significant proportion of cost, and focus will shift to optimizing drill-and-blast operating practices. Dragline operations are now the majority of total cost, and there will be extreme focus on productivity and equipment uptime. Beyond 70 m, as truck and shovel prestrip is introduced, it will work around the dragline process, and its role will be to ensure cost-effective dragline operation. At extreme depths (100 m of truck and shovel, and 70 m of dragline), waste stripping dominates the cost structure with truck and shovel operations now contributing as much cost as all of the other operations together. The coal mining and dragline operations will work around the truck and shovel operation to ensure its cost-effectiveness. The mine design will be modified to optimize truck and shovel at the expense of all else. The scenario also shows the additional cost loading due to task—the additional depth has a linear impact providing that the same haul cycles can be maintained, but simple dump geometry dictates that with depth, not only is there more waste, but it also has to be hauled farther and higher. The additional cost from this increased task is shown in Figure 10.8-8 as the 6-truck to 12-truck cost increment, with the result being an exponential cost increase. At this point, attention will be given to seeking out optimized dumping practices, new dump locations (potentially on top of high-cost coal or future underground areas), and innovative waste movement methods (conveyors being one example).

Consideration at this point should be given to the relative cost of underground operations as an alternative means of generating raw coal for processing. A 4-m-thick seam at around 70-m depth will be exposed by dragline for approximately the same operating cost per metric ton as a longwall operation and for around the same mining capital investment. The choice of approach around this approximate opencut stripping ratio of 12:1 prime to raw coal (9:1 for a pure truck and shovel operation) will be governed by practical considerations. Opencut mining is inherently lower risk and has a wider envelope of application given that underground operations can be severely impacted or even excluded by factors such as geological faulting, intrusions, weak immediate roof, seam gas, seam water, and so on.

Other Operational Aspects

Three other operational aspects are worth discussing in respect to their unique impact on strip mining. These are the storage or disposal of washery rejects and tailings, river and creek diversions, and water management.

Rejects and Tailings Storage or Disposal

Typical product yields range from 50% to 90% by mass for all material fed into the coal washery. Coal washery by-products, the remaining 10% to 50% of the mined coal mass, include coarse reject and wet tailings with the bulk by volume being the coarse reject material. Coarse reject is often stored in close proximity to the wash plant, either in a stockpile on a natural surface or, if available, a completed pit void, and it is placed there either by conveyors or trucks. Tailings are either placed in a conventional wet tailings facility constructed as a dam, or codisposed with reject in either a dam or completed pit void. Wet tailings facilities have large footprints, are high in capital to construct, are expensive to rehabilitate, and carry significant environmental risks both during their operation and post-rehabilitation. For this reason, a completed pit can often be seen as an ideal storage and disposal solution.

Deposit geometries, however, generally do not offer up completed pits early in the mine life, as a strip mine will work the entire strike on a cost equivalence basis for the entire mine life. Little economic delineation exists between pits that are often arbitrary subdivisions of what is usually a single deposit broken up by operational needs such as coal access ramps or creek corridors. More commonly available are final ramp voids left behind as the deep operation has moved to fill the mouth of a ramp as a short-haul dump option. Unfortunately, a competing alternative use for any final voids, either ramps or completed pits, is a potential low-cost dump, and given the cost ratio between horizontal and vertical haul, it is surprising how far away a truck system can reach economically when its alternative is to elevate overburden. For this reason, the best economic use of voids may not be to fill them with wet tailings, especially when water itself for many mines is becoming a scarce and valuable commodity. In these cases, a better alternative may be a partially or fully dewatered tailings paste or cake mixed with reject and disposed directly into the dump mass where it is contained and the long-term liability is minimized. No burial of washery wastes into the reclaimed overburden should occur without a thorough analysis of the wastes' potential for harm to the restored groundwater regime. This may be, among other things, an acid–base accounting or a column test for long-term solubilities.

River and Creek Diversions

Most strip mines are tens of kilometers long with few reasons to break a continuous strip into separate pits other than arbitrary subdivisions based on the needs of the mining operation; infrastructure corridors for road, rail, power, or water pipelines; and so on. It is highly likely that in this long strike there will be a number of water courses traversing planned mining areas. It then becomes an engineering and strategic analysis to weigh up the positive value of the coal that lies below a creek or river and the dump space created by removing a valley through the future maximum dump envelope against the negative value from the initial capital cost of a diversion, the ongoing operating cost to maintain the diversion, a final capital cost to reinstate the water course in or near its original course if applicable, and an estimate of the risk of exposure to a trailing liability to maintain the diversion into perpetuity. The nature of a strip mine means that it is likely that any permanent diversion will be quite long, whereas a temporary diversion can just shift the problem to another pit with the commensurate risk of reestablishing a water course through what is now effectively a postmining landform that is more susceptible to damage from water erosion.

Water Management

Because of their long strike and progressive development over time, mature strip mines can carry large internal water catchments. Environmental licensing conditions relating mainly to salt levels and turbidity can often mean that poor-quality mine water is not easily discharged off-site. For this reason, mine water is stored and either evaporated or partially consumed in the water-based coal processing operation. The large volumes that can accumulate over time or from single intense rain events often mean that a sacrificial pit is selected as the only economically viable water storage solution. The pit may be used for a number of years until it becomes the most attractive pit remaining on-site, at which point another pit is selected for water storage and the first pit is pumped out. After the water is removed, there is often a thick layer of mud in the bottom of the previously dormant pit that also needs to be removed. Mud removal is a slow and expensive process, and if not fully completed before stripping is recommenced in the affected pit, can lead to ongoing spoil stability issues. Massive spoil failure in a deep pit is prohibitively expensive to remediate. It is conceivable that for a very deep pit subjected to a massive failure, it would not be economical to recover the pit because of the large capital cost involved; thus, significant resource sterilization could occur if extraction by underground means is not deemed viable.

ALTERNATIVE STRIP MINING STRATEGIES

The four most common strip mining strategies will be examined as follows:

1. Cast, doze, excavate operation
2. Single-seam dragline operation with prestrip
3. Multiple-seam dragline operation with prestrip
4. Truck and shovel operation

A strip mining strategy may be typified by a unique combination of pit configuration, equipment selection, and operating methodology with the combination essentially a response to the deposit being worked. For this reason, a methodical approach making use of the following discussion framework will be applied to examine each of the four major strip mining strategies deployed in mines today:

- A brief generic discussion of the mining strategy
- A specific mine case study used to examine
  - Pit configuration—mine location and layout and the deposit's geological orientation,
  - Equipment selection—the physical and volumetric scale of extraction, and
  - Operating methodology—an operational description in terms of overburden movement and coal mining
- Reference made to variants of note as applied at other mining operations

Other variants within the presented strip mining strategies are deployed where the specific circumstances warrant it. The combination of final and interseam waste removal and coal mining in thin-seam mines may be achieved by the application of continuous surface miners or graders. Steep-dip mining, as in Colombian thermal coal mines or the United States anthracite district, gives rise to operational variations of the truck and shovel strategy, whereas mountain-top removal

in the United States' Appalachia region is unique and can be considered to be a multiseam modified area mining method.

Cast, Doze, Excavate Operation

"Cast, doze, excavate" refers to a strip mining technique whereby the overburden is cast blast, followed by significant removal by large bulldozers, and the remainder of the overburden is removed using an excavator and trucks, or sometimes by draglines. This method is most applicable to relatively shallow deposits.

In these operations, the overburden blast is designed to not only fragment the overburden to enable removal, but also for the blast to significantly move the overburden into the adjacent open void, reducing the amount to be removed with mining equipment. This style of overburden blasting is referred to as cast blasting. Because of the increased blasting vibrations and noise, the method should not be used near dwellings and residential districts without first determining potential dust, noise, and vibration levels.

Bulldozers are more productive and hence more economically attractive for combinations of relatively short push distances and fairly flat grades. Where bulldozers can be used in this manner they are usually lower total cost than truck and loader systems. In an ideal situation, the bulldozers are used to remove the overburden until the push distance and grade combination is no longer lower cost than the next alternative (either truck and loader systems or draglines). In some situations, cast doze is used to remove all of the overburden material.

Case Study: Groote Eylandt Mine

Groote Eylandt is located off the coast of east Arnhem Land in the Gulf of Carpentaria about 640 km from Darwin, Australia. The mining leases are located on the western plains and cover 84.5 km^2 or 3.74% of the island's area.

Pit configuration—Geological orientation. The Groote Eylandt ore body occurs as a subhorizontal sedimentary layer, gently undulating and dipping to the west. It is a continuous horizon, ranging in thickness from a few centimeters to 9 m, consisting of hard, high-grade, cemented pisolitic and massive manganese oxides. The overburden ranges in thickness from 0.5 to 35 m and consists of lateritic overlying clays and gravels.

The ore body is vertically zoned and can be mined as two distinct layers:

1. A middle mining horizon consisting of massive mangite, cemented mangan-pisolite, or loose mangan-pisolite
2. A bottom mining horizon consisting of siliceous mangite

The beneficiation plant is located in the middle of the mining leases, with 90% of the resource within 8 km of the processing plant.

Equipment selection—Physical and volumetric scale of extraction. The mine typically removes 18 Mbm^3 of overburden each year, comprising 0.4 Mbm^3 of topsoil, 17 Mbm^3 of dozer production, and 0.6 Mbm^3 truck and excavator operation. This total overburden removal exposes 6.9 million t of run-of-mine (ROM) ore to be delivered to the primary crushing station to yield 3.6 Mt of manganese product.

Current mining equipment is a mix of stripping dozers, excavators, and rear-dump trucks. The mining blocks or cuts are 40-m wide and 200-m long, with strips arranged to follow ore-body contours and to control groundwater.

Operating methodology. The Groote Eylandt Mining Company Pty Ltd. (Gemco) mine is a conventional, shallow, opencut strip mining operation involving the removal of manganese ore. The mining sequence is a continuous cycle; areas from which ore has been extracted are backfilled with overburden from the next strip to be mined before then being rehabilitated. This method results in the mining site moving across the ore body disturbing only a small section of land surface at any given time. To meet Gemco's customer product-quality requirements, ore can be mined from a variety of pit sources.

The first step is to clear trees on the planned mining blocks, using a bulldozer with a tree rake. The topsoil is then removed and returned to prepared backfill areas or stockpiled for future rehabilitation.

Overburden is primarily removed using a fleet of Global Positioning System–equipped track dozers that push the material into the adjacent mined-out cut (strip mining technique). The dozers are used to remove all overburden, exposing the ore. Typically, the dozers work in two separate teams, each team working a strike length of 250 m to 500 m and a pit width of 40 m. At times they are used as one fleet to provide peak capacity for short-term ore requirements. Historically, scrapers were also used to remove topsoil and overburden when the overburden was significantly thinner. To reduce costs and handle a wider range of material types, production dozing was introduced. A small amount of overburden is removed using a truck and excavator method, and this method is applied in thicker overburden areas and where digging from above with excavators is used to better handle wet conditions.

A rotary percussion rig is used to drill the ore horizon, and blasting is conducted using emulsions for both wet and dry holes. The blasted ore is removed using a hydraulic excavator. The excavator is also used for overburden stripping for initial or box cuts. Ore is trucked from the pits to the primary crushing stockpiles in 85-t-capacity rear-dump trucks. Some direct haulage also goes to the primary crusher, provided the ore type coincides with the ore treatment campaign through the plant.

Approximately 22 stockpiles are maintained near the primary crusher and categorized according to grade and lump-to-fines ratio. The haulage distance from the pit to the stockpiles varies from 2 to 10 km. In total there are about 30 km of haulage roads that are serviced by ancillary equipment.

Rehabilitation of mined areas started in 1970. Seeds from approximately 25 native forest species are collected from within the mine lease. This seed is stored until the wet season when it is broadcast over areas that have been backfilled and covered with topsoil. Backfill areas are designed to maintain the general premining slopes.

Single-Seam Dragline Operation with Prestrip

For single coal seams that occur deeper than 30 m and where economies of scale allow, a single-seam dragline method is often applied. Although multiple seams may be recovered, for the purposes of terminology where only one seam is directly exposed by dragline operations, it is called a single-seam dragline operation. Because of their specific geometric limitations, efficient dragline operations are dictated by the interaction of the particular deposit geometries and the machine's key working dimensions. A dragline moves overburden by a simple repetitive cycle involving filling the bucket through a combination of pulling in the drag rope and letting out the hoist rope, raising the bucket by the reverse rope movements,

swinging to face the spoiling area, emptying the bucket by releasing the tension on the drag rope, and swinging back to return the bucket to the dig face or bank.

Strip width is typically 50–70 m wide with the strip being placed into the adjacent mining void in discrete excavation blocks of 25–30 m in length, depending on the dragline operating level. A number of different dragline methods are available to place the overburden in the previous void. Selection of method is driven by a number of factors:

- **Deposit geology**—The number of seams to be uncovered by the dragline and the overburden and interburden thicknesses
- **Geotechnical stability**—Certain materials in the strata may be either unsuitable to place the machine on or unsuitable to place in certain locations within the spoil
- **Spoil fit**—The machine will need to sit low enough to reach the top of the coal, but it will also need to sit high enough to ensure it can place the spoil into its final position
- **Productivity**—Will be maximized with lower average swing angles, but swing angle may be less of an issue if there are a large number of hoist-dependent swings (where the swing speed is less than maximum due to the machine waiting on the bucket to be hoisted to height)
- **Scheduling**—At times it may be necessary to adopt a dragline method that may be less productive overall due to increased relocation times but that releases coal sooner and more consistently

Dragline methods are analyzed in two- and three-dimensional (2-D and 3-D) volumetric models as well as simulations. Two-dimensional analyses called range diagrams are used to check for theoretical spoil fit and calculate sectional rehandles. Figure 10.8-9 shows an example of a range diagram sequence. The section is perpendicular to the strip and shows where material is dug from (A), dumped to (A'), and the operational sequence (steps and fill type). Where topography is variable or the influence of certain design features are such that a 2-D analysis is unsuitable, a 3-D check for spoil fit and rehandle rates can be undertaken. In addition to the simple dig-to-dump balance, more sophisticated software models can be used to simulate the dragline machine itself to yield theoretical production rates in cubic meters per hour based on a dynamic analysis to determine the average swing angle and relative frequency of hoist and swing dependent cycles.

A brief overview of the main dragline methods are given in the following paragraphs. A completed range diagram is shown in Figure 10.8-10.

In the side cast method, the overburden is dug from in front of the machine to expose coal and dumped directly in the void from the previous strip (Figure 10.8-10A). It is most often used for shallow overburden thicknesses where the dip is relatively flat and there is no requirement for selective placement of overburden in the spoil. It is also used for multiseam operations for exposing the top coal seam as there is a large void to spoil the overburden into.

The key bridge method (Figure 10.8-10B) is suitable for deeper deposits up to the dragline's ideal operating envelope. Sequentially it involves excavating a block of overburden 30-m long to create the new highwall (the key) and using this overburden to build a bench out into the previous strip's void. The dragline then progressively repositions across the bench, excavating overburden and exposing coal as it goes

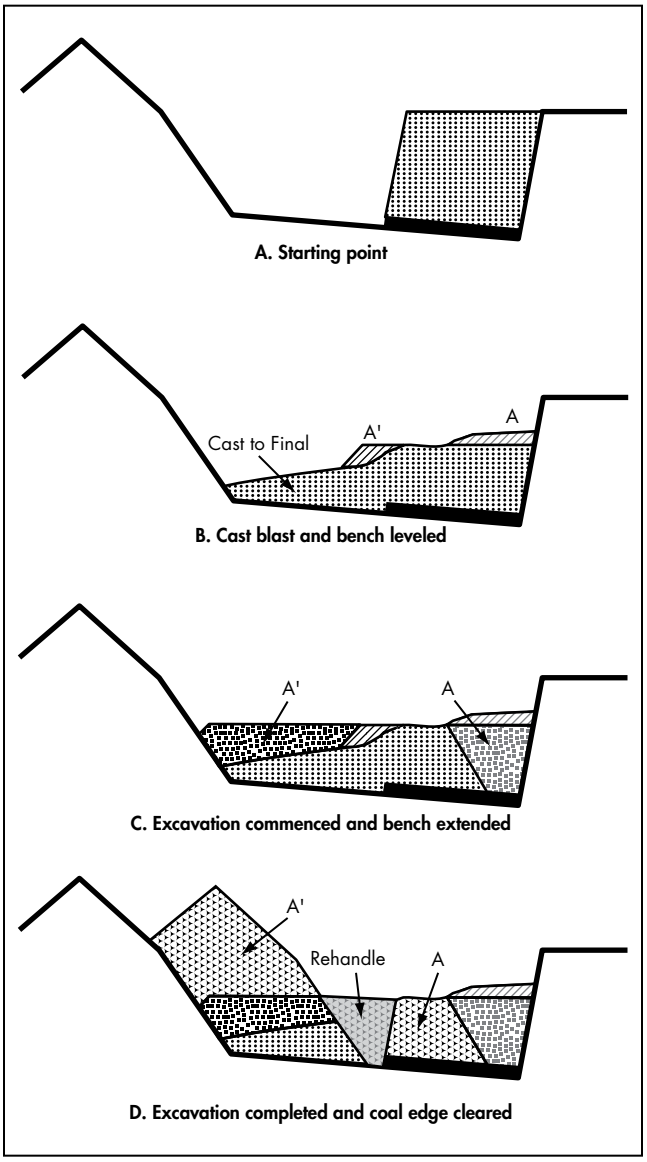

Figure 10.8-9 Range diagram sequence

(the block). After it has uncovered the full strip width of coal, it repositions diagonally down the strip into position to commence digging the next key. The method has higher rehandle but is productive because of the short swings, the previous strip floor can be cleaned up prior to overburden being placed in it, the highwall is dug in-line giving a safe wall, the coal edge is also excavated in-line, and it is a simple method to execute. A variant of this, called the extended key with in-pit bench method (Figure 10.8-10C), involves the key being excavated for 10 or 20 blocks and an in-pit bench built on the low-wall side. At the end of the extended key, the dragline then repositions to the in-pit bench and "pulls" the remaining blocks for the length of the extended key, exposing coal. An advantage of this method is lower rehandle than the key bridge, as the in-pit bench does not have to be filled in completely from the highwall to the low-wall side (no "bridge" required).

In the chop cut with in-pit bench method (Figure 10.8-10D), use is made of throw or cast blasting to move as much of the

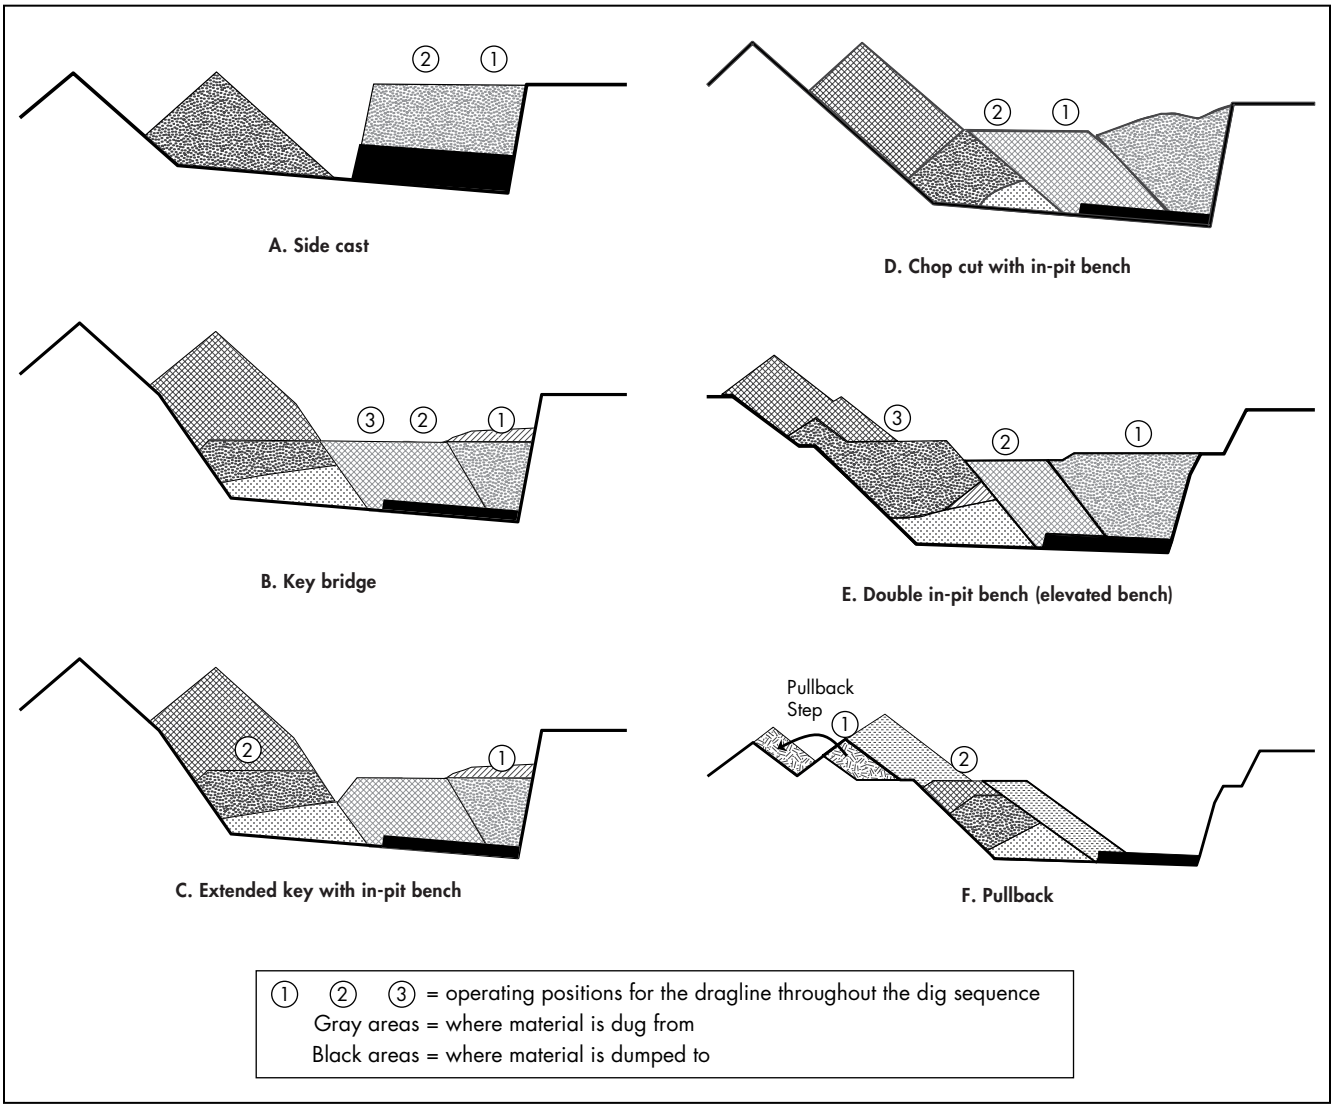

Figure 10.8-10 Main dragline methods

prime material across to the low wall as possible. The dragline excavates the key area along the strip by digging perpendicular to the new highwall and creates an in-pit bench toward the low-wall side of the strip. The dragline then retreats along the in-pit bench and excavates the block that it was previously sitting on and places it in final position. The method has low rehandle and high prime productivity but is a more complicated two-pass operation that gives poor control of highwall.

The double in-pit bench method (Figure 10.8-10E) is used when the depth of material is such that the dragline operating envelope is not sufficient to place all of the overburden into a final position from a single working level. For this reason it may also be known as an elevated bench method. An extended key or chop cut with in-pit bench method is used, but instead of the bench being fully excavated to final position, a partial excavation, or trim, is undertaken and the overburden placed to create another bench at a higher working level. When a suitable length of upper bench is created, the dragline moves onto the upper bench and excavates the remaining waste to expose the full strip width of coal. The higher second bench increases the volumetric capacity of the dragline and so allows the exposure of deeper coal. Walking delays increase, overall productivity is lower, the method is more complex, and coal exposure is more intermittent.

Although not a specific method, the pullback technique (Figure 10.8-10F) involves walking the dragline up into the spoil to pull existing overburden back prior to placing overburden from the current strip. It is time-consuming to prepare access for the dragline, and the pullback material does not expose coal so it is all rehandle, but productivity can be reasonable depending on the volume to be excavated. It is rarely used as part of an ongoing operation because of its high cost, but it can be used in areas where spoil room is particularly tight, such as around ramps or deep boxcuts or to recover from design errors or geotechnical failures. Operationally this method can be delivered by two separate draglines: one on spoil in the pullback mode and one on the bench to be mined.

As the seams progress to greater depths, typically at around 85 m, a truck and loader prestrip operation must be introduced to assist the dragline to continue to reach the top of the coal by creating a working level for the dragline that is lower than the natural topography. Prestrip may have

been introduced sooner than this, however, depending on the deposit and dragline geometry and general economics. Prestrip may be directed to relieve the dragline in tight spoiling areas such as when crossing ramps or endwalls or where the natural topography is variable, or prestrip may be applied more generally across the whole strip.

Case Study: Norwich Park Mine

The Norwich Park hard-coking coal opencut mine is located on the western fringe of the Bowen Basin coalfield in Central Queensland, Australia. The economic seams are contained in the Mid- to Late Permian German Creek Formation, which are overlain by up to 55 m of poorly consolidated cemented sediments consisting predominantly of sand and clay with irregular gravel beds and weathered basalt flows.

The depth of weathering varies from 15 to 25 m north of Leichhardt pit to 25–50 m in the Leichhardt pit and south. Four coal seam groups are present over the mining area with the dip of the sequence to the east and varying from 2° to 10° in some areas.

Equipment selection—Physical and volumetric scale of extraction. Initial mining operations commenced on the subcrop of the Dysart seam(s) in 1979 to uncover coal in strips oriented along the strike of seams. Mining has progressed along the strike and downdip over the intervening period.

Surface features are generally flat with a few ephemeral creek systems running across the deposit. The mining area has been divided into a number of pits with these features incorporated into the layout design. The mine processing plant and other facilities are located on the western side of the deposit in a generally southern location.

Currently, the mine employs a fleet of major mining equipment consisting of six electric walking draglines supported by excavators and rear-dump trucks for waste removal and front-end loaders and bottom-dump trucks for coal mining and haulage.

The coal haulers haul ROM coal to the crushing and processing plant along a haul road network. Total annual product metric tons are typically 6 Mt from a plant feed of 8.5 Mt running at an average yield of approximately 71%. Total annual prime overburden moved is typically 100 Mbm^3 giving a prime-to-product strip ratio of approximately 17:1. Allocation of this prime is mainly to dragline (60 Mbm^3/yr) followed by prestripping (27 Mbm^3/yr) and the remainder to production dozing and minor waste operations.

Operating methodology. Figure 10.8-11 provides a schematic of the mining process representing the typical dragline and truck and shovel activities. Truck and shovel stripping is used to complement and expedite dragline productivity with waste hauled around the dragline operation and dumped on top of dragline spoil. Typically, the truck dump is two spoil peaks behind the current dragline strip.

Single-seam dragline methods are used in the Price and Leichhardt pits, where successive seams are uncovered using trucks and excavators, as well as areas of Campbell and Roper where the upper seams are coked or weathered. The two methods used in the single-seam areas can be broadly categorized as the Jensen and Curtis off-line key bridge method (conventional or extended key), and the extended key and elevated bench method. The conventional Jensen and Curtis method progressively uncovers the full seam width, whereas the extended key does not. The extended key method is used where the height of the elevated bench above the in-pit bench is too great to use the conventional Jensen and Curtis method. This might be the result of an area that has a very low in-pit bench because of the blasting and dozing techniques, or an area where the elevated bench has to be built high to enable the dragline to exit the pit. The latter is often used from the endwall back and is known as a reverse key.

Little difference exists in the planning requirements in regard to range diagram analysis for spoil fit for these two methods. The main difference relates to the timing of the coal exposure. The conventional Jensen and Curtis method has continuous coal exposure whereas the extended key method has sporadic coal exposure due to the need to return to the front of the strip to pull blocks to expose the full seam width.

Jensen and Curtis off-line key bridge method—Leichhardt pit example. After blasting and any dragline prestrip, a dragline access road is formed to the ramp mouth. If time permits, dozers will be used to bulk push waste across the pit and lower the in-pit bench level. The dragline will then be walked to the ramp mouth and the dozer key will be set up to break away from the ramp mouth. This initial waste is spoiled behind the dragline to form the in-pit, or chop, bench. The dragline will then be positioned on the chop line to start working away from the ramp. The dragline digs key material and dumps it into the in-pit bench. The dozer will be cleaning coal and pushing up spoil on the low-wall side at this stage. The dragline will widen, or trim the key, and throw the material to final spoil. The dozer will continue preparing the in-pit bench. The dragline works off the in-pit bench and throws the remaining low-wall side material to final spoil. At this stage the dozer will be working against the highwall, cutting down the key material and cleaning the highwall. For the rest of the strip, dozer push will be used to excavate the highwall portion of the key and expose down to the top of the coal. The progress of the method in sectional view is identical to the example range diagram sequence provided in Figure 10.8-12. Operationally, the method makes extensive use of dozer operations to cost-effectively supplement the dragline operation.

Extended key and elevated bench method—Roper pit example. Using this technique, the floor of the previous strip is cleaned before blasting. Any mud and water is dammed up on the low-wall side. The area is not presplit before blasting. The overburden material is cast blast onto the pit floor with the blastholes drilled at 75°. After blasting, the dragline takes a highwall trim from the surface (Figure 10.8-12A) down to 20 m below the surface and forms a safety bench. The dragline or dozers then prepare an access into the pit and will prepare the chop bench. The dragline will walk into the pit and commence digging off-line extended keys from the ramp mouth (Figure 10.8-12B). The spoil will be used to build an elevated bench. When coal needs to be exposed to suit coal-mining requirements, the dragline will form a ramp up onto the elevated bench and will walk back to the front of the strip to pull blocks, exposing the full width of the Dysart seam (Figure 10.8-12C). Additional low-wall trim will be taken to ensure a stable low-wall angle and a defined low-wall edge offset.

Truck and shovel prestrip. Prestrip is usually conducted by contract. Planned prestrip is the difference between the waste removal requirement to uncover the annual coal production and the installed dragline capacity. Shovel/truck priorities include geotechnical recommendations, spoil relief, and post-strip activities. Free-dig prestrip areas comprise horizons that cannot be drilled because blastholes will not stay open (i.e., they are too sandy).

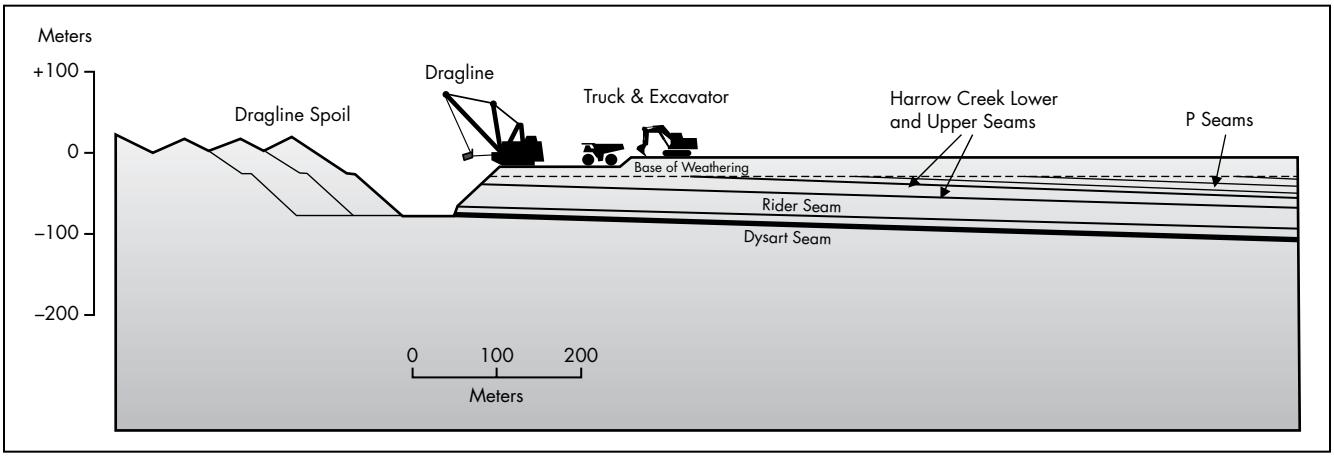

Figure 10.8-11 Cross section of Norwich Park mine

Variants at Other Mining Operations

A number of possible variants of single-seam dragline operations exist. Track dozers may be deployed to assist the dragline operation and speed up coal exposure rates as at the nearby Gregory mine. This mine has also used excavator and truck fleets to remove the dragline key material to accelerate coal exposure. The advantage is that this material is placed outside of the dragline operating area and does not contribute to rehandle, unlike production dozing. Shallow mines in the United States have employed a direct-cast or side-cast method. The operating strip width is narrower and the waste-to-coal ratio is such that the dragline is able to directly place all material into the final position without building working pads and thus incurring rehandle. For steeply dipping seams or highly faulted deposits, the dragline may expose a "false floor" and leave the remaining wedge of material overlying coal to be removed by smaller truck and excavator methods.

Multiple-Seam Dragline Operation with Prestrip

For multiple coal seams that occur deeper than 30 m, and where economies of scale allow, a multiple-seam pit configuration is selected. Within this broad configuration a combination of a number of the single-seam dragline methods is applied to uncover each successive seam. Strip-and-block geometry is similar to single-seam dragline methods, but the geometry dictates significant time and effort to move the dragline up and down between what can be quite different working horizons. A brief overview of the two broad categories of multiple-seam pit configurations—namely, stacked and offset—follows.

Stacked Configuration

In a typical stacked configuration, the dragline removes the overburden in a sequential operation working from the top of the sequence to the bottom. Multiple dragline passes are required with one coal seam being exposed on each pass. Generally, the first pass is a simple direct-cast operation into the void from the previous strip. Subsequent passes will generally involve key or chop operations and extended benching to expose the coal and place the spoil into its final position. The stacked configuration can result in low rehandle (25% or less) and high productivity, especially for narrow strips. One disadvantage is that the lower-pass burden blasts are buffered by upper-pass overburden, and so less cast blast is achieved and fragmentation can be poorer, leading to reduced digging productivity. A second disadvantage is that the material from the upper pass ends up on the floor of the whole spoil pile, may not be suitable to use as a spoil base, and can frequently remain in the base of the pit for extended time between passes where it undergoes further degradation. A third disadvantage is that if lower passes are relatively thin compared to the upper pass, high rehandles can result.

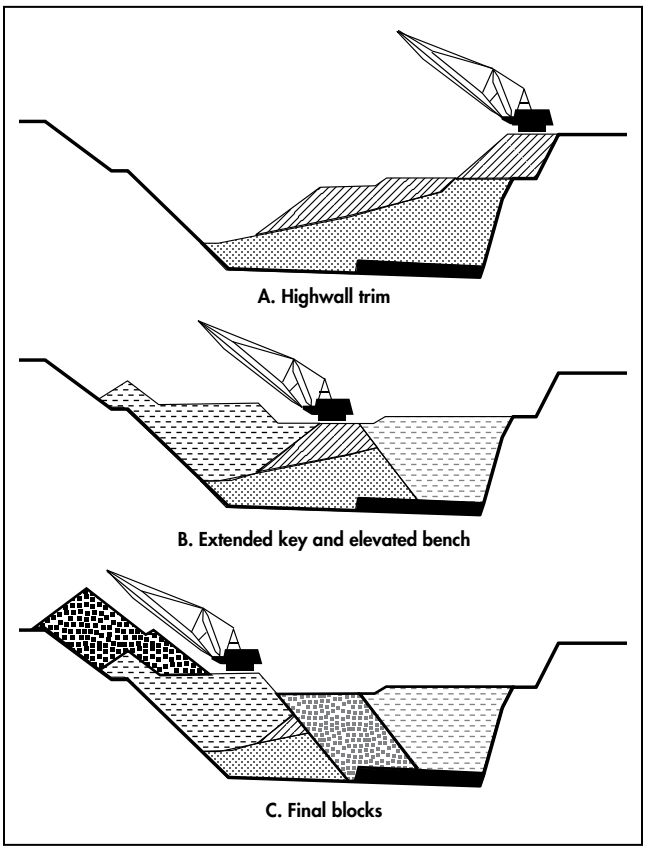

Figure 10.8-12 Extended key and elevated bench sequence

Offset Configuration

In a typical offset configuration, the upper seam is offset at least one complete pit width from the lower seam. This allows

the lower pass to be blasted first, followed by the upper pass, which is generally cast as much as possible to lower the dragline working level. The overall sequence is then very similar to an extended bench method where the extended bench covers the entire lower seam. It is important that the bench level is as low as possible as the bench is built entirely from rehandle. Advantages include the exposure of two coal seams simultaneously, which allows them to be mined at the same time enabling blending. Blast performance is improved for the lower pass as it is not buffered, and scheduling is simplified as the dragline does not require an alternative working area while a seam is mined out and the next pass of overburden is drilled and blasted. Disadvantages are that overall rehandle is generally higher and can increase dramatically with increased total waste allocated to the dragline, and in deeply prestripped mines the large open void requires a significant investment in working capital to establish and maintain as well as placing further stress on the dump volume balance.

The selection of one configuration over the other is dependent on an analysis of many factors:

- Seam dip
- Relative geometry of the upper- and lower-pass overburden and seam thicknesses
- Geotechnical characteristics of the overburden
- Scheduling and blending considerations

Case Study: Goonyella Riverside Mine

The Goonyella Riverside high-quality hard-coking coal opencut mine is located on the western fringe of the Bowen Basin coalfield in Central Queensland. The mine area has a strike length >30 km arranged in two groups of parallel pits representing the originally separate Riverside and Goonyella mines. In the west, pits target the single basal Goonyella lower seam (GLS); in the northeast, pits target all three major seams: the Goonyella middle seam (GMS), Goonyella upper seam (GUS), and the GLS; and in the southeast, pits target the GMS. An underground longwall operation is currently installed in one of these pits and is extracting GMS coal from panels oriented perpendicular to the strike.

Pit configuration—Geological orientation. The Goonyella deposit contains economic seams in the Late Permian Moranbah coal measures that are approximately 300-m thick. The Moranbah coal measures are Mid- to Late Permian age and are characterized by several laterally persistent, relatively thick coal seams interspersed with several thin minor seams.

The Permian coal measures dip east at 3°–6°. The mine area is covered by 0.5–30 m of poorly consolidated Cainozoic sediments consisting of lenses of river channel gravels and sands separated by sandy silts, sandy clays, and clays. The Tertiary silts and clays are densely compacted, hard, and generally dry.

The major seams commonly exhibit decreasing ash content and increasing vitrinite content toward their base and are recognized for their superior coking properties.

Equipment selection—Physical and volumetric scale of extraction. Mining operations commenced on the subcrop of the GMS in 1971 to uncover coal in strips oriented along the strike of the seam. In 1983, mining of the GLS commenced following the commissioning of the Riverside mine updip of the GMS operation. Also in 1983, the Goonyella mine commenced mining the GLS in addition to the GMS in a double-seam operation.

Surface features are generally flat with a few ephemeral creek systems and the Isaac River traversing the southern portion of the mining lease. The mining area has been divided into a number of pits with these features incorporated into the layout design.

Currently, the mine employs a major mining equipment fleet consisting of seven electric walking draglines supported by a number of electric rope shovels, hydraulic excavators, and rear-dump trucks to effect waste stripping. Coal mining is undertaken by front-end loaders and rear-dump trucks. The trucks haul ROM coal to one of two crushing and processing plants along a haul road network. Total annual product metric tons are typically 16 Mt from a plant feed of 20 Mt running at an average yield of approximately 80%. Total prime overburden moved is typically 125 Mbm^3/yr giving a prime-to-product strip ratio of approximately 10:1 for the opencut coal component. Allocation of this prime is mainly to truck and shovel (80 Mbm^3/yr) followed by dragline (45 Mbm^3/yr).

Operating methodology. Figure 10.8-13 provides a schematic of the mining process representing the typical dragline and truck and shovel activities. Truck and shovel waste is hauled around the dragline operation and dumped on top of dragline spoil. Typically, the truck dump is two spoil peaks behind the current dragline strip.

The four northern double-seam pits target the GMS and GLS and account for 70% of opencut production. The GUS is being exposed and mined in the prestrip areas of these pits. The double-seam pits in the north have the lowest strip ratio, and production is concentrated in this area. All double-seam pits have low-wall access ramps. The remaining single-seam pits target the GLS in the west and the GMS in the east and account for the remaining 30% of opencut production. As the single-seam GMS pits advance downdip, they are picking up the GUS in their prestrip operations.

The choice of dragline technique depends on a number of pit-specific conditions. Several dragline techniques are used that can be broadly categorized as

- Single-seam key bridge methods,
- Single-seam key bench methods,
- Double-seam offset methods, and
- Multiple-seam stacked methods.

Although the techniques are long-established for each pit, the basic selection criteria for single-seam methods is whether the low wall is geotechnically stable, with an extended key/bench method used where it is and a key bridge method used where it is not. In the dual-seam areas, the offset method is favored unless the interburden is considerably thinner than the overburden.

Double-seam offset method—Redhill pit example. The first step is to blast the interburden, which is cast blast followed by blasting of the overburden with material spilling over the interburden bench. The dozers then form a working pad on the shot overburden. Sitting on an off-line position, the dragline will then uncover the full width of the GMS. This essentially consists of a combination of off-line key and trim (widening) of that key to expose full-seam GMS. The spoil is cast beyond the GMS coal edge. Ideally, the entire length of GMS in the strip will be uncovered before the dragline has to move onto the in-pit bench. A combination of selective placement with the dragline and use of dozers creates an in-pit bench. The dragline forms and walks across a bridge onto the in-pit bench. This bridge is subsequently removed.

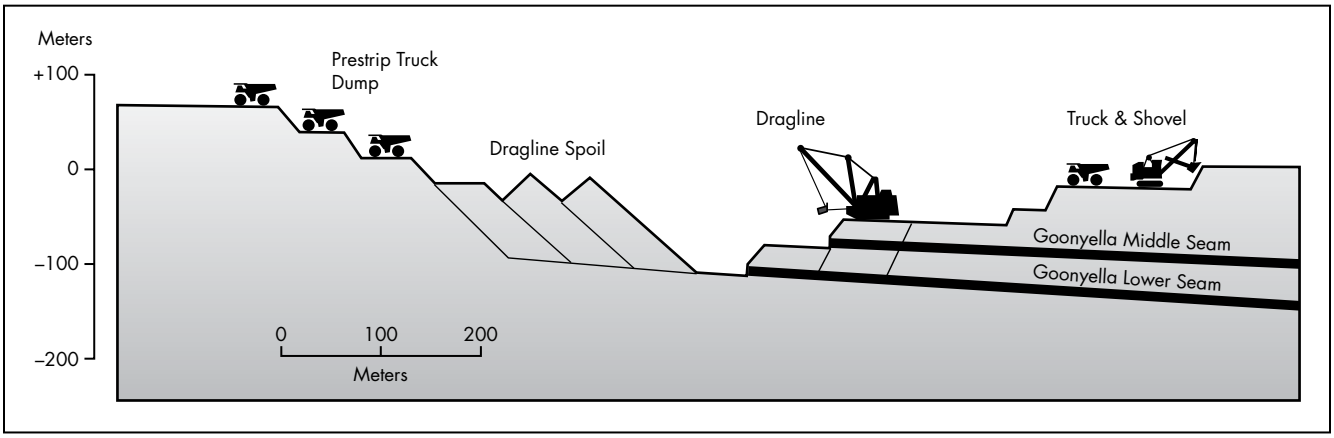

Figure 10.8-13 Cross section of Goonyella Riverside mine

The operation is now the same as a conventional off-line key/elevated bench method. From an off-line position, an extended GLS key and trim is taken, and the spoil is used to build an elevated bench. The dragline walks up onto the elevated bench and pulls blocks to uncover the full width of GLS coal. The GMS coal is accessed from the highwall whereas the GLS coal is accessed by a low-wall ramp at the southern end of the strip.

Multiple-seam stacked method—Thiess pit example. The upper split of the GLS (GLUS) overburden is blasted and a working pad is formed on top of the blasted ground. Full-width GLUS is uncovered by taking an on-line key, then trimming (widening) the key until the GLUS is exposed. This is essentially a side-casting operation. After the GLUS is exposed, it is accessed via a temporary coal ramp that is later removed by the dragline. Then the interburden is drilled and fired. The operation is now the same as a conventional off-line key/elevated bench method. From an off-line position, an extended GLS key and trim is taken, and the spoil is used to build an elevated bench. The GLS blocks are pulled from the elevated bench to expose the full strip width of the lower seam coal. The GLS is accessed by a conventional center ramp.

Truck and Shovel Operation

As previously discussed, truck and shovel strip mining is selected where flexibility beyond that offered by an efficient dragline method is required. Typically, these applications are in more complex multiseam and/or steeply dipping deposits. Truck and shovel is preferred in steeply dipping deposits where waste spoil room in the previous strip is insufficient within the efficient operating envelope of a dragline. Truck and shovel is also used for shorter life operations where there is insufficient mine life to provide a payback for the higher capital investment of draglines.

The two main types of truck and shovel mining operations are conventional along-strike operations, with the pit progressing downdip with each successive strip, and downdip mining or terrace mining, where the strips are excavated downdip usually to the final highwall and then progressed along the strike (effectively at right angles to a conventional along-strike method). The advantage of terrace mining is that the waste material can be short hauled either across the blasted waste or around the ends of the strips to the adjacent waste dump. Typical dimensions for terrace mining in Australian coal mines are 200 m downdip using 70-m strip widths. Terrace mining is very attractive for steeply dipping coal seams where the steep floor conditions significantly reduce the spoil room available for conventional along-strike methods. Examples of terrace mining include Australian coal mines such as Macarthur Coal's Moorvale mine, Peabody's Burton mine, Jellinbah Resources' Jellinbah East mine, and Cockatoo Coal's Baralaba mine.

Case Study: Mt. Arthur North Mine

The Mt. Arthur North mine is an example of a conventional along-strike truck and shovel operation. It is located in the Upper Hunter Valley of New South Wales, Australia. The mine site has a topography that is moderately undulating, steepening near the base of Mt. Arthur. Domestic product is transported via an overland conveyor connecting the mine to the Bayswater Power Station, and export product is shipped from Newcastle.

Pit configuration—Geological orientation. Coal seams within Mt. Arthur Coal's leases are contained within the Wittingham and Greta coal measures, which are separated by a thick noncoal-bearing unit known as the Maitland Group. Coal seams split and coalesce throughout the area, with 20 discrete seams splitting to some 80 unique coal plies.

In the northern part of the deposit, the seams dip from subcrop toward a major monocline at dips of 5° to 10°. Across the monocline, seam dip increases to 10º–25º before flattening again to dips of 2° to 4° in the broad Calool syncline. Indications are that the seams roll over a broad and less-well-defined Denman anticline west of the Calool syncline. To the west of the Denman anticline, seams are down-thrown by the Mt. Ogilvie fault zone.

The in-situ waste strip ratio (cubic meters per metric ton) generally increases to the southwest with current open-cut planning targeting areas of up to a 5:1 strip ratio, which extend downdip to the edge of the eastern monocline. Beyond the monocline, the dip steepens locally and the basal seam plunges to depths >400 m before the seams flatten out.

Equipment selection—Physical and volumetric scale of extraction. The mine is currently capable of operating at a nominal 14.5 Mt/yr, based on 73.5 Mm^3/yr waste prestripping capacity (including contractors) at a 5.1 m^3/t strip ratio.

The choice of mining equipment was dictated by equipment operating at the adjacent Bayswater No. 3 mine—electric rope shovels and hydraulic backhoes, which were progressively transferred to Mt. Arthur North during 2001–2002. Although the rope shovels provided a proven low-cost prestrip capability, their inability to operate on steep dips and their

limitations in shallower interburden resulted in the procurement of additional hydraulic backhoes to mine the "wedge" of overburden that remains beneath the rope shovel floor and the next coal seam as well as interburdens in the 2-to-10-m-thickness range. The rope shovels are generally limited to the "base-of-weathering" pass and the thicker prestrip passes. The current distribution of prestrip by operation type is 35% by rope shovel, 45% by large hydraulic excavator, 10% by smaller hydraulic excavator (coal/parting fleet), and 10% by mining contractor.

An 80-m strip width was chosen to maximize the use of two electric rope shovels while providing sufficient width to operate. Overburden is blasted prior to excavation. Coal is mined using smaller hydraulic excavators and a front-end loader. Coal is "free-dug" in situ. Very thin coal seams may be ripped by a bulldozer and pushed into piles for more efficient loading.

Operating methodology. The mining method is open-pit strip mining, using truck and shovel methodology, spread over multiple prestrip horizons, as shown in Figures 10.8-14 and 10.8-15. The advantages of this system are low technical risk, high resource recovery, and flexibility to change sequencing and production rates as required.

The pit design is based on a strip mining layout where the strips are oriented parallel to the strike. Having fully developed along a 6-km strike length, the mine progresses downdip in 80-m-wide strips. The coal seams dip at between 5° and 8° over the majority of the lease; however, the dip increases in the far southeastern corner to 15°–20° where a bench mining technique and through-seam blasting is used.

In the main pit there are large areas where the seams dip <7°, allowing hydraulic excavators and rear-dump trucks to work on grade. Thicker interburdens are dug by rope shovels and hydraulic excavators. The rope shovel is used to prestrip the majority of the interburden, leaving a remnant wedge for a backhoe to remove. Above 7° dip, it is necessary to reduce the apparent dip and work off temporary benches. In these steep dip areas, track dozers are required to prepare work area pads and/or push down and stockpile material ready for loading.

Material to be excavated is first prepared by blasting or ripping, or it is free-dug. Waste rock is hauled from the highwall to the low-wall side of the mining void to backfill mined-out areas. To cross the mining void, truck haulage is either along the mining strips and via the pit endwalls or via highwall ramps and low-level cross-pit bridges that connect the highwall to the low wall. Although generally a shorter distance, the cross-pit bridge system may necessitate significant de-elevation and re-elevation of material. Most mining blocks will have a choice of the two types of routes, and the one that offers the quicker cycle time is the one that will be selected. A high-level cross-pit bridge is installed between the main pit and the Ayredale pit and functions as an endwall.

ROM coal is mined in situ using hydraulic excavators in both backhoe and shovel configuration, according to the working section thickness. Coal is hauled to the ROM coal receiver hoppers for delivery to the coal handling and processing plant. ROM coal can also be stockpiled nearby to the receiver hoppers and rehandled later as required. Coarse reject from the coal washery is conveyed to an overhead truck loading bin, situated adjacent to the coal receiver hoppers and backhauled by trucks into the spoil dumps on the return haul to the coaling face.

Spoil dumping has migrated from ex-pit dumps during the start of the operation toward in-pit placement. This involves dumping on sloping floors up to 9° and generating a layback of the dump profile for stability. The layback is enhanced by a low-wall ramp and haulage system incorporated into the dump face. Nominal batter heights of 20 m and bench widths of 40 m are used for initial dump design and suitable for standard truck-tipping operations at the crest. This profile of 2:1 is able to be locally optimized to larger batter heights and smaller bench widths where floor conditions are deemed suitable and material composition is homogeneous and competent.

Floor preparation standards are enforced on the Ramrod Creek coal seam floor. This normally involves ripping and removal of silt, water, and remnant coal. Floor blasting has not been required but will be evaluated for future steeper dip areas. Placement of material in the dump is managed, and standards exist for the type of material to be placed on floors or high tip faces. Coal reject and base of weathering material

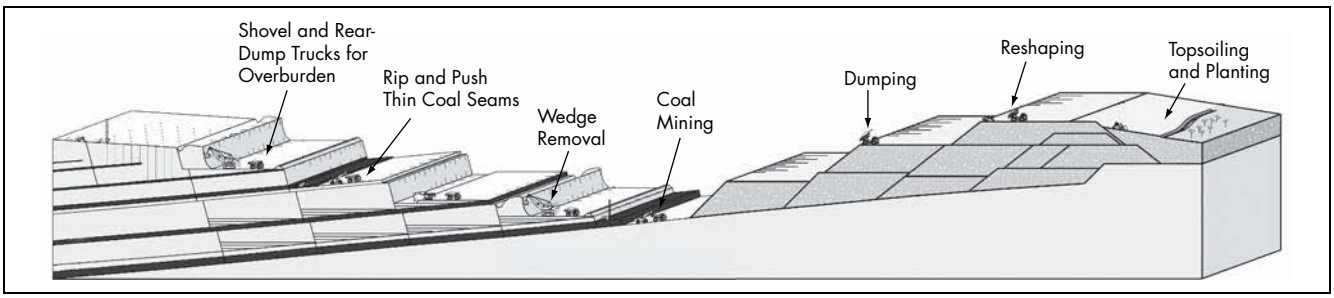

Figure 10.8-15 Mt. Arthur mining method

Table 10.8-1 Strip mining strategies compared by selection driver

Subcriteria	Driver	Strip Mining Strategies		
		Cast, Doze, Excavate	Dragline	Truck and Shovel
		Geology		
Faulting	Complex geology of ore–waste interface impacts, ore recovery, and equipment productivity. Selective mining practices are required.	Small scale of equipment units enables effective operation.	Ancillary equipment required for ore–waste interface. Large draglines can result in significant ore losses.	Flexibility of equipment enables resource recovery but with slower loading rates and some impact on costs.
Material strength	Instability due to low bearing capacity of soft waste material	Dozer production is only slightly impacted due to low equipment ground-bearing pressure. For extreme cases, install wider dozer tracks.	Dragline can sink into soft material. For localized weak materials, dragline can be used to dig off soft material and replace with competent. For more extensive occurrences, a buttress needs to be maintained to provide stable ground for the dragline. Equipment modifications include larger tub and wider shoes.	Shovel is also prone to sinking in unstable material. Equipment modifications include significantly wider tracks. For shallow soft waste, the shovel can be operated on the stable floor below the soft material, and if necessary, dozers can lower the material to a workable bench height.
Slope stability	Unstable material results in flatter highwall and low-wall batters and less-stable working faces.	Negligible impact due to the normal dozer operation having relatively flat highwall and low walls	Flatter working slopes require longer boom and smaller bucket dragline configurations to provide the required reach resulting in higher unit costs.	Fairly insensitive to working slopes with minor increase in haulage distances resulting in very minor increases in unit costs.
		Deposit		
Depth	Waste-stripping cost as a proportion of total mine costs	Optimal cost for shallow depths 40 m or less; deeper than this, dozers become less productive with long and uphill pushes.	Optimal cost for 40–85 m, may need some prestrip assistance; deeper than this requires a significant waste-stripping operation above the dragline.	Optimal cost for waste above 85 m.
Dip	Geotechnical stability and deposit geometry starts to favor certain equipment characteristics.	Suitable for flat to moderate dips; at steep dips, need to cast blast to a false floor and pick through rest of waste to expose coal with secondary truck and excavator operation.	Best for flat to moderate dips; at steep dips, low-wall stability can be an issue and capacity of dragline to reach top of coal and place the overburden in a final position is severely limited. Can expose a false floor and follow up with excavator and trucks.	Ultimate flexibility for all dips. For very steep dips, excavators will pick through waste and coal and may need to load trucks on the same level the excavator is sitting on; less productive.
Seam thickness	Impact of economics for thick seams and driver to selective mining	Ideal for thin seams where dozers and excavators can expose the coal with minimal loss; tool is selective and operator is close to the coal–waste interface.	Best for seams 1 m and greater; thin seams can be severely disrupted by large blasts, and bucket is a large digging tool trying to follow a waste; coal interface many meters away from the operator; excessive losses an outcome for thin seams. Thick seams will be profitable if mine is able to fund capital-intensive draglines.	A thick seam can subcrop economically at a depth beyond the reach of a dragline; leads to deep truck and shovel boxcut; potentially stick with truck and shovel due to impracticalities of getting dragline in and out of a very deep pit.
Number of seams	Waste geometry between seams drives selection of most appropriate method.	Overburden pushed into the low wall needs to end up in a final spoil position away from the coal to be mined; many seams will result in dozed spoil rilling back against the coal edge; will lead to loss or dilution.	Best operating on a few relatively thick waste sections; intensive set-up effort to get a dragline to ramp down into a pit and out again and will prefer to have a reasonable task when it is set up; prefer interburdens of minimum 10-m thick. Multiple seams at the bottom of the pit with thin interburdens mean the dragline will not be able to effectively clear the coal edge, leaving spoil up against it; creates a truck and excavator task to excavate the low wall back.	Best for many thin seams especially where waste between seams is thin or seams are split; is able to take the waste completely away from the coal, leaving it to be recovered cleanly.

Table 10.8-1 Strip mining strategies compared by selection driver (continued)

		Strip Mining Strategies		
Subcriteria	**Driver**	**Cast, Doze, Excavate**	**Dragline**	**Truck and Shovel**
Stratigraphy development	Impact of upper seams subcropping at depth	This method is generally limited by depth; however, if upper seams subcrop, they interfere with the effectiveness of the cast operation, with thin overburdens difficult to cast and upper overburdens potentially buttressing lower interburdens and reducing overall cast effectiveness.	As more upper seams enter the sequence, the whole mine, driven by the downdip advance of the dragline, will actually generate more coal; one option is to expand output, but if this is not economical, the choice is either to lift draglines up in the sequence and abandon lower seams, raise dragline level to reduce advance (give more waste to the dragline), or, if it is a multiple dragline mine, to stand some draglines down as no longer required as the mine transitions to source more of its coal from the overlying truck and shovel pit.	Working multiple subcrops at once can lead to spoil from the downdip pit being placed on top of future potential resource as the updip pit catches up; truck and shovel systems provide the flexibility to place overburden more selectively to allow updip pits to mine through more effectively.
Size	Resource size will determine the ultimate scale of the mine to be constructed.	Optimal for small deposits that cannot justify large capital expenditures with long payback periods	Optimal for large long-life deposits seeking to generate large volumes for a long period of time where capital payback occurs. Comes in large lumps of capacity, so potentially need to supplement with truck and shovel stripping capacity. Ends up as either prestrip or a satellite truck and shovel pit only.	Highly scalable equipment that can be selected to match the deposit, both initially and also as it develops over time.
Topography	May influence choice of equipment and therefore mining method	Will affect balance between cast, doze, and excavate.	Highly variable topography is problematic for dragline; will generally lead to supplementary truck and shovel stripping.	This is the most flexible mining system, but truck grade limitations and variable topography can result in waste being brought forward in the schedule to access upper benches. Dumps can also lose capacity if topography is falling away on the dump side.
Geometry	Physical constraints to mining operations will influence selection of equipment and therefore mining method.	Highly flexible and well suited to variable deposit geometries	The preference is long, straight strips; short strips lead to lots of walk time and reduced productivity. Bends in strips can lead to inside corners that create spoil tight spots; this can be alleviated with truck and shovel assistance. It is very difficult to extend the strip after the mine has been developed to depth, essentially trying to dig a deep boxcut; this generally needs to be done with a truck and shovel. Vertical development to pick up deeper seams is a similar problem; a truck and shovel is needed to develop.	A coal seam that subcrops at the lease boundary means that the boxcut may need to be constructed by truck and shovel and the waste hauled elsewhere. Multiple valleys through low-wall dump mass means that for pits deeper than 150 m, total dump balance will come under stress; this may favor a move to hauling to highwall side and other out-of-pit locations; or for really long hauls, a conveyor waste system may be more economical.
Location	Lack of supporting infrastructure may influence choice of equipment and therefore mining method.	Smallest equipment and easiest to support from an infrastructure point of view	A lack of availability of electrical power, in total or reliable supply, may preclude use of draglines. It may be difficult to bring large equipment to location. A lack of specialist operating labor and technical support labor may also detract from draglines.	A lack of electrical power may preclude use of electric rope shovels and lean toward diesel over hydraulic excavators. A lack of specialist technical support labor may also drive toward smaller equipment.

Table 10.8-1 Strip mining strategies compared by selection driver (continued)

		Strip Mining Strategies		
Subcriteria	**Driver**	**Cast, Doze, Excavate**	**Dragline**	**Truck and Shovel**
		Environment		
Noise	Noise limitations on operation due to proximity of third parties	Tracks and engine revolution are main sources, but activity is mostly in-pit, hence less off-site impact.	Significant noise from bucket and rigging. Dragline regularly dumping above natural surface and can carry off-site. At worst, may exclude draglines from sensitive areas close to third parties.	Significant noise from engine revolutions on acceleration and tipping, horn signals, and reversing alarms. Trucks are often dumping at height and locations remote from the active pit near the mine boundary. This can be reduced by technology ("whisper quiet" trucks). For sensitive areas, a limit on traffic intensity and hours of operation can be required.
Dust	Proximity to third parties	Minimal as mostly slower material speed and restricted to in-pit, therefore less impact	Significant due to dumping at height driven by dragline geometry	Significant with dust generated at the load point, haul roads, and final dump. Dust is usually controlled by adequate work area and haul road watering. Controlling dust generation from large elevated dumps is a challenge.
		Economics		
Capital	Capital cost per bank cubic meter	Lowest with shortest lead times due to factory line production of equipment	Highest and longest lead times due to single unit fabrication and on-site erection	Mid-range with variable lead times (1–3 years) depending on supply–demand balance
Labor	Total cost of labor and accommodation per bank cubic meter	Mid-range with typically 10 operators per operating shift for 15–20 Mbm^3/yr capacity	Lowest with typically 2–3 operators per operating shift for 15–20 Mbm^3/yr capacity	Highest with typically 15 operators per operating shift for 15–20 Mbm^3/yr capacity
Other costs	All other operating costs per bank cubic meter	Mid-range	Lowest with largest cost driver being electricity	Highest with largest cost drivers being fuel, tires, and maintenance
Expansion capability	Ability to increase production incrementally	Additional units add small capacity steps.	Minor step increases possible via motor upgrades; beyond this, additional units provide large-capacity steps.	Additional capacity by adding trucks up to loader; beyond this, additional units provide large-capacity steps.

Table 10.8-2 Forces for change and their impact on strip mining

Fundamental Force	Drivers for Change	Potential Outcomes
Health and Safety Focus • Regulators demand safer mines • Shareholders demand safer mines • Mine operators and mine workers demand safer mines	• Continuous reduction in injury rates demanded by all • More research reveals adverse long-term health outcomes from shift work and other mining-related activity • More risk of injury for aging work force	• "Smart" mining equipment and maintenance tools detect unsafe practices and require third-party risk assessment and lockout override before proceeding • "Smart" personal monitoring system detects unsafe behavior and raises central alarms and automatic notification to wearer and supervisor • Remotely operated, semi- or fully autonomous equipment with robots undertaking routine maintenance
Environmental Concern • Global warming • Climate change • Land degradation • Biodiversity	• Public perception of greenhouse gas–intensive companies and their products; remoteness of most mines does not deter environmental action groups from focusing public attention • Carbon taxes and trading • Water scarcity with users competing for allocations (domestic, industrial, and agricultural); mine discharge water quality becomes higher profile as background or natural flows reduce • Food security becomes topical with opencut mining targeted as an activity that degrades prime agricultural land	• Time-based Google Earth with enhanced image-processing tools means anyone on the Internet can monitor net land disturbance and rehabilitation deficits, leading to more focus on progressive rehabilitation • Electricity generated by nuclear power potentially tips economics toward electrically driven equipment, leading to emergence of widespread use of electric excavators and electric trucks using overhead cables; alternatively, more use of conveyors to move waste • Water collected from across the whole mine site at closure and directed into final voids that have been left open as large catchment dams, leading to treated water sold to local users • Underground mining becomes only form of mining allowed in areas of, or near, high-quality agricultural land • Carbon taxes tip economics heavily in favor of underground mining due to much-reduced energy expenditure
Social Forces • Urbanization and aging work force • Environmental values	• Increasing service gap between metropolitan and regional or remote areas; harder to attract highly skilled personnel to remote areas • Societal pressure for increased external control of licenses and leases (the social license)	• More-prevalent fly-in/fly-out as the standard model • Number of personnel on-site an absolute minimum • Real-time terrain acquisition means most geology, survey, engineering, as well as equipment performance and condition-monitoring tasks occur off-site in centralized technical centers • Region must be persuaded of sustainable development before it awards the social license
Technology • Automation • Increased equipment scale	• Need to eliminate safety incidents • High cost of labor and associated costs including accommodation • Increasing strip ratios for deeper strip mines • Shortage of suitable experienced personnel	• Less human exposure to accidents • Fully automated operations: truck–shovel fleets, draglines, and production dozing • Reduction in on-site labor requirement to maintenance and control functions • Significantly higher productivity • Lower maintenance costs as more predictable operating practices • Outcomes would have the largest impact on truck and shovel costs
Market Forces • Continued globalization • China/India industrialization	• Vertical integration for commodity security; commodity consumers buy and develop mines • Supply-side consolidation; companies continue to aggregate to pursue improved economics • Long-run prices reflect relative scarcity of energy and metallurgical coal in the face of sustained increasing demand but with short-run volume and price volatility	• Marginal undeveloped deposits become economical; thinner seams, so more likely to be truck-based mines • Existing deposits economical at greater depths • Huge variation in prices in short-term timeframes means there are no final highwalls; major mining companies exit mines and they are purchased by equity hedge funds trading on cash generated between care and maintenance and incremental marginal extraction cycle • China becomes a major manufacturer of draglines and earthmoving equipment; much reduced-capital pricing fundamentally shifts relative economics of equipment

must be incorporated into the dump tip faces and blended with stronger material to minimize their negative stability impact.

STRIP MINING STRATEGIES COMPARED BY SELECTION DRIVER

Having outlined the four major strip mining strategies, it is useful to explore the relative suitability of each strategy in a given mining application. Four significant decision criteria have been identified: geology, the deposit, environmental considerations, and economics. For each of these, a number of subcriteria and their respective drivers and influences on each strip mining strategy are summarized in Table 10.8-1.

FUTURE TRENDS

This chapter has outlined a range of pit configurations, equipment types, and operating methodologies that represent the breadth of current strip mining practices. Although the specifics of the future are uncertain, one thing is definite—change comes. In closing out this topic, Table 10.8-2 identifies some of the major forces at work today, comments on the drivers for change they introduce, and speculates on their potential outcomes.

The past 100 years in strip mining has seen the emergence and continuous development of powered earthmoving equipment. Today's trucks move >300 t/cycle and are filled by large hydraulic excavators or rope shovels in as few as three passes. Electric walking draglines have a dig-to-dump range >100 vertical meters, a similar operating radius, and move more than 200 t per 1-minute cycle. Advances have primarily come through scale (enabled by improved materials and engineering design), application of low-cost and mechanically reliable electric motors, and technology generally for improved mine planning, equipment operation, and condition monitoring. The result has been existing strip mines that remain economical at depth and previously uneconomical deposits now within reach. Recent rapid development in the areas of geospatial awareness, image processing, real-time communications, and general computing power suggest that the industry is on the brink of significant breakthroughs in remote and autonomous equipment and even whole-of-mine operation. A step change in the relative economics of conveyors over trucks could see conveyor waste systems deployed extensively in those mines where the deposit allows. These changes will fundamentally shift how strip mines are designed and operated with an accompanying continual improvement in mine safety and reduction in cost while, as always, improving underground operations will continue to offer a viable alternative.

CHAPTER 10.9

Strip Mine Planning and Design

Ernest T. Shonts Jr. and Jerry M. Nettleton

INTRODUCTION

Modern strip mining began with the development of the steam shovel used in the excavation of the Panama Canal. However, underground mining continued to dominate the extraction industries until the early 1900s, when strip mining proved itself to be more economical for near-surface, flat-lying deposits.

Strip mining is a form of open-pit mining that uses strip cuts to mine generally shallow, flat-lying deposits. Strip mines are typically layered deposits—a classic example is surface coal mining. This chapter will concentrate on considerations in the mine planning and design process of strip mines. The primer for mining engineers is *Surface Mining* (Pfleider 1972); see Kennedy (1990) for the updated second edition of that text.

Mine Planning and Design

There are two general approaches to mine planning. The first is the development of a greenfield or new property. Capital investments have not been committed; the property may already have been acquired or is in the process of evaluation. The prefeasibility study establishes the value of the property and potential capital commitment. Prefeasibility may require a general mine plan to establish if mining is practical and may go as far as suggesting what equipment would be used. The feasibility study then details the capital commitment and life of the property, and includes a detailed economic evaluation. To develop economics in terms of cash flow, expected net present value (NPV), and internal rate of return (IRR), the feasibility study requires a detailed mine plan, equipment selection, schedules identifying the timing and amount of capital expenditures, and estimates of projected revenue and costs. Information on mining economics can be found in Stermole and Stermole (1987). Table 10.9-1 is a list of items to consider in a mine plan feasibility study.

An existing property or brownfield expansion considers an operation where equipment and facilities are already in place and future development is planned. Mine planning for existing operations may require a different approach to address market conditions and the need to expand, scale back, or maintain a steady-state production level.

In an existing property, where equipment and facilities are established, the two stages of mine planning are the short-term mine plan and the long-term or (life-of-mine) plan. These stages are significant in that mines often assign designated staff and instigate significant mine planning efforts to best meet the differing requirements and level of detail for these two functions. See Table 10.9-2 for a list of items to consider in the mine planning process.

Short-Term Mine Planning

The short-term mine plan (or operating plan) generally relates to a period of less than 5 years and is typically broken down into stages of monthly, quarterly, and annual operating plans. Each stage reflects a level of detail designed to guide the mining toward fulfilling annual production and economic budgets. Short-term mine plans consist of details and sequences for drilling and blasting, quality control, and material excavation and placement to be used by operations to direct equipment operations and meet production goals.

Long-Term Mine Planning

Long-term mine plans usually cover a period greater than a year beyond the current active operations, up to and including the point when the life-of-mine plan starts. Typically, these long-term mine plans are broken down into levels of detail that include quarterly plans for up to 5 years, annual plans out to a minimum of 10 years, and general plans out to the life-of-mine planning horizon. The defined planning periods can vary depending on the size and life of the reserves, along with the general purpose and objectives of the operation. The objectives of the long-term mine plan include identifying and scheduling labor levels, equipment production levels, and capital requirements (including major equipment purchases, infrastructure expansion, reserve expansion, acquisition of new reserves, and end-of-life reclamation). Other applications of long-term planning are to determine production sensitivity to revenues and costs (which would affect production rates),

capital projects, and the life of the reserve. Both short- and long-term mine plans are decision tools to help manage the risk and reward opportunities that confront mine management.

Risk and Reward

The successful implementation of a correctly formulated mine plan will yield the optimal recovery of the resource, as measured by optimizing the resulting revenues (reward) and effectively controlling costs (risk). Costs for a new property can vary substantially because of unknown conditions. It is the mining engineer's task to identify and characterize key conditions and factors, and to assign costs to them that realistically represent the risks involved in developing and safely mining the reserve. It is also the mining engineer's function to get the most value from the reserve by using proven methods to mine and produce the resource in a timely manner. Determining the time value of money—or the NPV of a project—is the most common method of measuring the economic balance between risk (costs) and reward (revenues) for a mine development project.

A base-case mine plan is typically developed to identify and quantify the costs and revenues associated with developing the property. Successive planning scenarios may then be developed to evaluate the cost/revenue effects of changing mine plan layout, sequencing, production schedules, equipment, or other parameters to minimize cost impacts and maximize the resource recovery and revenues to optimize NPV.

OUTLINING RESERVES

Mapping

Project mapping often begins with a general location map that shows geopolitical boundaries, towns, roads, general topographic features, the mine location, and any nearby residences or structures. Planning starts with more detailed mapping of topography, surface drainage features, surface and mineral

Table 10.9-2 Major steps in surface mine development preceding production buildup and full production*

Assembly of Mineable Coal Package	Market Development	Environmental and Related Studies	Preliminary Design, Machine Ordering	NEPA Process	Permits	Design and Construction	Mining Preparation
Lease acquisition	Market survey	Initial reconnaissance	Conceptual mining development	Identification of lead agency for EIS	State water well rights appropriation permits	Preliminary design and estimation	Stripping machine(s) erection
Mapping the area	Potential customer identification	Scope of work development	Economic size determination	Draft EIS	State special use permit, such as a reservoir	Material ordering and contracting	Loader erection
Drilling program	Letter of intent to develop and supply	Consultant selection	Mining system design, layout, and development	EIS review and comments	State mining permit	Water well development	Support equipment readying
Surface drilling rights acquisition	Contract negotiation	Implementation	Equipment selection	EIS hearing and record	State industrial siting permit	Access road and site preparation	Labor recruitment and training
Drilling, sampling, logging, analysis		Environmental impact report	Stripping machine ordering	Federal EIA review	Federal NPDES permit	Railroad construction	
Mineral evaluation (determination on commercial quantities present)		Environmental monitoring	Mine plan development	Council on Environmental Quality filing	U.S. Forest Service special land use permit	Power supply installation	
Drilling on closer centers (development drilling)				Mining and/or reclamation plan approval		Facilities and coal handling construction	
Sampling, logging analysis						Warehouse building and yards	
Surface acquisition						Coal preparation and loading facilities construction	
						Overland conveyor construction

ownership, existing facilities and infrastructure, and potential mine area and disturbance boundaries. Aerial flights provide an up-to-date surface contour of the property and help to identify existing structures, facilities, and other surface features. Ground surveys using Global Positioning System equipment provide additional detail and will become the basis for the ongoing process of mapping and documenting mining and related activities. Infrastructure includes the location of existing features—roads, rail lines, pipelines, power lines, communication lines, wells, buildings, and structures on and adjacent to the mining property—that may be used for or affected by mining activities. It is important to identify not only features related to the mining activities, but also features and resources that may require special environmental considerations, such as streams, forest land, wetlands, wildlife habitat, and other protected or environmentally sensitive areas. Initial geological maps should include surficial geology (outcrops, surface geologic exposures, structural features), and indications of strike and dip of structures. Maps prepared by governmental research organizations such as the U.S. Geological Survey are a typical starting point for new operations. Conversion of GPS surveys to a geographic information system format will allow the ongoing collection and integration of ownership, environmental, geologic, and mine and reclamation planning and operational information.

Since modern mapping is computerized, map information is developed and saved as individual layers that can then be selected and combined to produce a range of specialized maps. Although it is important to define and establish a common mapping datum for compatibility, determining a map scale is not critical because scale can be adjusted later to meet map presentation requirements. After a standard mapping datum is established, all mapping should be completed and input to that datum. The mapping datum and coordinate system should be compatible with the maximum area expected to be affected by mining and should accommodate both short- and long-term planning. It is important to document the basis for the mapping information (metadata) and to preserve original data in a digital format with appropriate backups.

Drill-Hole Coverage

Sufficient drill-hole information is critical for the development of geologic and mine planning models. If a company has a history of drilling in the area, then all known drilling information should be reviewed and evaluated for reliability and content. Information is then consolidated into a geologic computer model. In a new operation (or one that is expanding into a new reserve area), a drilling program will be required to collect enough information to adequately evaluate the property. A resource is typically defined by the level of confidence in the occurrence and extent of the mineable seams. In open-pit mining, the terms *measured*, *indicated*, and *inferred* convey both the extent of drilling and the level of confidence in the reserve characterization. In surface strip mines, the deposits

tend to have consistent thickness characteristics; therefore, drill spacing for exploration often involves a grid spacing of 0.4 to 0.8 km (0.25 to 0.50 mi). Areas that require more extensive drilling (or seismic studies) are seam boundaries, structural features, and surface disconformities such as valleys, surface displacements indicating faulting, and depositional unconformities. The greater the variation in reserve characteristics, the greater is the need for increased drilling density or supplemental data collection. Data quality can be evaluated and supplemented using geostatistics techniques, which take into consideration variances in the ore body when drill data are being correlated. In operating mines, drilling information can be supplemented by structure and quality information obtained from drilling and blasting activities in active operating areas. The engineer should become familiar with the reserve and should identify where structure, thickness, and quality issues may exist in planned mining areas.

Geology to Mine Planning

Using the drill-hole information and surface structural features, a geological model is developed. This model should include seam identification, structure, thickness, quality, and characteristics that may affect mining efficiency such as overburden/interburden thickness and characteristics, fracturing, variations in thickness, washouts, and water table. The engineer should be looking for inconsistencies in quality and thickness to determine the extent of mineable seams and the mining characteristics that would affect equipment selection and productivity. It is also important to understand overburden/interburden characteristics and structural constraints as indicators of potential stability problems. Information on highwall angle and spoil angle can be estimated by material type and stability characteristics. Thickness, strike/dip, strip ratio, and quality maps should be developed for all potentially mineable seams. This can either be a fairly straightforward process, or more complex and time-consuming if seams combine and split. Transitioning from a geologic model to a mining model requires the understanding of reserve characteristics, potential structure hazards, equipment capabilities, and strip mining methods. Geological cross sections, history and knowledge of the area, research on similar deposits, and knowledge of mining methods are all resources that the engineer can tap into in order to optimize mine planning.

The basis for a good mine plan is a good understanding of the topography and geology of the property. To facilitate this, an accurate topographical map must be developed with a minimum 6.1-m (20-ft) contour interval, and a grid base must be used that has a minimum spacing of 61 m (200 ft) and covers all of the projected mining area along with potential facilities and any significant surface structures. In addition, it is necessary to become familiar with the drilling information, including seam characteristics, structure, and the quality information for each mineable seam (referred to as target seams). Contour thickness maps (also known as isopach maps) should be generated for each of the targeted seams and should include information on overburden, interburden (waste material between targeted seams), and the undiluted thickness of the targeted seams. Quality maps should also be created for each targeted seam. Geologic structure maps need to be developed to identify any structures (e.g., faulting and offsets) that would affect the mining method or decrease recovery and increase dilution and waste.

Coal loss due to ribs, barriers, top/bottom of coal seam dilution, and overblasting can be as high as 10% in eastern operations (Anon. 1977).

Reserve Evaluation

Modern mine planning starts with a computer model of the resource. The extent, structure, quantity, and quality of the resource and the associated burden material should be well defined. These data will allow the engineer to develop a mining model. The mining model will incorporate and consolidate data on the resource into a model of mineable seams, waste, and soil materials (sometimes referred to as suitable plant growth material). For this purpose, a reserve is identified as a resource that is delineated by its economic strip ratio.

Strip Ratio

The economic stripping limit is usually the first factor to be determined in establishing the mine plan. The economic stripping ratio is defined as the cubic meters (yards) of waste material to be removed to uncover one metric ton (short ton) of product. For illustration purposes in this chapter, coal will be used as the resource. Developing maps that show the ratio of overburden thickness to a mineable coal thickness is a good place to begin. This ratio can be converted to a strip ratio map by mapping the thickness of the overburden and interburden converted to cubic meters and divided by the thickness of the coal converted to metric tons (short tons). This ratio is calculated using the cumulative thickness of both overburden/interburden and coal seams down to and including the lowest mineable seam.

For example, for a 61-m (200-ft) cumulative overburden/interburden thickness with a total coal thickness of 6.1 m (20 ft), and assuming the average density of bituminous coal at 1.28 t/m^3 (80 lb/ft^3), the stripping ratio would be calculated as follows:

$$\text{burden} = 200 \text{ ft} \times 3 \text{ ft} \times 3 \text{ ft} \div 27 \text{ ft/yd}^3 = 66.7 \text{ yd}^3$$
$$\text{coal resource} = 20 \text{ ft} \times 3 \text{ ft} \times 3 \text{ ft} \times 80 \text{ lb/ft}^3 \div 2{,}000 \text{ lb/st} = 7.2 \text{ st}$$
$$\text{stripping ratio} = 66.7 \text{ yd}^3 \div 7.2 \text{ t} = 9.26{:}1$$

or

$$\text{burden} = 61 \text{ m} \times 0.91 \text{ m} \times 0.91 \text{ m} = 51.0 \text{ m}^3$$
$$\text{coal resource} = 6.1 \text{ m} \times 0.91 \text{ m} \times 0.91 \text{ m} \times 1.281 \text{ t/m}^3 = 6.47 \text{ t}$$
$$\text{stripping ratio} = 51.0 \text{ m}^3 \div 6.47 \text{ t} = 7.88{:}1$$

These calculations can be used to define an economic limit:

- Cost for overburden/interburden mining is \$1.63/m^3 (\$1.25/yd^3)
- Cost of coal mining is \$2.76/t (\$2.50/st)
- Estimated revenue is \$13.23/t (\$12/st)
- Economic stripping ratio (ESR) is
  (\$13.23/t – \$2.76/t) ÷ \$1.63 = 6.41 or 6.41:1;
  (\$12.00/st – \$2.50/st) ÷ \$1.25 = 7.60 or 7.60:1
  = 6.41 m^3/t (7.60 yd^3/st) = 6.41:1 (7.60:1)

  Note: Ratios differ between metric (International System of Units) and English units because stripping ratios mix units: cubic meters to metric tons and cubic yards to short tons.

The ratio becomes the economic mining limit and is the first step in establishing the economically mineable reserve. The formula can become more complex as issues of quality affect the economic value of the coal. It is important for the engineer to understand what the economics are and what

contract restrictions, including penalties and bonus provisions, may affect revenues. Other adjustments to coal recovery (and actual mineable reserves) would be dilution and in-seam losses, which tend to downgrade the stripping ratio by increasing the cubic meters (cubic yards) of waste and decreasing the number of metric tons (short tons) of resource. Depending on mining conditions and on thickness and quality of the seam, losses can amount to several percent and have a significant impact on the reserve.

RESOURCE CONTROL

Land and Mineral Ownership

Ownership of land and minerals is a key consideration that should be determined and addressed early in the planning process, as it can affect development time frames, permitting requirements, development cost structure, and project profitability. Land ownership typically consists of two components: the surface estate and the mineral estate. Either or both may be held by private (fee estate) or public (public estate) entities. In some cases, the surface and mineral estates may be held separately (severed estate).

The rights to access and utilize the surface and to develop and produce the mineral resource can be secured through direct ownership (purchase of the surface and/or mineral estate), lease, agreement, or a combination of these legal vehicles. In many cases, the right to develop and produce the mineral resource (particularly where public-estate minerals are involved) carries with it certain rights of surface access and use.

With the exception of direct ownership, other access and development rights typically involve structured payments to secure and exercise these rights. These typically take the form of advance payments to secure the rights, flat-rate annual fees for use of the lands, royalty payments based on mineral production rates, fee payments keyed to specific activities, or combinations of these payment mechanisms.

Secure, well-defined access and development rights are an important element of a stable cost structure and are key to project cost control and profitability. It should also be emphasized that ownership rights for the project area and an adjacent buffer zone can be important in minimizing and successfully addressing potential conflicts with adjacent landowners and uses.

Other Resources

In Wyoming (United States), gas collected from coal seams (i.e., coal-bed methane), has become a significant consideration relative to permitting and the timing for development of coal reserves where both (independently recoverable) resources exist. Existing oil and gas (or other mineral) leases must be a consideration in the extent of and timing for development and production of reserves.

PERMITTING

Mine permitting is the process of preparing and submitting relevant project information for review and approval by jurisdictional government authorities to verify project plan compliance with applicable laws and regulations. In general, applicable laws and regulations as they relate to mining are designed to prevent, control, minimize, or effectively mitigate potential adverse mining-related impacts on the environment and on human health and welfare.

Mine permitting may involve submittal of individual permit applications for approval of specific mining-related activities (mining and reclamation, air emissions, water discharge, facility construction, and so on). Alternately, it may involve environmental analysis and plan approvals for the project as a whole. Or a combination of all of these approval mechanisms may be involved. An outline of typical mine permitting requirements is provided in Table 10.9-3.

Typically, the process involves review by national or state/provincial agencies that have approval authority over land uses or mining and reclamation plans. It may also involve review by agencies with authority over specific environmental resources such as air, water, wildlife, and other specific project aspects. Normally, some provision is provided in the permitting process for input by affected parties and nongovernmental organizations.

Environmental Baseline

At the start of the permitting process, it is important to effectively characterize environmental resources and values as they exist in the project area (baseline) prior to mining disturbance. Generally, baseline characterization involves field studies by qualified professionals of all resources and values that may be affected. The following resource values are typically characterized:

- Land use
- Cultural, archaeological, and paleontological resources
- Geology
- Meteorology and air quality
- Surface and groundwater hydrology
- Soils
- Vegetation and wetlands
- Fish, wildlife, and related habitat values
- Aesthetics and noise
- Socioeconomic conditions

Baseline characterization then forms the basis for development of specific measures to prevent, control, minimize, or mitigate the potential impacts and for evaluation of potential mining-related impacts with consideration of planned control and mitigation measures.

Mitigation Plans

At the point in a project at which permitting activities are initiated, mining and reclamation plans are generally well defined, including the locations, extent, and nature of surface-disturbing activities. Comparison of the extent and nature of mining activities with information from environmental baseline characterization provides the basis for development of project mitigation plans. In many cases, required mitigation measures are defined to some extent by specific regulatory requirements. A common example is the requirement for the collection and treatment of runoff from mine disturbance areas to comply with effluent standards before water is discharged to natural drainages. To address site conditions and constraints or enhance postmining land use, the mine operator may have an opportunity to develop site-specific mitigation plans or to modify mitigation plans within the limits of regulatory constraints.

Impact Analysis and Monitoring

Environmental impact analysis is an integral part of the permitting process, whether it is the evaluation of regulatory compliance as part of a permit review or of the significance of potential impacts.

Table 10.9-3 Typical mine permitting requirements

Mining and Reclamation Permit(s) (National/State or Provincial/Local Mining, Natural Resource, or Land-Use Authorities)	Water Discharge Permits (National/State or Provincial/Local Environmental or Natural Resource Authorities)	Air Emission Permits (National/State or Provincial/Local Environmental or Natural Resource Authorities)	Other Permits (National/State or Provincial/Local Environmental, Natural Resource, Land-Use, or Safety Authorities)
General information (mine overview and information on permit preparation) Exploration plans and compliance Legal information—owner/operator, surface and mineral ownership, right-of-entry Other permits and regulatory compliance information Environmental baseline information Land use • Cultural, archaeological, and paleontological resources and values • Topography and geology • Meteorology and air quality • Surface and groundwater hydrology • Soils • Vegetation and riparian/wetland resources • Fish, wildlife, and related habitat values • Aesthetics and noise • Socioeconomic conditions Mining and reclamation plans • Boundaries of mining, disturbed, and affected areas • Duration and sequencing of operations • Operating schedule(s) • Description of mine development and operations • Mine equipment and labor • Mine facilities and roads • Descriptions of specific mining and related activities – Drainage and sediment control – Soil material removal – Blasting – Overburden removal – Ground control – Material processing and handling – Mine and process waste handling – Material transportation • Environmental monitoring plans and reporting • Reclamation and land restoration/management – Facility conversion, salvage, or demolition – Backfilling and grading – Drainage reestablishment – Soil material replacement – Revegetation – Postreclamation management and monitoring • Reclamation bonding and bond release Environmental and socioeconomic protection and mitigation plans and measures	Source and location of discharge(s) Ambient flow and water quality conditions (receiving stream) Use(s) (receiving stream and downstream waters) Quantity and quality of discharge, and seasonal or temporal variations Treatment methods (if any) Water quality control/ protection measures (i.e., spill plans, retention structures, etc.) Monitoring plans and reporting requirements Discharge effluent limitations	Source and location of emission source(s) Ambient air quality and meteorological conditions Quantity and type(s) of emission(s), and seasonal or temporal variations Control methods and efficiencies (if any) Monitoring plans and reporting requirements Air emission limitations	Land use/zoning permits Safety permits/approvals (training, personal protection, noise, electrical/mechanical equipment, blasting, haulage, ground control, and impoundments) Riparian/wetland protection/ mitigation permit Water supply permit Wastewater control permit Solid and hazardous waste handling and disposal facility permit Radiation source permit (monitoring devices) Explosive material handling and storage permit Communication system permit

In the context of a permit review, impact analysis focuses on whether or not the proposed mining and related activities (and planned mitigation measure) meet specific regulatory requirements and performance standards.

For environmental factors, impact analysis typically includes the evaluation of direct, indirect, and cumulative impacts and assesses whether or not potential impacts meet an objective, or indeed the subjective measure of significance.

Prepared and evaluated as part of the permitting process, monitoring plans provide a mechanism for the direct measurement of impacts on specific environmental resources. If properly designed and administered, monitoring can identify significant changes in resource conditions. It can be used to assess the effectiveness of mitigation measures and the accuracy of impact assessments and to modify operating and mitigation practices.

Timing

It is critical to allow sufficient time in the project schedule for project permitting. It normally takes between 12 and 18 months to collect adequate information for environmental

baseline characterization. Depending on project complexity, permit preparation may require between 6 and 24 months. Required agency reviews and approval may extend the overall permitting schedule by another 6 to 24 months. Important factors in minimizing permitting time frames include ensuring adequate and timely baseline characterization, conducting effective ongoing communication with stakeholders, and coordinating closely with jurisdictional agencies.

INFRASTRUCTURE

Existing Infrastructure

Existing infrastructure (i.e., roads, water wells, gas pipeline, or power lines that run through the property) must be identified and mapped, and the landowners must be contacted and told the intent and potential impacts of mining. Where existing infrastructure may be affected by mining, mitigation action may be necessary, either in the form of compensation or relocation/replacement of the structures.

Mine Infrastructure

The necessary infrastructure to support mining and related operations will need to be planned, developed, and accounted for in the economic evaluation process. This infrastructure will include roads and utilities, office and changehouse facilities, warehouse and maintenance facilities, material handling, processing and product transportation facilities, drainage and sediment control systems, and so forth.

Infrastructure Mapping

Maps showing both existing and planned mine infrastructure are typically developed as part of the mine planning process. Features that will be mined around, or that are not within the mining area, are not shown on the reserve map. Some structures require economic analysis to determine whether mining around or compensation/relocation/replacement is the better economic approach. These areas may be included in the reserve, but until the status of the areas is resolved, they should be excluded in the base-case mine plan as nonmineable reserves.

PIT DESIGN

Mining Methods

For surface strip mines, the choice of mining method is dictated by the terrain, geology, and depth of the resource. The terms *contour mining* and *area mining* are used to describe mining methods that are suited to specific geologic and topographic conditions.

Where the terrain is variable and multiple seams are present, contour mining may be the best option. In the Appalachian mines of the United States, thin seams, undulating topography, and sometimes steeply dipping seams require equipment that is highly adaptive and mobile and can move material relatively long distances. These conditions favor contour mining using large-tracked dozers, rubber-tired scrapers, shovel-truck or loader-truck equipment fleets, and occasionally small draglines (23–35 m^3 [30–45 yd^3]). As the economic stripping ratio increases, contour mining may be coupled with follow-up to auger or with conventional underground methods.

Where the terrain is relatively uniform and the seam or seams are flat-lying, area mining is often the preferred approach. Relatively large flat-lying deposits such as the coal reserves of Wyoming's Powder River Basin (PRB), phosphate deposits in Florida (United States) and the Middle East, and the Canadian tar sands are well suited to area mining methods using large draglines (46–120 m^3 [60–160 yd^3]), fleets of large-scale shovel trucks (shovel capacity 46–76 m^3 [60–100 yd^3]; truck capacity 140–230 m^3 [180–300 yd^3]), or even bucket-wheel excavators (BWEs) and cross-pit conveyor systems. Using large stripping equipment and moving large quantities of material keeps unit operating costs to a minimum. The PRB mines were typically mined at a 1:1 stripping ratio in the 1980s; however, by the 1990s the stripping ratio had increased to more than 2:1. As mining progresses to the west, the stripping ratio increases as the coal seams dip between 1% and 2% and the overburden gets thicker. This increase in strip ratio is also reflected where split seams occur. Coal quality also increases from north to south, which can have a significant effect on the ESR. Changes in geology must be taken into consideration in pit design and equipment selection. Bise (1986) gives several examples of equipment selection. Bucyrus-Erie Company (1979) is a good source of information on shovel/truck selection and operation.

Large electric shovels are used in both contour and area mining. They offer good flexibility, reasonable mobility, and moderate to high loading capacity, and they can be used both for stripping overburden and for ore loading. However, electric shovels do require a truck fleet, along with associated haulage-road requirements, which can increase production costs.

Draglines are high-production machines used to strip and move overburden over short distances. Draglines have limited mobility and are generally not suited for loading product. It can take up to a year to construct a dragline, and its cost can range from $50 to $100 million. Nevertheless, draglines are dominant in the large surface coal mines in the United States and in other large flat-lying deposits throughout the world (Cassidy 1973).

In the lignite mines of Europe and the U.S. Gulf Coast, large BWEs and conveyor-belt systems are used to excavate and move large volumes of overburden and product economically. The BWE is a continuous-excavation machine capable of removing up to 240,000 m^3 (314,000 yd^3) of material per day. BWEs are found mostly in coal mining in Europe, Australia, and India. A BWE can cost more than $100 million and take 5 years to construct.

A compilation of equipment application and various mining scenarios as applied at operating properties can be found in Chironis (1978) and Kirk (1989). Support equipment including dozers, scrapers, loaders, graders, water trucks, and—depending on individual mine requirements—a multitude of other equipment required to complete the mining cycle is a significant capital and operating cost. Sources for accounting for this equipment include vendor publications such as the *Caterpillar Performance Handbook* (Caterpillar 1995) and vendor Web sites.

Cast blasting is a technique that is used in combination with dragline operations to increase overburden production capacity and reduce costs. Cast blasting utilizes the blast energy and gravity to cast overburden from the highwall side of the pit both into the pit and onto the spoils. The portion of the overburden cast into the pit is then moved onto the spoils using the dragline effectively, thereby reducing overall dragline production requirements and rehandling. However, effective control of blasting is important to prevent loss of the underlying resource, particularly in multiseam pits.

Highwall mining is a method of increasing coal recovery in a pit where the stripping ratio has reached its economic limit and surface operations are no longer cost-effective. Two types of highwall mining are commonly used: auger mining, in which a large-diameter auger bores parallel holes into the exposed coal seam; and conventional mining, in which a remote-controlled continuous miner, coupled with an extensible conveyor, extends parallel entries into the exposed coal seam. For highwall mining to be effective, the key criterion is that the coal and surrounding rock must be competent enough to be self-supporting when a portion of the coal seam is removed. Geotechnical calculations determine the size and allowable depth of the auger or miner entries. Recoveries above 50% are possible with augers as large as 2.4 m (8 ft) in diameter, and conventional methods can result in slightly higher recoveries. Experience has shown that highwall mining is not well adapted to steeply dipping seams.

Pit Geometry

After the boundary of the mineable reserves is established, the geometry and structure of the reserve dictate pit orientation and configuration. When the pit orientation is laid out, the mapped dip and strike of the seams and any geological structures such as faulting or discontinuities should be taken into consideration. Geotechnical evaluations provide additional valuable information for determining highwall and spoil slope angles, slope angles for waste and soil stockpiles, pit-end and inter-bench slope angles, and the overall highwall angle for multiple-seam operations.

For both planning and operations tracking/reporting, a standard naming convention should be established for designating and referring to specific mining areas, pits within each mining area, and cut sequencing within each pit. This naming convention should designate and explain mining units to be used in the scheduling process. The width and length of the pits are typically constrained by the pit geometry, physical limitations of the equipment (e.g., dragline reach), and the targeted production rate required. Pits are broken down into mining cuts based on both production scheduling considerations and the accuracy required for reporting volumes. Short-term planning often requires smaller cuts, depending on drill spacing and quality variations, but it provides increased accuracy relative to production volumes and quality. Long-term planning does not require the same accuracy, so larger cuts or mining blocks may be acceptable, thereby reducing data requirements and the amount of time required to input and analyze the data for mine scheduling.

Points to consider when developing the design of mine pits include the following:

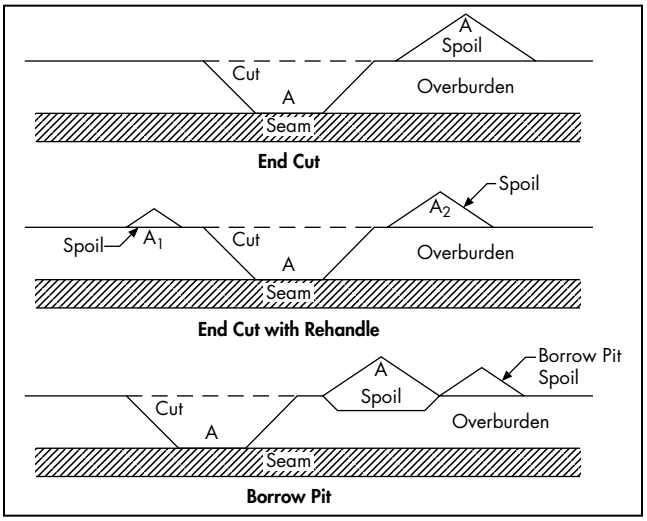
- Orientation of the pit with respect to the strike and dip of the seam and site topography. Pits with inside curves result in insufficient spoil room and additional rehandle. Outside curves create additional spoil room and provide for spoil-side access to the coal seam. Similarly, mining updip creates more spoil room and reduces the potential for spoil failure. If the terrain is relatively flat, straight pits usually give better control over the pit and tend to result in better productivity.
- Prominent structural features, such as faulting, along with intersecting drainages and groundwater. Dewatering may be required, which would have an impact on highwall stability.
- Length and width of the pit. Generally, a maximum pit length of 1.6 km (1 mi) is a good rule of thumb where ramp access to the pit floor is sufficient. Most ramps are spoil side, but there are occasions when highwall ramps and drilling and blasting ramps are required. Minimum pit width is driven by the depth of the pit and equipment clearances needed in the pit bottom. There generally needs to be sufficient width in the bottom of the pit to operate coal-loading equipment with truck and drill access. Keeping the pit width to a minimum is necessary to minimize rehandling.
- Haul access. This consideration of pit design should provide sufficient room for drilling, blasting, and coal extraction. Intermediate spoil ramps, usually at least one per pit, are required to access the pit bottom from either side of the main haulage ramp. Pit-end ramps are also a consideration, so that coal extraction, drilling, and blasting are not cut off by overburden operations. Haulage access design becomes more complex for multiple-seam operations.
- Highwall and pit-end ramps. These are used when spoil material is unstable. The disadvantage of highwall ramps is that the ramp must be reestablished after each cut, and the main haul road requires relocation when mining advance encroaches on the existing haul road.

Rehandle

Rehandle is defined as material that is moved more than once to uncover the same amount of resource. A normal amount of rehandle for a dragline is 10%. Some circumstances require increased rehandle, such as when overburden depth is increasing above the average design thickness for the equipment being used. In such cases, rehandling material may be more cost-effective than purchasing additional equipment or using equipment that is more costly on a unit production basis. When rehandle costs and volumes for major production equipment increase beyond normal limits, it reduces the availability and effective productivity of the equipment for stripping. Utilizing shovel-truck prestripping on a dragline pit may decrease rehandle significantly, resulting in additional stripping capacity. Managing rehandle becomes a trade-off between production capacity and lowest-cost utilization of the equipment.

Unnecessary rehandle can occur when stockpiles are placed too close to the active pit or when production scheduling requires rehandle of stockpiled material. Spoil and highwall failures, which can also result in unnecessary rehandle, may result from poor maintenance of the pit bottom, stacking spoils too high, or highwall/spoil angles that exceed design parameters. An elevated water table, water in the pit, and poor surface-water drainage all can greatly influence highwall and spoil stability. Unplanned rehandle is an unnecessary cost that can have a direct impact on production cost.

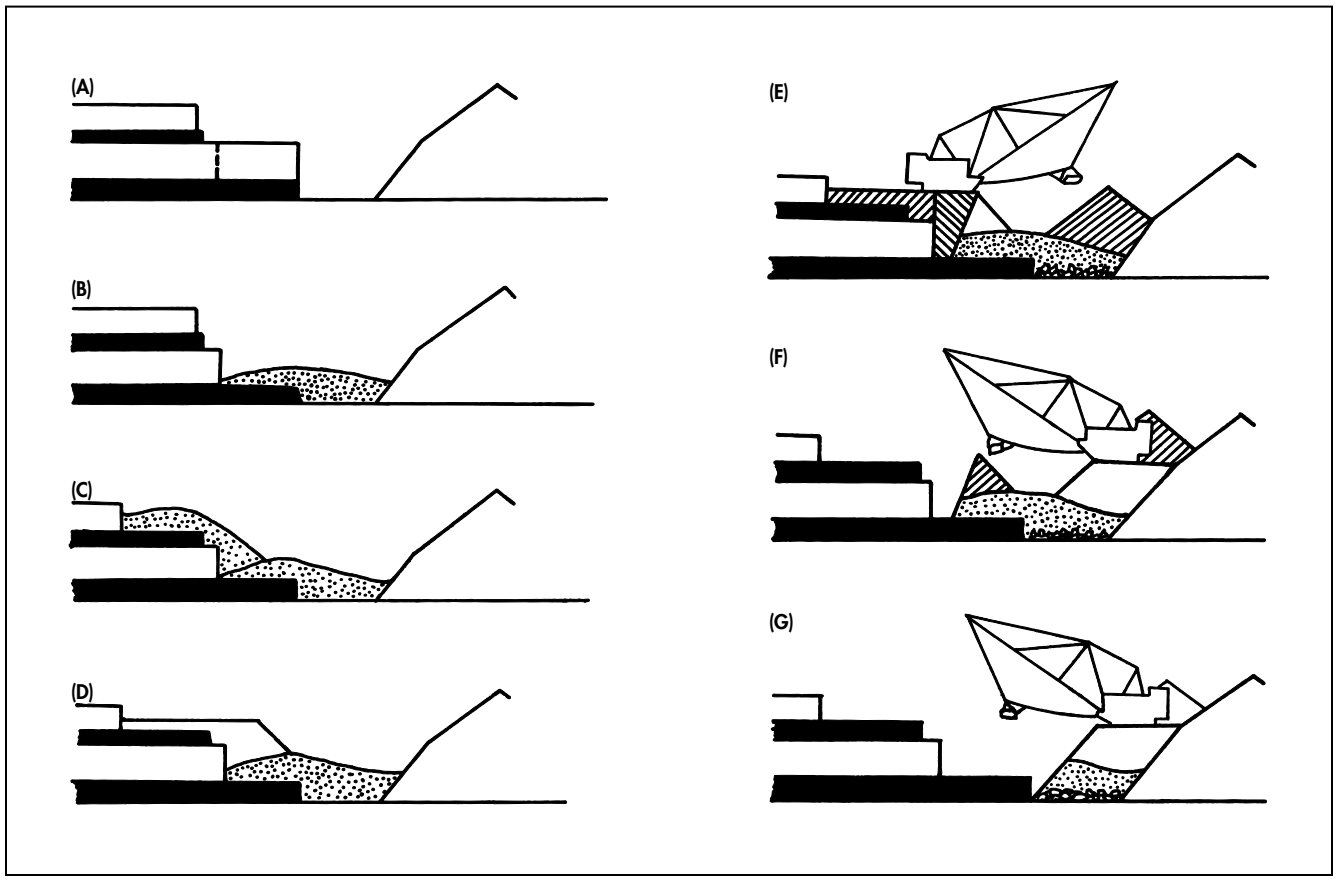
Mining Sequence



For a new property, the mine planning process comprises setting a target production, selecting the equipment necessary to meet that production rate, and running a projected production schedule to determine the economics of the plan. Production sensitivities are then run to determine if the plan can be improved by changing the production level, equipment, production sequence, or other preselected parameters. It is not uncommon to run several iterations to generate an economically optimized mine plan.

For an operating mine, production targets and equipment fleet may be preset. In such situations, meeting the target production rate becomes the focus of planning runs to best fit adjustments to pit configuration and sequencing to the equipment for a given production rate. In this case, planning options may include supplementing, replacing, or idling existing equipment to meet the required production rate. The mining sequence is considered in the pit design phase.

A typical example of mine sequencing is a dragline operation, which is initiated with a box cut. In a dragline operation, the box cut is typically the initial excavation, which creates sufficient spoil room for the first dragline pit. Figure 10.9-1 illustrates three box-cut scenarios.



A typical mining sequence would involve topsoil removal, overburden removal, coal removal, backfilling of the resulting pit with overburden spoils, and grading of the spoils to the final reclamation configuration, followed by reclamation grading, replacement of soil materials, and revegetation. For most regulated operations, unless there is a variance in the permit, soil materials and, in some cases, underlying weathered materials are stripped and stockpiled for future replacement on regraded spoil materials. In some cases, these materials can be directly replaced on existing regraded spoil areas, avoiding the need for stockpiling and often resulting in better reclamation.

Figures 10.9-2A–G illustrate the steps in a typical dragline sequence. Figure 10.9-2A shows the pit as it would look at the end of the previous cycle. The coal is extracted and the pit is ready for the next cut, which is shown by the vertical dashed line. Figure 10.9-2B and Figure 10.9-2C illustrate the results of cast blasting on both the upper and lower seams. Figure 10.9-2D shows the upper bench being graded in preparation for the dragline bench. Figure 10.9-2E illustrates the several phases of stripping that a dragline would perform; the first is extending the bench to allow the dragline to walk out

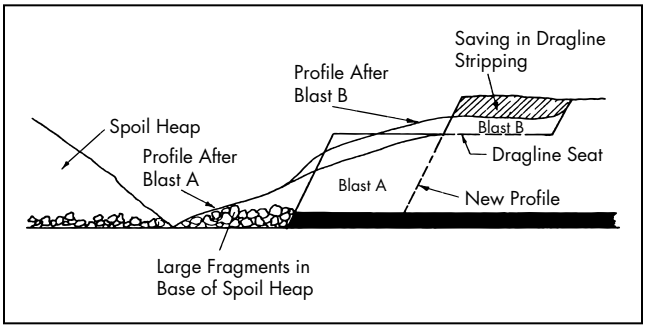
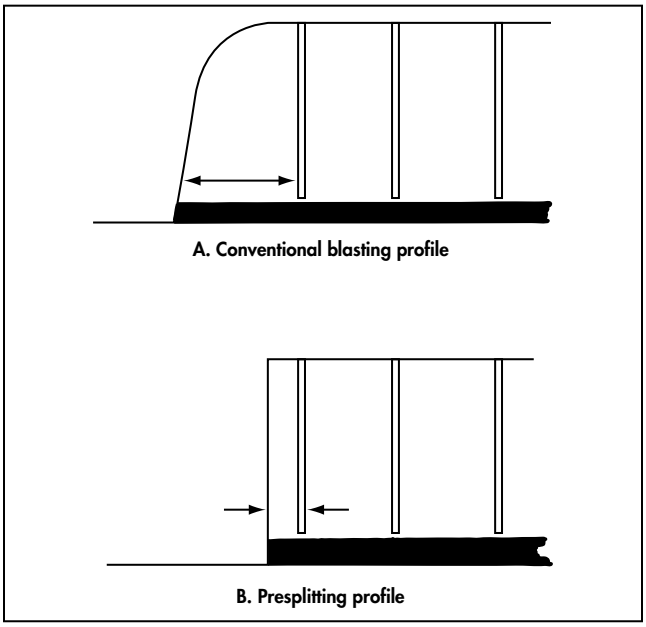
far enough to cast the next cut of spoil to build a spoil-side bench for the dragline to sit on. In Figure 10.9-2F, the dragline is moved to the spoil side, where the bench has been graded to an elevation that allows the dragline to uncover the coal seam. Finally, Figure 10.9-2G shows the section immediately before removing the coal, which is the last step in the cycle. When the coal has been extracted, the cycle is repeated.



The purpose of generating range diagrams is to determine the amount of material moved by the production equipment in each sequential step. These volumes are then used to determine the productivity of the equipment for that specific pit geometry. Overburden thickness and changes in the coal seam geometry can affect the production levels, and a different configuration may be required.

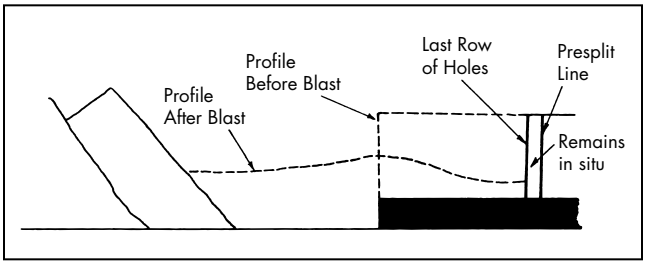
The trade-off with the cast-blasting technique is the loss of coal and dilution due to fracturing of the coal seam at the exposed highwall of the pit. Other configurations that could be compared to cast blasting would be a pre-bench shovel-truck or scraper fleet, depending on the depth of the material above the first seam.

Computer programs that simulate dragline scenarios are used to generate the equipment volumes needed for scheduling. By adjusting the equipment configuration for different geometries, a database of scheduling volumes can be generated by equipment type, with rehandle quantities and expected coal production volumes being taken into account. Each schedule is run through an economic model, and scenarios are compared to evaluate the impacts of each on NPV. This process is used in both proposed and ongoing mine projects to provide justification for equipment purchases and modifications to the mine plan.



Specialized Blasting Techniques

For strip (open-cast) mining, overburden must often be fragmented by blasting so it can be efficiently and economically



Source: Hrebar and Atkinson 1998.
Figure 10.9-4 Blast cast profile

excavated. For many years, mining engineers have considered cast blasting (explosives casting) of overburden both to take advantage of the explosive energy used to fragment the overburden and to reduce material excavation and handling costs (Brealey and Atkinson 1968; McDonald et al. 1982). The low cost and high gas pressures of ammonium nitrate and fuel oil (ANFO) explosives make cast blasting more attractive as a production tool. The advantages of cast blasting become increasingly significant for thick overburden with resistant layers requiring high powder factors (kilograms of explosives per cubic meter [pounds per cubic yard] of overburden blasted)—0.65 kg/m^3 (1.1 lb/yd^3) is typical for some very strong sandstones, for example, in South Africa and Australia. Applications have shown that in certain circumstances, cast blasting in deep overburden can be more economic than conventional stripping. This method, which is based on reducing the primary overburden cast by the dragline (Figure 10.9-3), has the added advantage of promoting gravity segregation of the cast material. Large rock fragments come to rest near the pit floor to form the base of the spoils, thereby improving spoil

Figure 10.9-6 Blasting with parallel tie-up

drainage and stability. Figure 10.9-4 illustrates a typical blast cast profile.

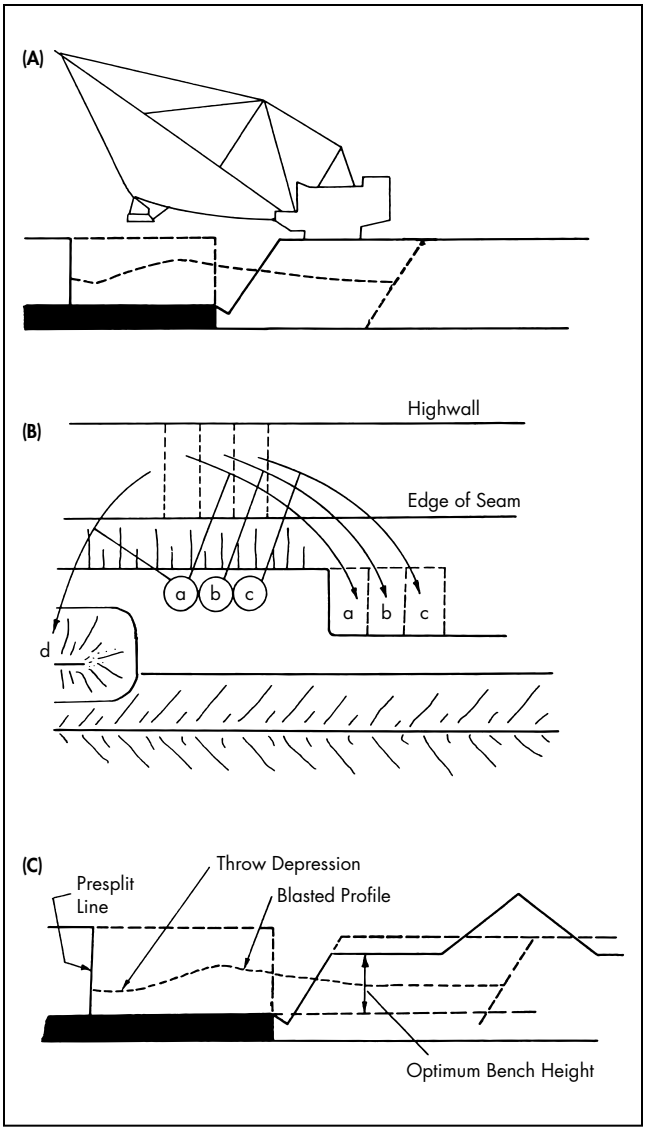
Presplit blasting may be used in conjunction with cast blasting to dewater permeable overburden. Additionally, in strong ground, a vertical face can be created in conjunction with cast blasting, rather than the irregular sloping face produced by conventional blasting (Figure 10.9-5). It is obvious from Figure 10.9-5B that the vertical face, with greatly reduced distance from the front row of blastholes to the toe of the highwall, will result in far more efficient cast blasting. Nonvertical highwalls with an inclined presplit line can be incorporated into the blast design along with modification of the blasthole pattern. Where clay-rich and similar materials are absent, low-cost bulk-placed ANFO has been used in place of more expensive water-resistant explosives (e.g., water gels, heavy ANFO).

The geometry of the spoil after cast blasting must be controlled to provide a section suitable for dragline operations while moving as much spoil as possible across the pit. Conventional blasting patterns in strip mining are usually square or rectangular; rows of holes perpendicular to the highwall are detonated sequentially so that the spoil is thrown parallel to the highwall toward the last open cut. In cast blasting, rows of blastholes parallel to the highwall are detonated sequentially, initiated from the highwall progressively from

Source: Hrebar and Atkinson 1998.

Figure 10.9-7 Blasting method

front to back, resulting in maximum spoil cast across the pit. Experience shows that marginally more spoil is cast using this design, but a section of overburden between the presplit line and the last row of blastholes may remain in place (Figure 10.9-6).



The best results appear to occur with about a 30° offset using a staggered V1 pattern with relatively long, inter-row delays. Figure 10.9-7 illustrates a typical section and the desired section. The throw depression can be greater than desirable, and some minor rehandle of the thrown spoil is necessary to establish a bench for dragline operations. The spacing/burden ratio of the blasting pattern should be determined using site-specific factors and requires detailed consideration to control the trajectory of the thrown spoil.

A means of evaluating the feasibility and effectiveness of cast blasting is the use of the depth/width (d/w) ratio. This is a ratio varying from 0.4 to 0.9, where d is the pit depth from the highwall crest to the bottom of the lowermost seam and w is the width of the exposed pit bottom (toe of highwall to toe of spoils).

Blasthole diameters of 254 to 311 mm (10 to 12.5 in.) are typical. It is doubtful whether larger-diameter holes will provide additional advantages in strong ground, unless explosive density/energy can be increased in the blasthole. Closer spacing rather than larger blasthole diameters may be preferable.

Cast blasting (Walton and Atkinson 1978) can facilitate spoil-side dragline operations, which offer several operating advantages:

- Access ramp roads can be located on the highwall side of the pit, eliminating problems caused by lack of spoil room at the junction of the active pit with the access ramps.
- The stripping sequence is uninterrupted, since access ramps do not have to be reestablished on the spoil side, resulting in increased dragline productivity.

Source: Hrebar and Atkinson 1998.

Figure 10.9-8 Cross-pit, chop-down with single-seam method of operation

- Equipment scheduling is simplified.
- Access to individual seams is simplified in multiseam operations.
- Surface reclamation is simplified since spoil grading does not have to address reclamation of access ramps.

Disadvantages of spoil-side operations are limited, but include the following:

- The dragline may operate in the less efficient chop-down mode.
- Separate power distribution systems are required on both sides of the pit—on the spoil side for the dragline and on the highwall side for blasthole drills.

Single-Seam, Cross-Pit, Chop-Down Operation

A dragline used in the chop-down mode is about 60% efficient compared with the conventional drag mode. Bucket maintenance costs are also higher (although this is considerably alleviated by the better fragmentation achieved in cast blasting). The depth/width ratio of the pit should exceed 0.4 for cast blasting to be considered (i.e., this method is best suited to deeper pits).

Figure 10.9-8 shows the method of operation. The dragline bench height in Figure 10.9-8C can be fixed so that the spoil crests are essentially level, virtually eliminating the need to grade the spoil peaks during reclamation. This advantage can only be fully realized, however, if the height of the dragline bench above the top of the seam does not exceed the optimum digging depth. Where this height exceeds the optimum digging depth, the bucket must be cast and dragged prior to the swing cycle, thereby increasing cycle times. In these circumstances, it is usually more economic to level the spoil peaks with either the dragline (rehandle) or conventional mobile equipment.

The single-seam, chop-down method may be used to strip seam partings in multiseam operations. This operation results in a reduction of dragline productivity of up to 50%, but if the ratio of parting to lower seam thickness is low, this approach can be an economical option.

Two-Seam Method

The steps utilizing cast blasting are illustrated in the following sequence (refer to Figure 10.9-2A–C, and as described previously in the "Mining Sequence" section):

1. The pit section prior to blasting (Figure 10.9-2A).
2. Interburden blasted into the void left after extracting the mineral from the previous strip. Large rocks will form the base of the spoil heap and are not handled by the dragline (Figure 10.9-2B).
3. Blasted overburden. The throw depression of the interburden blast is filled by overburden spoil (Figure 10.9-2C).

This method results in an increase in dragline productivity above that of conventional dragline stripping, but insufficient experience is available in comparable conditions to quantify this increase. There are, however, other marked advantages:

- Both seams are exposed, allowing simultaneous seam recovery. The upper seam can be dozed over the side of the bench (or by other suitable means) onto the lower seam, thereby concentrating and simplifying mineral loading operations and improving blending. The volume of in-pit exposed reserves is increased, allowing greater flexibility in operation.
- Spoil stability is enhanced by gravity segregation of the cast-blast materials, with larger durable rock forming a base for the spoils.
- With both seams exposed simultaneously, additional dragline moves and dead-heading can be eliminated or reduced.
- Reduced need to handle durable rock materials with the dragline can result in reduced bucket maintenance costs.

This method can also be used for single-seam, thick-overburden applications to eliminate chop-down operations for upper overburden benches. Where weathered material exists near surface, the upper bench can be presplit with more closely spaced holes than for the lower, more competent overburden. Provided that weathering is not too deep, the upper bench slope can be increased, up to a maximum of 90° (vertical), since presplitting will limit blasting effects and reduce drainage concerns.

Stripping Previously Worked Deposits

In some situations, thick coal seams that have been previously partially extracted by underground methods (e.g., room-and-pillar mining) can be economically recovered by strip mining. In these situations, stability and the safe operation of the dragline can be in question where conventional dragline stripping is proposed. Cast blasting provides an alternative stripping method for suspect areas where the dragline is not located over the pillared coal, thereby minimizing stability and dragline safety concerns.

Equipment Selection

The following criteria are among those that should be considered when selecting equipment for a new or expanding operation:

- The life of the project. Certain capital and operating cost considerations should be evaluated. Smaller equipment (e.g., scrapers) has lower capital costs but much higher operating costs, depending on the haul distance and the unit volume moved. In comparison, draglines have much higher capital costs and much lower unit operating costs. For example, a scraper may have a capital purchase cost of $2 million, with a recurring replacement cost every 5 years, a unit capacity of 23 m^3 (30 yd^3), a life of 35,000 hours, and an operating cost of $0.98/$m^3$ ($0.75/$yd^3$) varying with the haulage cycle. A 115-m^3 (150-yd^3) dragline might have a capital purchase price of $50 million, an operating cost of $0.20/$m^3$ ($0.15/$yd^3$), and a life of 150,000 hours. It typically will last for the life of the project, which could be 30 years, with a single major rebuild costing $10 million.
- Depth and thickness of the seam(s) overburden and coal, with total depth to last mineable seam. Typically, pits up to 150 m (500 ft) in depth can be surface mined.
- Strike and dip of the property. Is the deposit type more suited to area mining or contour mining?
- Comparison with similar operations. Consider similar operations, but do not restrict the decision by existing convention. In the 1980s, there were only truck-shovel operations in the PRB. The first dragline was introduced in 1982, and since then, draglines have dominated United States surface mines in Wyoming, Montana, Colorado, Texas, and North Dakota.
- Combinations of mining methods.
- Equipment type and size. For draglines, evaluate the equipment type and size by generating range diagrams from cross sections across the length of the reserve. Figure 10.9-3 illustrates a typical range diagram and the volume distribution. Choose typical cross sections that represent variations in the reserve. For shovel-truck operations, bench height and passes per cycle help to determine equipment matching. Three to five bucket passes by a shovel to fill a truck is considered a good match. It will be important to select equipment that can handle changes in pit geometry.
- Dragline capacity. Multiple-seam operations require handling of intermittent coal and interburden, which will impact the productivity of a dragline and require loader truck equipment to handle the smaller seams. Dragline capacity must take into account such production interruptions.
- Haulage scenarios. Evaluate haulage scenarios for truck-shovel and scraper operations.
- Cast blasting. Look at the possibility of augmenting production with cast blasting.
- Used draglines. Evaluate the market for used draglines that are currently idle. Finding a dragline that can be relocated for half the cost of a new dragline may fit the mine plan needs.

All options should be evaluated for the highest NPV and IRR.

Ground Control and Pit Slope Stability

Effective ground control and planning for pit slope stability comprise a two-step process. First, geological structures and groundwater conditions that may affect stability need to be identified and characterized. The planning process then focuses on the proper layout and design of the pit geometry and mine structures to address site-specific structural and groundwater conditions.

In addition to adequate exploration drilling, sampling, and logging to characterize geology, lithology, general structure, water levels, and reserve characteristics, seismic studies can prove invaluable in delineating structural features and characteristics. Groundwater studies can also provide supplemental information on groundwater occurrence and flows.

Proper pit layout minimizes exposure of structural unconformities in the pit highwall, provides for effective drainage of both surface water and groundwater, and avoids geometries that tend to adversely concentrate ground forces (i.e., noses or notches). Similar considerations are appropriate for mine structures, including mine spoils, overburden and waste piles, tailings facilities, water impoundments, and mine buildings.

For pit slopes and spoil piles, as well as engineered structures such as tailings facilities and water impoundments, geotechnical analysis by qualified professionals is appropriate. These analyses assess both static and dynamic (seismic) stability and are often required by applicable regulations. In the case of engineered structures, foundation testing is often a component of the geotechnical analysis, and specific recommendations for foundation preparation and drainage measures are incorporated into project construction plans.

MINE SAFETY

As a critical element of modern mining operations, safety must be a key consideration in planning all aspects of mine operations: layout and design of pit geometry and mine structures and facilities, road design, equipment selection, and operations planning and scheduling.

Applicable regulatory requirements often factor in safety as well as environmental considerations. However, effective protection of worker safety and health requires thought and effort well beyond the scope of regulations. For this reason, the planning phase should address both engineered safety considerations (i.e., pit design and equipment safety features) and safety systems (i.e., worker training, safety awareness, equipment inspection and maintenance, and health monitoring).

LAND REHABILITATION

On completion of active mining operations, whether for an individual mining area or for the mine as a whole, mine disturbance areas should be returned to a stable condition. The potential for any short- or long-term adverse environmental

effects or hazards to human health and safety should be minimized, and productive postmining land use(s) should be supported. Generally, this involves backfilling and grading mine pit areas to blend with the surrounding terrain and promote effective drainage, replacing stockpiled soil materials, and reseeding with compatible native vegetation species.

As part of the planning process, it is sometimes possible to enhance the natural conditions and land uses that existed prior to mining or to make land modifications that may facilitate higher and better land uses.

Effective land rehabilitation can minimize the potential for any short- or long-term liabilities and maintain or increase the value of mined lands. Land rehabilitation is important in promoting a positive perception of the operator and the mining industry as a whole as being environmentally aware and responsible.

ACKNOWLEDGMENT

The authors thank chief engineer and friend J.P. Storrs of Natchitoches, Louisiana, United States, for his inspiration in developing this chapter.

CHAPTER 10.10

Highwall Mining

Eric N. Berkhimer

INTRODUCTION

The concept of highwall mining refers to recovering coal by boring openings beyond the highwall limits produced by strip mining after the economic limit is reached due to increasingly high strip ratios. In general, the term encompasses traditional auger mining as well as the more recent advances using a relatively new class of equipment under the heading of "highwall miners." Auger mining is, in essence, the practice of using a large drill, turned horizontally to bore into the coal seam, and is generally limited to thicknesses of 0.6 to 4.8 m (2 to 16 ft). It began in West Virginia (United States) in the mid-1940s, but the machines at that time were limited in the penetration they could achieve. Advancements in technology were made intermittently over the ensuing decades and peaked in the 1970s and 1980s with higher horsepower units that could achieve a deeper penetration into the seam. Highwall miners, developed primarily in the 1990s, use continuous miners to advance into the coal seam and are able to achieve greater penetration depths and increased coal recovery.

Highwall mining is most commonly practiced when contour strip mining has been exhausted, such as in the Appalachia region of the United States (mainly Kentucky and West Virginia). It has also found some application in other parts of the United States as well as a number of coal regions around the world. According to Newman and Zipf (2005), the concept of highwall mining has been used effectively to mine

- Abandoned pre–reclamation law highwalls,
- Points or ridges that are considered uneconomic to mine by traditional underground or other surface methods,
- Outcrop barriers left at the entrance to underground mines,
- Previously augered areas containing otherwise inaccessible reserves, and
- Multiple coal seams.

In another paper, Zipf (2005) further reports that highwall mining may account for approximately 4% of total U.S. coal production or upward of some 60 Mt (65 million tons) of raw coal annually. There are reported to be approximately 60 highwall mining systems and as many as 150 auger systems in use across the United States.

SITE REQUIREMENTS AND CONDITIONS

In order for a site to be considered for highwall mining, a number of site conditions must be taken into account. Important details include the overburden thickness (including maximum expected thickness in mountainous areas), the pit floor condition, the possibility of intersecting abandoned or current underground mine workings, any intersection of previously drilled auger holes, and any fractures or jointing in the highwall. Highwall stability is a major ground control–related safety concern because of the proximity of the highwall mining equipment to the highwall. In fact, some states have certain regulations for reclaiming areas mined by highwall mining as well as for working below a highwall (including the requirement for benching of the highwall). For example, Ohio and Kentucky (United States) mining regulations include special requirements for reclaiming mining pits that have been auger mined (McCarter and Smolnikar 1992). These include special sealing of the auger holes and time requirements for backfilling the area when the augering has been completed.

Other geologic condition requirements include continuity of the coal seam, a relatively uniform seam thickness, and a near horizontal orientation (less than 10° pitch). These are considered essential because of the potential adverse effects encountered, particularly related to contamination/dilution of the coal.

Any highwall mining plan should consider the hole width (or diameter), the web pillar width (coal left in place between holes), barrier pillar width (a wider block of coal left between two series of holes), and the number of holes between barrier pillars. Additional care must be taken regarding the design if operations are recovering multiple seams in close proximity to one another.

The most widely accepted empirical formula for relating pillar strength to coal strength, pillar height, and pillar width in the United States is the Mark–Bieniawski pillar design formula, which, because the pillar length is much greater than either the pillar height or width in highwall mining, can be simplified to

Eric N. Berkhimer, Senior Applications Engineer, P&H Mining Equipment, Milwaukee, Wisconsin, USA

Table 10.10-1 Pillar width calculation based on mining height and depth of cover

Source: Adapted from Vandergrift et al. 2004.

$$S_p = S_c\,[0.64 + (0.54 \times W/h)] \qquad (10.10\text{-}1)$$

where S_p is the pillar strength, S_c is the in-situ coal strength, W is the pillar width, and h is the pillar height.

According to Vandergrift et al. (2004), a standard figure of 6.2 MPa (899 psi) for coal strength can be applied for an initial calculation.

After pillar strength is calculated, pillar loading is required to calculate a safety factor. Pillar loading can be estimated using the tributary area method:

$$L_p = S_v\,(W + W_E)/W \qquad (10.10\text{-}2)$$

where L_p is the average vertical load on the pillar, S_v is the in-situ vertical stress, and W_E is the entry width.

Finally, an appropriate safety factor must be determined. Although this is somewhat dependent on specific site conditions, a web pillar safety factor of 1.5 and a barrier pillar safety factor of 1.0 are adequate for many sites.

Table 10.10-1 shows the results of pillar width calculations for the case study detailed later in this chapter based on varying seam heights and overburden cover depths (affecting the vertical load on each pillar). Numbers have been omitted where the W/h ratio is less than 1.0.

The major equipment manufacturers often offer their experience and expertise to users to design the web and barrier pillars and for hole pattern planning. In addition, several modeling programs are available to assist with highwall mine design. LAMODEL is a nonlinear boundary-element method used to examine in-seam pillar behavior. UDEC is a distinct-element code used to examine the stability and interaction of the floor, seam, and roof. Additional details can be found in the paper by Vandergrift et al. (2004).

Preparation in advance of using a highwall miner is relatively straightforward. The highwall should be groomed to remove any loose materials that could fall. The pit floor needs to be leveled and cleaned, and a roadway parallel to the highwall should be constructed for access to the equipment and for beltways and/or truck transportation to move the mined coal. The area should be at least 15 to 25 m (50 to 70 ft) in width, although some design engineering is under way to make the equipment more compact for working on narrower benches.

ADVANTAGES AND LIMITATIONS

Highwall mining methods are generally a low-cost, high-production application. Operation is generally considered to be safer than traditional surface or underground mining, but equipment size is somewhat limited. It can often result in less ash (from dilution by the surrounding rock) than surface mining. Maximum recovery is achieved with straight highwalls, while the inside and outside of curves require fanning of the holes and loss of the reserves located between holes. Because of this, careful mine planning is required.

Figure 10.10-1 shows a typical range of costs per metric ton of coal recovered by highwall mining. As shown, the primary factors influencing costs are seam height, and roof and floor conditions. Seam height is defined as low (<1 m [3.2 ft]), medium (1–2 m [3.2–6.6 ft]), and high (>2 m [6.6 ft]). Roof and floor conditions include flatness, smoothness, and hardness of the floor material as well as competency of the roof material. For example, a floor that has less than a 1° incline and is free of undulations will have a significant cost advantage over an area where the floor is at a higher angle or has undulations that are cut with the coal causing contamination of the coal or a roof that has material that will fall once the coal is removed. These have been classified as easy, average, and difficult.

Augers are also a highly productive method of coal recovery with relatively low capital and labor requirements. A three- to four-person crew can average 90 to 2,200 t (100 to 2,500 tons) per shift. However, because a web pillar generally of 0.3 m (1 ft) for every 0.6 m (2 ft) in hole diameter is left in place, recovery averages only 40% to 60%. Additionally, productivity decreases as the depth increases because of the greater torque requirements from the power unit. After the auger is in the seam, the operator cannot see the moving machinery, so operating an auger unit is a highly specialized skill requiring an experienced operator. Further, guidance is difficult as holes tend to drift downward and in the direction of rotation. Most auger mining is limited to a penetration distance into the coal seam of 90 to 150 m (300 to 500 ft) or less.

Because of these limitations, more advanced highwall mining systems were developed in the 1990s. These units also allow operation with three- to four-person crews, but they can produce at a considerably higher rate than traditional auger miners—up to 3,600 t (4,000 tons) per shift. The coal recovery is also improved, up to 70% of the coal being recovered. Penetration into the coal seam can be up to nearly 500 m (1,640 ft). Technological advances also allow better ability for the operator to keep the unit operating in a straight line and in the coal.

EQUIPMENT AND OPERATION

Augers are essentially large drills turned and used in a horizontal direction. They can range from 0.6 to 2.4 m (2 to 8 ft) in diameter and 18 to 61 m (60 to 200 ft) in length. A typical auger consists of the cutterhead, auger flights to add increased penetration depth and move the coal to the surface, and a prime mover to provide the power to drive the auger. Augers achieve production by exploiting the low tensile strength of the coal rather than overcoming its high compressive strength. As such, the key parameters in achieving production are the cutterhead (auger) diameter, the available power, the penetration depth, and the coal type and hardness. Auger performance is directly related to the machine power and the cutterhead diameter.

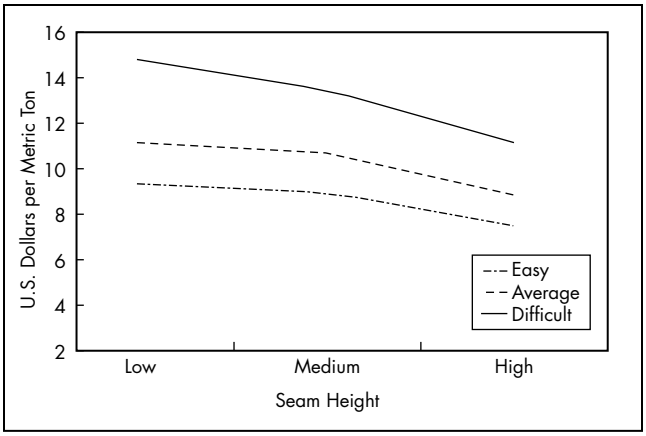

Figure 10.10-1 Comparison of mining costs based on seam height and floor conditions

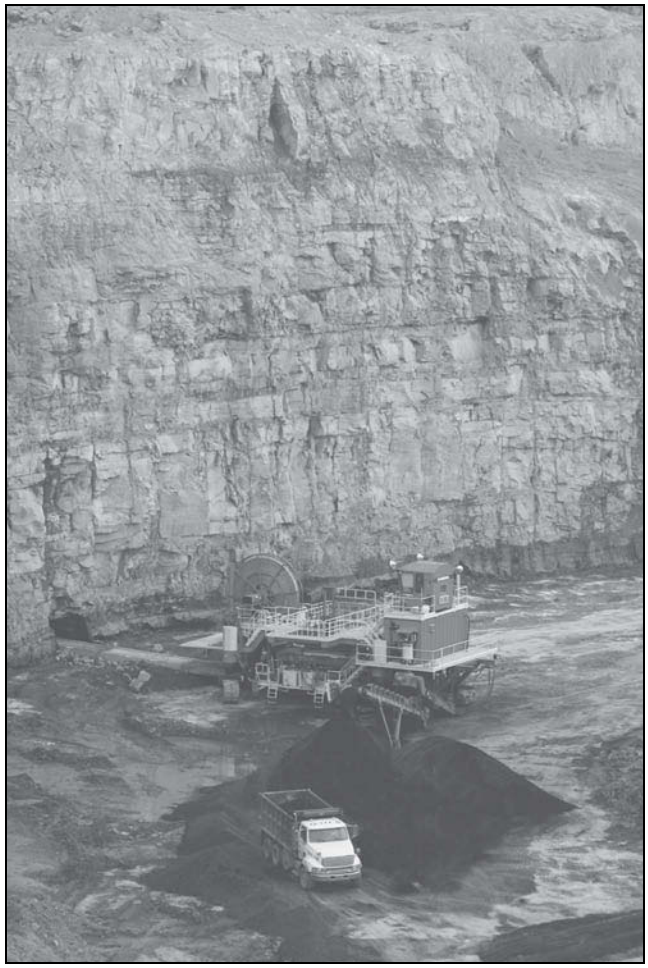

Highwall mining systems were developed in the 1990s to combat the deficiencies experienced with traditional auger mining. Dominated principally by two original equipment manufacturers (OEMs), these systems consist of four basic parts: (1) the cutterhead module consisting of a continuous miner head and gathering arms; (2) the powerhead assembly, which pushes the cutterhead forward; (3) some type of loading and conveying system; and (4) the base unit, which contains the electrical and hydraulic systems. These units are used to mine parallel entries rectangular in cross section into the coal. The cutterhead modules range from 0.75 to 5 m (2.5 to 16 ft) in diameter. A highwall miner is shown in Figure 10.10-2.

RECENT DEVELOPMENTS AND FUTURE ADVANCES

In the mid-1980s, the U.S. Bureau of Mines (Mayton and Volkwein 1989) conducted research in developing a thin-seam continuous miner with transportation to the surface using a multiple-unit continuous haulage system (as used in underground room-and-pillar mining). The key feature and development of this system was an onboard ventilation system that kept the air around the cutterhead clear to permit an operator, functioning by remote control, to see the face using video cameras. Although some features of this were put to use by the later highwall mining systems described previously, this system is not being used commercially.

As a system, recent advances in highwall mining (and particularly with the highwall mining systems described) have centered on greatly improved productivity, better clean coal recovery, and deeper penetration. OEMs have also labored to develop narrow-bench machines that allow operation on previously mined highwalls (highwalls that were mined before reclamation laws came into existence and are still open). In addition, a more global reach has been developed, resulting in highwall mining moving out of Appalachia to locations including, among others, the western United States, Russia, Australia, and South Africa. Finally, there has been a more engineered approach to web and barrier pillar design to improve overall highwall stability and safety for the mining crews, as evidenced by several studies and design formulae detailed previously and OEM involvement.

Future developments in the field of highwall mining are expected to center on achieving deeper penetration, resulting in higher productivity and the ability to work on steeper sloped seams (greater than 10° pitch). This will allow more applications to be used and better coal recoveries from a multitude of applications currently not conducive to highwall mining.

A BRIEF CASE STUDY

Vandergrift et al. presented a case study in 2004 detailing a project to perform highwall mining at Bridger Coal's Jim Bridger mine in southwestern Wyoming (United States). The mine was using the ADDCAR highwall mining system supplied by Mining Technologies, Inc., of Ashland, Kentucky. Potential target areas were identified in four areas of the mine with mining to occur on up to five seams.

Because of the large number of areas identified and the mining of multiple seams in each area, a number of geotechnical issues were first identified. In order to work through these issues, Bridger Coal drilled a series of five geotechnical core holes. Inspection, testing, and analyses of these cores provided the basic input parameters for later calculations.

Roof competency and stability was analyzed using the CSIR Rock Mass Rating (RMR) method. Pillar design calculations were then made using the modified Mark–Bieniawski formula (Equation 10.10-1), and pillar loading was calculated using tributary area theory (Equation 10.10-2). Table 10.10-1 shows the results of these calculations at different mining heights and cover depths.

The empirical results were then confirmed based on previous on-site experiences. Numerical modeling using LAMODEL and UDEC were then applied to confirm pillar stability, explore the effects of seam interaction, test designs against cascading pillar failure (when failure in one pillar results in stress transfer to adjacent pillars that, in turn, fail), and examine roof and floor stability. LAMODEL and UDEC modeling essentially confirmed the validity of other calculations and the design plan formulated.

When the design plan was completed, Bridger Coal filed the necessary applications and revisions with the Wyoming Department of Environmental Quality–Land Quality Division and the U.S. Mine Safety and Health Administration for mining permit revisions and ground control plan approvals. Final approvals were received in January 2003.

The mine then scheduled highwall mining and laid out the panels consisting of 20 entries each using the web and barrier pillar design tables developed previously. Subsidence monitoring (as a condition of the permit approvals) was established over the area to be affected. Mining was initiated in the D41 seam of the Northern area of the mine in April 2003 with the first hole completed on April 10, 2003. Average penetration of the first 18 holes was 458 m (1,503 ft) or 94% of the planned penetration. A previously undetected fault was then encountered in holes 19 through 40, which caused average penetration to drop to 71% of planned penetration—or 344 m (1,129 ft). The plan was then altered to mine only one additional panel at a planned penetration of 305 m (1,000 ft). This panel achieved an average penetration of 298 m (978 ft) or 98% of the target.

Despite the geologic problems encountered, the implementation of the ADDCAR system at the Jim Bridger mine is viewed as a success. Penetration depths as high as 488 m (1,600 ft) have been achieved, and the web pillar design has provided a stable highwall.

CHAPTER 10.11

Quarrying

Ian Brown

INTRODUCTION

Throughout the developed and developing world, vast quantities of aggregates are quarried every year, estimated at around 25 billion t (metric tons). Production in Western Europe and the United States is broadly static, whereas output in Eastern Europe, India, China, and Southeast Asia is increasing rapidly as these countries develop their infrastructures.

Quarried aggregates are essential materials for building the modern world, and these products are used every day in houses, roads, schools, hospitals, factories, shops, offices, airports, and railways. For these projects, aggregates are often used in the form of concrete and asphalt, but they are also used for industrial manufacturing purposes—for example, glassmaking, cement manufacture, paper, fillers, flue gas desulfurization (which results in artificial gypsum), and steelmaking.

The quarrying of rock for aggregates is similar to surface mining for various minerals (Figure 10.11-1), but there are a number of significant differences. The mines are often on a much larger scale, and there is usually a greater depth of overburden, which is still economic to move because the value of the minerals, such as coal, copper, or gold, is many times greater than the value of construction aggregates. The yield of minerals from the ore can be very low (<5%), which means that most of the material extracted from the mine remains on the site in either waste tips or as backfill. In comparison, the product yield from a typical aggregate quarry is commonly >85% and is sold off-site.

GEOLOGY AND LOCATION

Quarrying is the extraction of rock from the ground, usually through open-pit methods. As such, the geology of a country or region determines where a quarry is located. The type of rock also affects the end use of the aggregates produced; for example, granite makes good rail ballast, limestone is essential for cement, and graywacke is excellent for road-surfacing products.

The other key factor when considering geology is the distance from the marketplace, because aggregates are often a high-bulk, low-value product that is expensive to transport. Many construction materials can be produced from local materials, such as sand and gravel, which are abundant in many countries. The high value of cement makes it more worthwhile to transport this product farther.

Aggregates can be naturally occurring and extracted from a quarry, recycled from old construction materials, products of other processes, or artificially made. Some rock types are suitable for many uses; others are restricted to specific needs. The main general categories of rock are igneous, sedimentary, and metamorphic.

Igneous

The most common igneous rocks are granite or basalt, usually formed by the cooling and solidification of molten rock or magma. They can be extrusive from volcanic lava or intrusive as a result of slow crystallization in the earth's crust. Igneous rocks are high in silica, which make good construction materials, particularly rail ballast and aggregates for concrete and asphalt. However, they are more expensive to produce because of high rates of wear on processing equipment.

Sedimentary

The most common sedimentary rocks are limestone, sandstone, or graywacke, which are formed by the consolidation of sediment. Over millions of years, fragments of rock, sand, and soil are deposited by water action, wind, or ice and then compressed by increasing layers of material. When laid down in large quantities, material organically deposited from the shells of marine creatures can form limestone, a widely used rock quarried for cement, industrial powders, lime, flue gas desulfurization, and construction aggregates. Consolidation of chemical precipitates in multiple layers can also form sedimentary rocks.

Metamorphic

The most common metamorphic rocks are slate, quartzite, or schist, which originate from igneous or sedimentary rocks but have undergone a change due to exposure to extremely high temperatures and/or pressures. Quartzite is used in construction, and slate is extracted for specialist roof tiles and roofing felt.

Quarries can be split into two main types: rock operations or sand/gravel sites, each consisting of any of the main rock

Ian Brown, National Production Manager, Lafarge Aggregates, Mountsorrel Quarry, Loughborough, Leicestershire, UK

Courtesy of Lafarge.

Figure 10.11-1 Mountsorrel (United Kingdom) granite quarry showing multibench operation

types. Rock quarries extract material from a solid mass, from the side of hills, or from the surface working down into a pit. Sand/gravel is usually the result of weathering and consists of unconsolidated material that has been broken down and deposited some distance from the source rock—either as glacial moraine, in river floodplains, or in a marine environment. Sands and gravels usually exist together as a blend of different particle sizes and proportions. In addition, these materials will also be either rounded in shape or angular, depending on the extent of weathering by water, wind, or ice.

The location of any potential quarry should be considered vis-à-vis the distance to the market and numerous local factors when undertaking site investigations for a new quarry (Table 10.11-1).

Many countries have detailed geological records that have been built up over many years and should give an indication of the type of material and geological structure in any given area. Several methods are available to give a better indication of the type of material in a given piece of land. For rock deposits, a large drill rig is required, and the objective is to extract a solid core to allow further physical and chemical tests to be carried out. In sand and gravel deposits, samples of the unconsolidated material are brought up from much shallower boreholes by an auger. Also, geophysical surveys can be carried out, consisting of seismic testing, ground radar, and magnetic analysis to determine the size and extent of the mineral deposit.

When the geologist is satisfied that a particular area of land contains a large enough source of rock suitable for use as a construction aggregate or industrial mineral, the mineral surveyor either secures the purchase of the land or agrees to a lease with the landowner. Such negotiations usually include an upfront payment and a royalty paid on each ton of aggregate extracted. This usually time-consuming process can take many months or even years to achieve a satisfactory outcome.

The next stage is to obtain a permit or planning consent from the local regulatory authority to start operating the quarry. This process will vary from country to country.

PERMIT TO OPERATE

In most countries a permit is required before any organization can open a quarry. In many instances during the last 50 years, this process has evolved significantly and is now one of the most expensive and time-consuming aspects of setting up a quarry: US$3 million and a 5-to-10-year process span is not unusual.

Table 10.11-1 Factors affecting location of quarry

Geological Factor	Actions to Consider
Depth of overburden	A ratio of more than 2:1 is usually uneconomic.
Size of reserve	Reserve of 1 Mt (million metric tons) is the minimum required for a new sand and gravel quarry. A reserve of at least 10 Mt would be needed to justify a rock quarry.
Water table	If this is within the reserve, dewatering will usually be necessary.
Streams and rivers	An appropriate distance, usually at least 10 m, must be left between the site and water course. Sometimes a river or stream is diverted.
Rock type	Common rocks for basic products must be close to the market. Less abundant materials (for specialist uses) can be shipped some distance.
Visual impact on local residents	Landscaped amenity banks must be constructed and/or large numbers of trees planted.
Roads and railways	Reserves are sometimes lost because of the proximity of these structures, although they are also essential for product distribution. Roads or railways should be close to the plant area but not too close to the mineral reserves.
Distance to the market	Because of high transport costs, this is very important.

Local residents have a right not to be adversely affected by the quarry, and most governments have established a process to control all aspects of land development. Quarries are no exception, and permitting legislation helps to determine suitable locations and satisfy a number of conditions to ensure that the site is operated in an environmentally acceptable manner; in addition, a site restoration plan may be needed to implement when quarrying has been completed. To meet the demand of construction and other needs, the local regulatory authorities usually have a duty to grant sufficient permits to extract aggregates.

In the United Kingdom, the planning application is usually a set of documents and drawings submitted to the local mineral planning authority. The application is reviewed by professional officers and numerous third parties (such as the Environment Agency), and a decision is made by elected representatives. For example, the study work and drafting required to obtain the appropriate permits for the Lafarge Aggregates Brooksby Sand and Gravel Quarry, established in Leicestershire in 2006, consumed an estimated three full-time equivalent years. The final submission consisted of 30 separate documents, which came to approximately 750 pages and 25 detailed drawings or maps.

These documents and drawings contain a report on all potential areas of concern, with a detailed description of how the quarry will be set up and operated. The landscaping is shown, as are the site entrance, roads, weighbridge, offices, wheel cleaners, and so forth. Plans detail how the overburden will be stripped and stored, as well as how the mineral will be extracted. Details and drawings of the proposed processing plant and associated infrastructure are also included. The rehabilitation design is a key section of any application.

The planning consent or permit will usually include up to 100 separate conditions that must be complied with. Failure to

do so by the operator can result in fines or, in extreme circumstances, cancellation of the permit (Smith and Watkins 2007).

The following are examples of the type of conditions issued with a permit to open a new quarry or to extend an existing operation:

- An environmental management system is established to monitor compliance with the permit conditions and implement remedial action if necessary.
- Visual impacts and landscaping requirements include details of the type of soils mounds required around the perimeter of the site, a tree planting plan, and the site entrance design.
- Vegetation management requirements ensure that landscaped features are maintained in good condition by watering, weeding, and mowing. Trees or hedges should be replaced if they die.
- Biodiversity and ecological management may apply to animal habitats in and around the operation. For example, badger sets must be left undisturbed or relocated; ponds or lakes must be protected from pollution; and, where possible, quarry faces must be left for bird nesting.
- Fuel and chemical storage must be stored in well-maintained double-skinned tanks to prevent the risk of leakage.
- Water management plans must clearly show the location of water bodies on the site and how water is to be used on-site for mineral washing or dust suppression. Dewatering, abstraction, and discharge must be licensed and managed to ensure there is no risk of pollution by suspended solids or hydrocarbons.
- Solid waste management includes surplus materials from maintenance activities, such as scrap metal, conveyor belting, worn crusher parts, and office waste, that must be stored in segregated areas and disposed at a licensed facility, not just buried on-site.
- Dust from plant and machinery is not acceptable. It is detrimental to the health of the quarry work force, is a visual hazard to passing traffic, and can cause damage to nearby properties. Dust emissions must be minimized by the use of sprayed water or approved chemical additives during periods of dry weather. Enclosed crusher buildings can also help solve this problem.
- Noise from plant and machinery must not exceed statutory limits. This condition is imposed to protect employees' hearing and prevent operations from being a nuisance to local residents. This can be achieved by fitting suitable and well-maintained silencers to mobile equipment, putting crushers and screens inside insulated buildings, installing rubber-lined chutes, and fitting synthetic screen media.
- Vibration from blasting must be controlled. Most local authorities apply a vibration limit well below the level that may damage nearby properties. The operator is expected to design quarry blasts to achieve vibration levels within these limits. Monitoring the vibration level of each blast and reporting the results to the local authority is often a requirement of the permit.
- To minimize the effect of heavy trucks used for the distribution of aggregates on the local road network, various measures will be necessary. These include sheeting the loads, driving through a wheel-cleaning system, ensuring trucks are not overloaded, maintaining legal speed limits, and ensuring that trucks are well maintained. In some circumstances, trucks will be prevented from using certain roads based on weight limits.
- Archaeology must be investigated during soil stripping, and time must be allowed to ensure that historical remains can be investigated, recorded, and removed off-site, if necessary. This work is usually at the expense of the operator.
- Emergency procedures to protect the environment must be in place to be implemented if any installed system fails—for example, if a fuel tank leaks. It is also essential to train employees in this activity, including rehearsals/exercises.
- Soil-handling requirements during stripping and restoration are necessary. Soil can only be handled when the moisture content is low enough not to damage its structure and must be stored in separate mounds and retained on-site for use in rehabilitation.
- Time limits and hours of operation may be required. If operations are located a long distance from residential property, it may be acceptable to operate 24 hours a day. However, if not, it is common to restrict running the site between 7 AM and 5 PM, five days a week.
- A rehabilitation plan is required. When quarries were exhausted of mineral reserves in the past, they were often simply left. However, all modern operations have a rehabilitation plan built into the conditions of the permit. Options for rehabilitation include low-level agriculture or nature conservation (created by placing soils on the quarry floor), a lake formed by letting the void fill with water, or sometimes filling the site with domestic or industrial nonhazardous waste and returning it to agriculture. If the plan is established in advance, the mineral operator can plan the material handling to ensure that the final design is achieved economically and to the required standard.

These mineral extraction permit conditions have often evolved over time. Some will be the result of national guidelines or good practices applied to all mineral operators. Others will be based on the needs of local residents or are the result of negotiation between the mineral operator and the local authority.

When the conditions for the mineral permit have been agreed, it is not unusual for them to be enforced by a legal contract. Inevitably, the whole process takes months or even years to complete. The mineral operator must be prepared for a planning application for a quarry to take a long time and to make a submission well before on-site work needs to start.

QUARRY INFRASTRUCTURE

When commencing quarry work at a greenfield site, the location will have been chosen by the operator, based on the quality and quantity of the mineral and its location relative to the market and competitors.

After the necessary permits are in place, the first task will be to secure the site with fencing, gates, and tree planting around the boundary and by the main entrance from the nearest highway. At many sites, obstacles will need to be removed or diverted, such as public rights of way, overhead power lines, trees and hedges (to be cut down only if absolutely necessary), water courses, and pipelines.

If the product processing system includes a washing plant, then a water-handling system will need to be constructed. This usually consists of the licensed abstraction point from groundwater or from a nearby water course and the necessary pumps and pipelines. Water for cleaning aggregates will also need to be stored in a large-capacity pond. The residue from any washing operation is usually fine silt, which must be separated from the water before the water is reused or discharged off-site. The most economic method of handling silt is gravity settlement through a series of lagoons. Thickeners and mechanical presses are more complex and can cost up to 10 times more than settling ponds, but in certain circumstances they may be the only option. Some quarries extract from below the water table, in which case dewatering pumps and—if the waste is not then reused for mineral processing—settlement and discharge facilities will be needed.

The next task is to strip the soils from the first phase of the area to be quarried (most quarries are worked in a series of phases) and the land to be used for plant, roads, and buildings. Soils are often up to 1-m thick and can consist of topsoil and subsoil. This material is often used to rehabilitate the site in the future and should be stored carefully, including being handled only when it is dry and friable. Soil storage mounds are often placed around the boundary of the site to act as a noise barrier and minimize the visual impact for local residents.

During the planning/permitting process, a walkover and/or desktop study into the potential for finding archaeological remains on the site is conducted. The subsequent permit will instruct the quarry operator how to proceed and whom to inform if a discovery is made and what steps will likely follow. During soil stripping, an archaeologist usually observes the work in person; if anything of interest is located, the area will be cordoned off to allow further investigation, often with hand tools. This work will usually only lead to minor delays, but sometimes projects can be held up for months if the find is deemed to be archaeologically significant.

Overburden stripping is then carried out. This involves the removal of the material below the soils and above the mineral to be extracted. Overburden can consist of poor-quality rock, clay, sand, and peat, and can vary in depth from 1 to 20 m or more, depending on the local geology. The initial cut is often placed in storage for rehabilitation use at a later date. However, most of the remaining overburden should, wherever possible, be directly placed for rehabilitation in order to avoid the extra cost of multiple handling of these materials.

The most common equipment used for stripping soils and/or overburden is a combination of hydraulic backhoe excavators, articulated or rigid haul trucks, and tracked bulldozers. In the past, motor scrapers were commonly used for this work, but they are slowed by wet conditions and can cause excessive compaction of sensitive soils. However, they may still have a place in drier climates.

As the mineral is being exposed, it is usual to construct roads and foundations, install the electrical supply, erect the processing plant, construct the necessary administration buildings (such as an office, scale house, employee welfare facilities), and build the maintenance shop.

In the past, quarries have tended to extract the most easily accessible material, often with little regard for a proper plan and geotechnical design. This resulted in many accidents due to high faces collapsing or rockfall. Also, it was common for some reserves to be left in the ground because the haul road was "quarried away" prematurely and there was no access when needed.

Every quarry should have a design that includes the following:

- Local geological details
- Hydrogeology
- Direction of working or phasing and timetable
- Safe access roads
- Bench heights and widths
- Stability of the geology when material is removed
- Details of chemistry for cement or milling plant quarries
- Geotechnical surveys

The level of detail and complexity of the quarry design will reflect the scale of the operation. For example, the plan for a 100,000-t/a sand and gravel operation will contain significantly less detail than one for a 5-Mt/a blasted limestone quarry.

Although some governments have legislated in favor of strict geotechnical management of quarries, many quarries around the world still lack appropriate quarry working plans and likely operate at higher levels of risk and greater inefficiency than is necessary or indeed acceptable. The purpose of a managed geotechnical plan is to ensure the safety of the site employees and local residents and to secure the long-term economic viability of the site.

Quarry faces must be designed to ensure they are safe and the risks of rockfall are minimized. The geotechnical design must also include safe access roads, the overall slope stability of the operation, and a method to economically extract the mineral being quarried, without sterilizing any reserves. A risk assessment should be carried out to help determine how high the rock face should be; factors include the geology, results of blasting, and the size and type of the machine working the face. Historically, face heights were often limited only by drilling capacity, and 30 to 40 m was quite common. As a result of rockfall incidents, many jurisdictions have placed limits on the height of quarry faces; for example, in the United Kingdom, it is typically 12 to 15 m.

The face should be inspected daily, and loose rocks should be removed by scaling with a hydraulic excavator. All edges at the top of quarry benches must have edge protection strong enough to prevent a haul truck from going over the quarry face; this is usually an embankment of quarried material placed to a height of 1.5 to 2 m along the open edge of the haul road. Unworked faces should have rock traps at the base to ensure that falling rocks do not roll into a position of danger. Haul roads should be designed with a slope of no more than one in ten and should be at least three times the width of the haul trucks (Darlow 2007).

Stockpiles of soils, overburden, and quarry products must be designed to ensure they are stable. The underlying ground must be assessed to ensure it is able to take the weight of the stockpile, which may be more than 100,000 t, and taking into account the geology and the groundwater that may be present. The stockpile should be constructed by building up from the base and compacted in 1-m-thick layers. To ensure it is stable, the type of material being stocked will often determine the angle of the slopes of the stockpile's perimeter. The maximum safe height of the stockpile will be determined by the surface area available and the design of the slope. The location of the stocked material will also affect the factor of safety to be used in the calculations; if it is close to the site boundary, the processing plant, or water storage lagoons, the risk of damage would be greater if there was a failure. A drainage system should be

included in the design to ensure that heavy rain does not erode the surface of the stockpile or cause a major slip of the slope.

Geotechnical design should also be applied to water storage and silt lagoons, which must be constructed on a suitable base with the necessary drainage systems. The sides must be built using compacted material that will form an impermeable seal to prevent leakage from the lagoon. Sufficient freeboard, 1 to 2 m, should be included to protect against wave action, and an overflow system should be in place to cope with heavy rainfall.

All geotechnical structures must be designed by a competent engineer and constructed to that design. When in operation, these structures must be regularly inspected and maintained to ensure they remain stable and fit for purpose.

DRILLING AND BLASTING

Drilling and blasting is an essential part of the quarrying activity at a rock quarry and enables the operator to break the solid rock into suitable sizes for loading, hauling, and primary crushing. Five important factors should be considered:

1. **Safety.** There should be no premature initiation or fly rock (Darlow 2007).
2. **Ground vibration and air overpressure.** These must be minimized to avoid disturbing local residents.
3. **Fragmentation.** The rock is broken to a size suitable for further processing.
4. **Efficiency.** The operation should not take too long or be expensive.
5. **Optimization.** It is often cheaper to break rock chemically with explosives than mechanically with crushers. The blasted rock must be neither too small nor too large for the available processing equipment.

Since the 1950s, when technology rapidly developed, large-capacity drilling rigs have become the equipment of choice for creating blastholes in quarries. These machines are usually mounted on tracks or sometimes on wheels and are self-propelled with their own onboard diesel engines and compressors. Compressed air provides the power to operate the hammer drill and flush the holes clean of the rock fines generated during drilling operations.

The drill bits are often made from a wear-resistant material called tungsten carbide. However, different parts of the world prefer driving the bit in different ways. In Scandinavia, where many of these machines are manufactured, a hydraulically powered vibrating hammer is used to drill at the top of the drill rig mast. In the United Kingdom, the compressed-air-driven down-the-hole hammer is used to provide the vibrating power. In softer material, it may be possible to drill by using a hydraulic drive to rotate the drill tubes, which, in turn, rotate a tungsten carbide bit.

Whichever type of drill rig is employed, the objective is always the same: to create 75-mm- to 150-mm-diameter holes at the quarry face ready to receive explosives. Most quarry blasting is carried out using one or more rows of holes located parallel to the open quarry face (typically 12 to 15 m high). The spacing between holes and the burden (distance from the open face) is related to a number of factors and varies for almost every quarry. The blast design should start with a laser survey of the quarry face to be blasted, which assists the competent blaster in establishing the position of the face bottom, so that the burdens of the holes are within acceptable parameters. If the burden is too large, the blasted rock will contain oversize, or if too small, the risk of fly rock increases. The detailed design is usually calculated using proprietary computer software and taking account of local conditions relating to that particular face and the experience and knowledge of the blaster.

The cheapest and most commonly used explosive is ANFO, which is a mixture of approximately 95% prilled ammonium nitrate and 5% fuel oil (or diesel). This material can be mixed by hand on a small scale or more often by a truck-mounted mechanical mixer. However, ANFO needs to be initiated by a detonator-sensitive explosive and is not suitable in wet holes, as it dissolves in water.

Although nitroglycerine explosives were commonly used in quarries up to about 1990, in many parts of the world their use has been replaced by packaged slurry explosives or bulk emulsion, which are mixed from various ingredients, mostly ammonium nitrate, and are pumped into the blasthole from a truck. Initiation of these explosives was usually achieved with detonating cord, but this method was phased out and replaced by electric delay detonators in the 1970s. The microseconds delay between each hole being fired minimized the accumulated ground vibration without affecting fragmentation.

A decade later, nonelectric shock tube (known as nonel) became the most common means of initiating quarry explosives. This was due to the reduced risk of premature initiation from radios, thunderstorms, or other interference. Nonel systems were also cheaper to manufacture. In recent years, the world of electronics has been applied to quarry blast initiation. It is reliable, has almost infinite settings for accurate delays, and is safer to use. Although vibration control and/or fragmentation is often improved, the cost of programmable initiation is currently too high for its common usage in aggregate quarries.

FACE LOADING

Sand and gravel quarries are often to be found in valley floors or floodplains—that is, under the water table. The most effective way to deal with this is to dewater the working area and excavate dry, because it is often safer and cheaper. If pumping is uneconomic and working underwater is the only option, this can be done with a dragline or alternatively (due to significant improvements in technology) with a long-reach hydraulic backhoe excavator. Alternatively, when working sand/gravel from underwater, a dredger can be used. These machines are built on pontoons or attached to ships and can operate as suction pumps, grabs, or bucket elevators. Their operation is not dissimilar to dredgers used in mining of placer deposits. At the top end of the scale, these dredgers can operate in large freshwater lakes or at sea.

Because sand and gravel is usually unconsolidated, its extraction from the ground is achieved without the need for in-situ breaking, although some deposits may need some additional ripping with a tooth attached to the back of a large bulldozer or a heavy-duty excavator.

Since the post–World War II reconstruction boom of the 1950s and 1960s, diesel-driven draglines were commonly used in sand and gravel quarries to excavate and load haul trucks or field conveyors. Draglines were able to sit on top of the seam of sand and gravel and reach depths of up to 10 m, and it was not necessary to construct good quarry floors. They were also used on some sites to strip and cast the overburden.

Currently, many quarries use wheel loaders to excavate and load sand and gravel, as long as the floor is competent

Figure 10.11-2 Typical method of excavation of blasted rock by a backhoe machine

Table 10.11-2 Advantages and disadvantages of tracked and wheeled loading equipment

Backhoe Excavators	Wheel Loaders
Easy to operate	Easy to operate
Minimal whole-body vibration	Significant whole-body vibration
High rate of productivity	Variable productivity
Good fuel consumption	More fuel per ton consumption
Long-lasting tracks	Tire life dependent on ground
High breakout force	Lower breakout force
Slow mobility	Good mobility
Able to drop load into haul trucks	Loads on same level as haul trucks
Longer reach for scaling loose rock	Limited in scaling ability
Useful for secondary breakage	Load-and-carry capability

enough to carry heavy-wheeled traffic in all types of weather. This method is commonly utilized in North America, where in many areas these machines work safely and efficiently, as long as a number of core factors are present: competent operator, suitable sized machine, dry level working area, and a working face height that is less than the maximum reach of the machine. In many parts of the world, sand and gravel quarries do not have the right geological or weather conditions to operate using wheel loaders, so the machine of choice is the hydraulic backhoe excavator. Set up correctly, such machines will work the sand and gravel face in a safe and cost-effective manner.

Loading at the face in a rock quarry has closer links to open-pit hard-rock mining for metal ore than to a sand and gravel operation, but the type of machines available are similar: wheel loaders, face shovels, and hydraulic backhoe excavators. However, the equipment in quarries and mines is usually larger than that employed with sand and gravel.

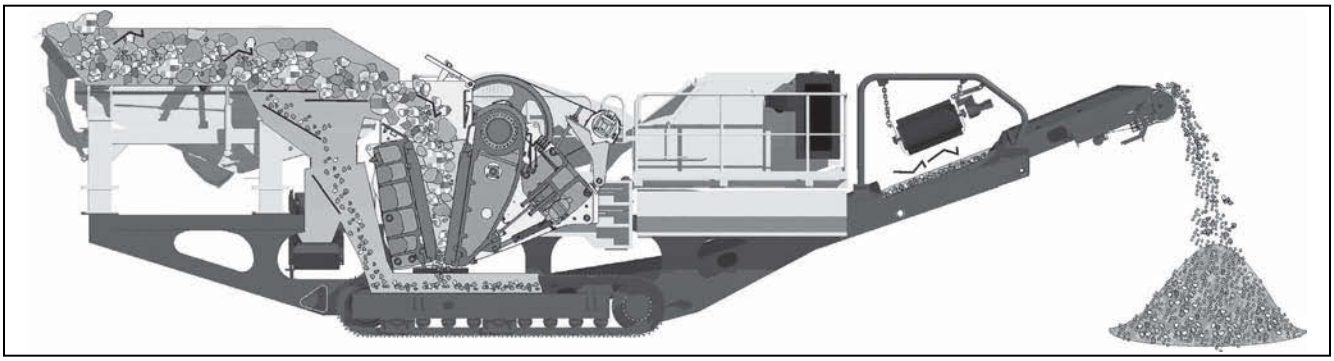
In North America, the blasted rock is usually loaded into haul trucks by wheel loaders. The trend on other continents is to excavate and load shot rock using hydraulic backhoes or face shovels (Figure 10.11-2). Because both methods have advantages and disadvantages, each quarry operator should consider its own application carefully before deciding on which method (and equipment) to employ (Table 10.11-2).

HAULING TO THE PLANT

After the sand and gravel or blasted rock has been excavated, it is often transported to a fixed processing plant, which is usually on the same site and within 1 km of the working area. Since World War II, the diesel-driven haul truck (in ever increasing sizes) has monopolized this work. The haul truck is simple to operate, flexible because it can drive anywhere within the quarry, reliable, and effective.

Two main types of haul truck operate in modern quarries. The rigid haul truck (RHT) is a two-axle machine with rear wheel drive and easily recognizable by the large body canopy extending over an offset cab. Its capacity ranges from 30 to 300 t, and it is more commonly found in a rock quarry where its higher payload provides economies of scale. Some large sand and gravel quarries in North America also use rigid haul trucks where the geology and weather conditions combine to allow good haul roads to be utilized.

The other category of haul truck is the articulated haul truck (AHT). This is a smaller machine, capacity 20 to 50 t, which has three axles and an articulated hitch between the centrally mounted cab and the material-carrying tipping body. Usually a six-wheel-drive machine, it is designed to cope with wet, sticky conditions and is commonly found in European sand and gravel quarries. AHTs are often used for hauling stripped overburden to stockpiles and tips, usually because all-wheel-drive traction is required for difficult ground conditions.



Several factors are important in optimizing the safe and efficient use of haul trucks, both RHTs and AHTs: a good haul road, the right-sized machine, and the size of the haul truck fleet.

Good Haul Road

The road should have as hard a surface as possible, an incline no steeper than 10%, and a camber to allow drainage into ditches or runoff areas. The road should also be at least three haul-truck widths wide and have edge protection made from quarried granular material at least 1.5 times as high as the largest haul truck tire using the route. The haul road must be maintained to ensure it remains safe and effective to use. For this work, the best machine is a road grader. In dry conditions a water bowser will also be required for dust suppression.

Right-Sized Machine

A truck that is too big to feed the processing plant or too small for the quarry excavator has few benefits to recommend it. The truck should be loaded in four to five passes of the excavator or wheel loader. To enable it to tip into the primary crusher, the capacity needs to be of an appropriate size. The tipping body should be suitable for the material being quarried. If the rock being carried by the haul truck is abrasive, additional protection will be carried to minimize the cost of excessive wear. Hardened steel or rubber liners can be effective. In particularly difficult conditions, a suspended rubber body could be fitted to the haul truck, similar to a steel haul truck body, except the floor is made of industrial rubber and suspended from the steel frame by special ropes. In cold conditions it may be necessary to heat the tipping body to prevent wet material from sticking. Heating is achieved by directing the engine's exhaust through channeling in the tipping body.

Size of Haul Truck Fleet

The factors that determine the size of the haul truck fleet are the size of the individual trucks, the tons per hour required to feed the plant, the distance and gradient from the loading point to the hopper, expected truck availability, and productivity. Having too many trucks will be expensive and lead to delays in the haul cycle. Too few trucks will produce inefficiency and leave the excavator and/or the plant running empty. In addition, maintenance of a single machine should not affect the production schedule.

For some quarries, particularly in sand and gravel, the most cost-effective method of material haulage is a field conveyor that runs from the excavator directly to a surge pile at the processing plant. This type of system is usually feasible only where it is unnecessary to blend material from different benches and where the gradient is shallow. Usually the conveyor system is made up of a number of straight sections, changing direction at transfer points. These transfer points often cause material spillage. During the last few years, some quarry operators have installed shallow radius curved conveyors, which can be a cost-effective way of avoiding expensive conveyor transfer points. As quarries are extended, often the most cost-effective means of connecting the new extraction area with an existing plant is by a long field conveyor from a hopper at the edge of this new area, which is fed by a smaller team of haul trucks.

A number of disadvantages are associated with conveyors: they are not very flexible, (i.e., they cannot be moved from day to day), the installation cost is often high, and difficulties often exist in providing power supplies. However, they do have many advantages. They require little labor; are reliable, productive, and quiet; reduce on-site heavy vehicle movements; and only need small amounts of dust suppression at transfer points. They do not require large haul roads and can be a safe and low-cost method of transferring material.

IN-PIT PROCESSING

The traditional quarry consists of the working face, a haul road, and a fixed processing plant. However, in the second half of the 20th century, during the huge surge in demand for construction aggregates, many North American operators set up quarries with portable equipment so they could supply projects in remote areas, such as dams, bridges, and power stations, and also optimize the use of their equipment during seasonal construction campaigns. Equipment suppliers rose to the challenge by designing and manufacturing portable quarry equipment, which has been further developed and improved over the years. A typical crushing *spread* consists of a number of wheel-mounted chassis for crushers and screens, with wheeled hoppers and stacking conveyors for stockpiling material. The machines are linked together and usually powered by a diesel generator.

In Europe since about 1990, there has been a revolution in the track-mounted aggregate processing plant. Scandinavian manufacturers, such as Metso (Eloranta 2009) and Sandvik, were the pioneers of this technology and are still the global leaders. The machines consist of a set of Caterpillar-type tracks, used on backhoes and dozers, and a strong chassis. Fitted at one end is a feed hopper and grizzly screen. In the middle are the crusher (jaw, impactor, or cone) and the diesel/hydraulic power source. At the other end is a discharge conveyor (Figure 10.11-3). Over the years, these primary units have been modified to include a sizing screen with more discharge conveyors and a closed-circuit return belt back to the crusher. This type of unit is now available from numerous manufacturers in a variety of configurations, including the installation of different types of screen, secondary and tertiary crushers, hoppers, stacking conveyors, and other attachments.

This type of track-mounted processing plant is usually located at the quarry face and can consist of one unit producing a crusher run material or can be linked by conveyors to a fixed secondary processing plant. Alternatively, it can be linked to two or three other track-mounted machines to form a complete plant on the quarry floor.

In-pit processing has an advantage in the following situations:

- If the quarry face has moved a long distance from the processing plant, expensive haulage with off-highway trucks can be eliminated by crushing at the face. The material can be transferred to the fixed secondary plant by a conveyor system.
- Small reserves of aggregate that do not justify the cost of a fixed plant can be operated using tracked mobile machines, which then move to the next reserve on completion.
- Seasonal campaign processing is common in parts of North America. A single portable crushing plant can travel between groups of quarries.
- In long-established quarries, the processing plant is commonly located on good aggregate reserves. As the original quarry becomes exhausted, it is often cost-effective to

Table 10.11-3 Advantages and disadvantages of belt conveyors

Advantages	Disadvantages
Continuous operation	High capital costs
Can move large volumes of material	Unreliable if not maintained properly
Simple to maintain	Not flexible, after it is installed
Quiet in operation	
Low operating cost

dismantle the old plant and extract the reserves beneath it with a tracked mobile unit.

MATERIALS HANDLING

Aggregates manufactured from rock (both blasted, and sand and gravel) consist of graded particles usually less than 100 mm in dimension, which are heavy and often abrasive for quarry plant and equipment. The crushing and screening of aggregates is a continuous process, and the handling of material between the plant's major components is as important as the crushing and screening operations themselves. A modern quarry plant will consist of hoppers, feeders, conveyors, storage bins, surge piles, chutes, and transfer points.

The most commonly used material-handling equipment is the belt conveyor. It has numerous applications and, if constructed and maintained in the correct manner, will be reliable and effective (Table 10.11-3).

Numerous types of conveyor are available for almost every conceivable application in a quarry.

- Field conveyor: long-distance material transport (Figure 10.11-4)
- Curved conveyor: wide radius curves to eliminate transfer points
- High-angle conveyor: very steep, or vertical, sandwich belt
- Plant conveyor: typical structural steel conveyor within a plant
- Truss conveyor: for heavy-duty applications bridging large gaps
- Stacking conveyor: inclined to discharge on a stockpile
- Radial conveyor: stacking conveyor that moves sideways in an arc
- Shuttle conveyor: moves horizontally to feed hoppers or storage bins
- Tripper conveyor: horizontal with a moving discharge point
- Pipe conveyor: where the belt wraps around to enclose the material

Conveyors move material around the quarry, but the material needs to be fed between conveyors or to/from processing equipment by feeders. There are several types:

- Belt feeders. Belt feeders are usually very short conveyors (1 to 3 m).
- Vibrating pan feeders. Usually electromechanical, the vibrating motion is provided by conversion of the rotary motion of an electric motor and an eccentric weight into an inclined stroke.
- Apron feeders. These feeders are heavy-duty chain-driven steel conveyors.
- Grizzly feeder. Often used to feed a primary crusher, its vibrating bars have a dual purpose of removing undersize material and feeding the oversize.

One of the most frustrating problems experienced when operating conveyors is potential material spillage around some transfer points and in particular underneath the conveyor from the return rollers. Many types of belt scraper are available for minimizing this problem. One method that can almost eliminate spillage under the conveyor is the belt turner, a device that turns the empty belt over at the conveyor's tail. This allows the belt to return right side up, with the clean side in contact with the rollers. As a result, any material that remains in the belt stays on it rather than being knocked off. When the belt reaches the head of the conveyor, another belt turner turns the belt over again to carry its normal load.

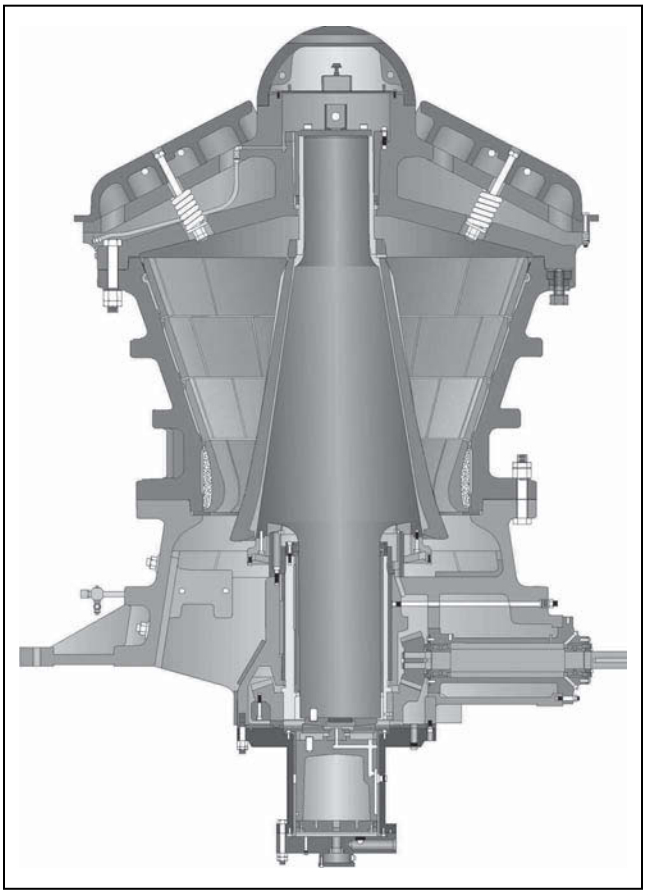
CRUSHING

The use of quarry explosives is the first application of energy to the virgin rock in its journey to being converted into a marketable product. Blasting is an important and effective form of crushing. A well-executed blast transforms a solid rock formation into fragments small enough to be accepted by a processing plant. It is generally cheaper to effect size reduction chemically (explosives) than mechanically (crushers), albeit with far less control (Rothery and Mellor 2007).

The manufacture of aggregates requires larger rocks to be broken down into smaller rocks; for example, blasted rock may be up to 1 m across, whereas rail ballast is a 50-mm-diameter product, and concrete aggregate is usually 20 mm in size. Various stages of mechanical crushing are necessary in the production of aggregates, with the following key objectives:

- Maximize product yield
- Minimize wastage
- Optimize the particle shape
- Remove deleterious material
- Minimize energy consumption
- Optimize crusher wear characteristics

A typical rock quarry will usually have three or four stages of crushing:



1. Primary crushing: Blasted rock is reduced from up to 1-m diameter to less than 300 mm.

2. Secondary crushing: The product from the primary crusher is further reduced in size to 50–60 mm, which may form some of the final products.
3. Tertiary crushing: Taking the secondary product produces the final aggregate sizes, usually –20 mm.
4. Quaternary crushing: This may be used to produce manufactured sand or recrush surplus oversize.

Several types of crushers are used in numerous applications: gyratory, jaw, cone, impact, and roll.

Gyratory Crusher

A gyratory crusher (Eloranta 2009) consists of a long spindle carrying a hard steel conical grinding element, known as the head, seated in an eccentric sleeve. The spindle is suspended from a *spider* and, as it rotates (about 80 to 150 rpm), it sweeps a conical path within a fixed crushing chamber. Maximum movement of the head occurs near the discharge at the bottom. During the crushing process, large rocks are compressed between the rotating head and the top shell segments of the crushing chamber, becoming smaller as the material drops through the machine. Gyratory crushers are large-capacity machines (up to 10,000 t/h) and are only used in primary applications. A gyratory crusher is suitable for most rock types (Figure 10.11-5).

Courtesy of Metso Minerals.

Figure 10.11-5 Cross section of a gyratory crusher

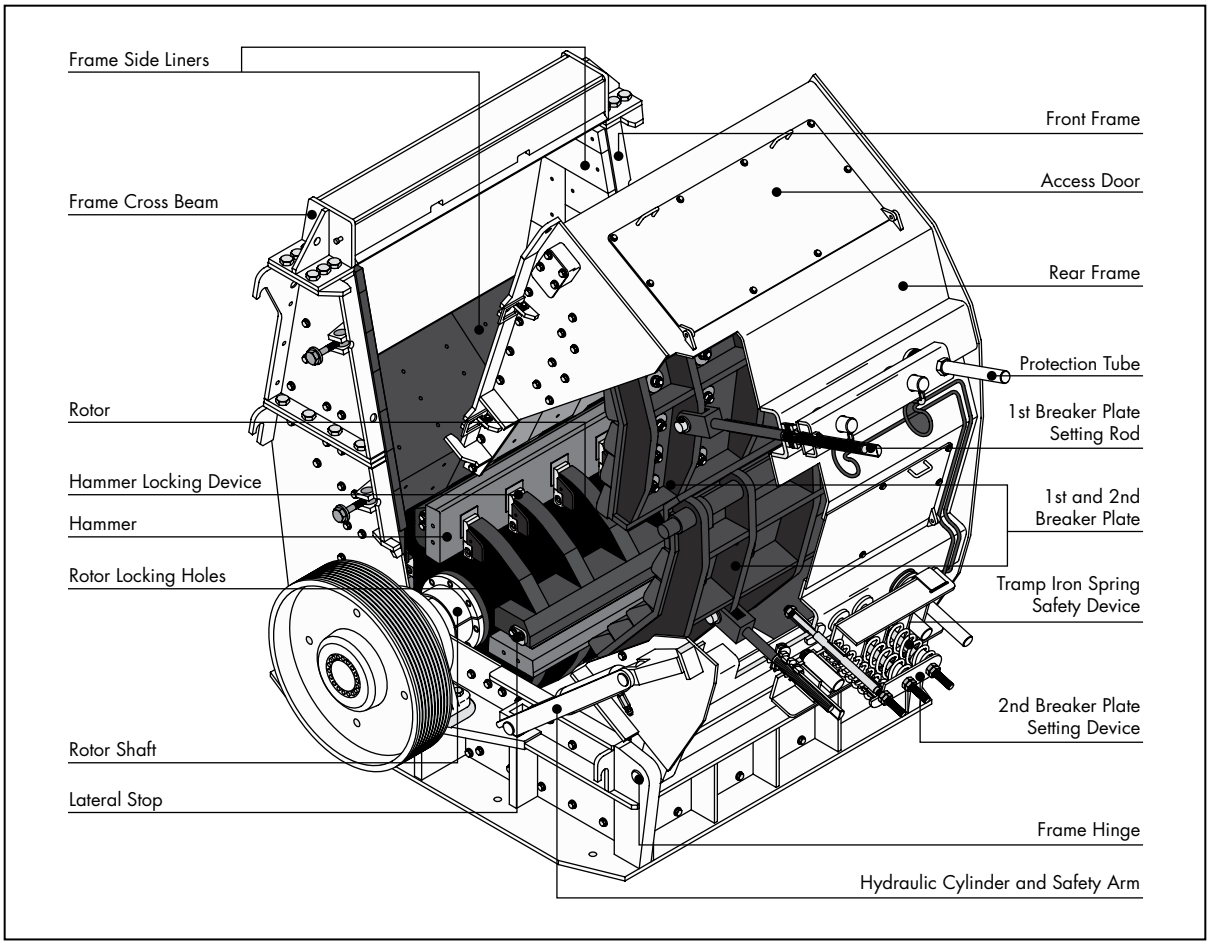
Jaw Crusher

A jaw crusher consists of two steeply inclined, heavy-duty metal plates (known as *jaws*) within a cast steel frame. A wide opening at the top receives blasted rock, and the product is discharged through a smaller opening at the bottom. One jaw is fixed, while the other is powered to swing back and forth.

Jaw crushers can be used as primary crushers for many different rock types unless very large capacity is required. They are usually designed according to the size of their feed opening. The first dimension is the width of the jaw, and the second is the gape (distance between the fixed and the swing jaws at the entry to the crushing chamber). *Scalping-off* (or removal) of –50-mm-diameter material usually takes place before the crusher and feeder, as this is essential for efficient operation. All jaw crushers have a large flywheel attached to the drive, which stores energy on the idling half of the stroke and delivers it on the crushing half. There are two main types of jaw crusher:

1. Double-toggle jaw crusher: The swing jaw is suspended from a shaft, and its crushing cycle comes from the rotation of the eccentric shaft, causing the pitman to rise and fall, which, in turn, rises and lowers the twin toggle plates, moving the jaw stock in and out. Although double-toggle jaw crushers are not commonly used, they are suitable for hard, abrasive rock.
2. Single-toggle jaw crusher: A driven eccentric shaft passes through the top of the swing jaw, creating an elliptical motion at the bottom of the jaw. This is a simpler design than the double-toggle machine, with fewer moving parts, and is suitable for many primary crushing applications.

Some older quarry plants may use small jaw crushers as secondary or tertiary machines.



Cone Crusher

A cone crusher is a smaller and modified version of a gyratory crusher. The shorter spindle of the cone crusher is suspended from a spider in some models but not in others. The capacity of a cone crusher is directly proportional to the diameter of the head, which can be quite high, given sufficient motor power. Also, the steeper the head angle, the larger the capacity. The *throw* of a cone crusher is many times greater than a gyratory crusher, and the cone crusher operates at higher speeds.

Older machines were designed to operate at a slower fixed speed, whereas newer models are faster and adjustable within a speed range. Cone crusher speed is inversely proportional to capacity but directly proportional to size reduction; for example, as the speed of a cone crusher increases, the capacity decreases, and the product becomes finer.

The wide displacement of the head at each stroke is at a speed that allows each piece of rock to fall under gravity and be caught farther down by the rising head (on its return stroke). In this way, the material passing through the crusher is subject to a series of hammer-like blows rather than being gradually compressed, as is the case in a gyratory crusher. At the bottom of the crushing chamber, the faces of the upper and lower mantles are parallel so that all rock will be crushed and at least one dimension is equal to or less than this closed side setting.

The cone crusher is a well-established machine in the production of aggregates and is suitable for many applications (except primary crushing) and most rock types. However, older cone crushers have been criticized for sometimes producing material with a poor product shape. The newer

Courtesy of Metso Minerals.

Figure 10.11-6 Cross section of horizontal impact crusher

generation of high-speed cone crushers virtually eliminates this characteristic.

General principles for good cone crusher performance follow:

- Ensure that the motor is big enough for the duty, and consider the benefits of variable speed inverters and direct drive from the motor to the crusher.
- A controlled and continuous unsegregated feed, distributed evenly to the full periphery of the crushing cavity, is essential for good performance.
- Avoid feeding sticky, wet, or contaminated rock to a cone crusher because this will reduce its throughput capacity.
- The closed side setting (i.e., the smallest gap between the upper and lower mantle) should be set in accordance with the products required and once set should be monitored regularly to ensure it does not deviate.
- Magnets and metal detectors should be fitted within crushing circuits to pick off the numerous pieces of metal that wear away from the plant. Such devices protect the crushers from damage and unnecessary downtime.

Impact Crusher

An impact crusher (Eloranta 2009) consists of a fabricated steel chamber with breaker plates mounted at certain points. In the middle of the chamber sits a horizontal rotor, which, electrically driven at high speed, carries fixed blow bars or swing hammers. Large rocks are fed in at the top, and, after a series of high-speed collisions between the rock and the rotor, as well as between the rock and the chamber linings or even between rock particles, much smaller rocks are discharged from the bottom of the machine. Although most impact crushers have a horizontal shaft (Figure 10.11-6), some specialist applications, such as shaping aggregate or manufacturing sand, employ a vertical shaft impact crusher.

Impact crushers can be used in fixed or portable applications and at primary, secondary, or tertiary stages but only with less abrasive rock. The impact crushing process causes immediate fracturing of the rock, which can be important in the production of high-quality construction aggregates. Impact crushers are also well known for their high reduction ratio, good aggregate shape, and the generation of significant quantities of fines. When considering using impact crushers, the desired product type needs to be evaluated.

Methods of adjustment–product grading can be changed by altering the following:

- Rotor speed
- Feed rate
- Position of breaker bars
- Metallurgical content of blow bars
- Spacing of grid bars

Another type of impact crusher is the hammer mill, where high-strength metal hammers are pivoted on the rotor rather than as fixed blow bars. The hammers can pivot out of the way of oversize or tramp metal and are usually best suited for a smaller throughput and for softer material; otherwise the *way* rate would be too high. (Note: The way rate is that percentage of material that passes uncrushed through the mill.) The base of the crusher chamber is perforated so that only products of a certain size can pass through; any oversize passes through the crushing process again. The hammer mill will achieve much of its crushing by stone-on-stone attrition in the crushing chamber, which makes it difficult to control particle size. Although the product will contain a large proportion of fines, the aggregate products will have a good cubical shape.

Roll Crusher

Roll crushers are still used in some quarries, although in many cases they have been replaced with modern cone or impact crushers. However, they have a use for crushing friable, frozen, or sticky materials such as chalk, gypsum, and soft limestone.

The most common type of roll crusher consists of two horizontally mounted steel cylinders, which are free to revolve toward each other. One of the rollers usually rotates around a fixed-point axle, while the other has its axle set at a variable distance away. This mechanism provides the adjustment for different sizes of feed material and products. Diameters and speeds of the rollers can be varied to produce different sized products. Some roll crushers have a single cylinder rotating to a fixed plate, whereas others have multiple rollers, but these machines are less common.

The feed to a roll crusher must be evenly spread across the full width of the roller; otherwise wear rates will be differential. The rollers are often smooth and lined with abrasion-resistant manganese steel to make them last longer. For some particularly friable or sticky materials, the rolls are made with protruding, intermeshing teeth that dig into the material through a process of ripping and compression, which helps to pull the material into the machine for crushing.

SCREENS

Screening is the separation of aggregate particles into various size ranges and can vary from the separation of 50-mm scalpings from blasted rock to the separation of coarse dust from fine dust. A typical screen consists of a rectangular steel frame mounted on springs, to which the screen media is attached, and an exciter unit to vibrate the frame and create the screening action. The exciter unit usually consists of out-of-balance weights mounted on a shaft driven by an electric motor, which may be attached to the screen or mounted on the support structure and connected through V-belts. The weights can be adjusted to give the required amplitude and stroke of the screen, which, in turn, determines its performance in screening different types of materials into a wide variety of products.

The following screen types are used:

- Dry screens for blasted rock processing
- Wet screens for sand and gravel washing
- Inclined screens for general sizing
- Horizontal screens for final product sizing
- Dewatering screens for removing surplus moisture from sand
- Multideck screens for making more than one product
- High-energy screens for separating sticky material

The following are guidelines for good screen performance:

- Screens should be sized at least to 133% of the required capacity.
- Springs must be regularly maintained.
- Material bed depth should not exceed four times the aperture of the screen media.
- Material should be fed evenly across the full width of the screen.
- Discharge chutes should be large enough to avoid material flow restrictions.

Screen Media

Three main types of material are used: steel, rubber, and polyurethane, with numerous designs for each of these media. The selection of a particular medium depends on many factors and should be analyzed carefully. For example, polyurethane lasts much longer than steel but is also more expensive. Rubber will also last longer than steel but does not have as much open area. Typical screen media used in quarries are

- Punched steel plate for scalping blasted rock,
- Heavy-duty woven wire for medium-sized limestone products,
- Fine piano wires for removing oversize from dry sand,
- Tensioned rubber for wet screening and abrasive materials,
- Tensioned polyurethane for sticky or fine materials, and
- Modular polyurethane for dewatering screens and abrasive material.

SAND AND GRAVEL WASHING

The majority of sand and gravel produced around the world needs to be washed to remove deleterious material such as clay and silt. Sand and gravel deposits contain these materials because they have been laid down in relatively recent geological times by rivers or glaciers.

Most sand and gravel quarries produce less than 500,000 t/a. Therefore, the processing plant (Figure 10.11-7) is relatively small compared with many hard-rock quarries. Sand and gravel, brought from the quarry face by haul trucks or field conveyors, is usually fed to the plant from a hopper or a surge pile onto a washing screen fitted with numerous spray bars (delivering 20 to 40 L of water per minute per ton of feed). This screen simply removes any large lumps of clay or other oversized material, which is retained on the top deck. Gravel retained on the bottom deck is sent for further processing, and fine material passing the bottom deck, with most of the water, is sent for separate processing and dewatering.

Some quarries where the sand and gravel is contaminated with lumps of clay have fitted ingenious devices to remove this material. Part way along the conveyor to the first screen, the troughing rollers are sometimes replaced with flat rollers for a couple of meters to enable a rotating spiked shaft to be employed, which knocks large lumps from the belt. This is simple but effective.

Although the gravel from the washing screen may be clean enough to be screened into its product sizes, stockpiled, and sold, further washing is often required. Washing trommels or scrubbing barrels are large horizontally mounted cylinders, perhaps 2 m in diameter and up to 10 m long. Traditionally, a trommel was driven by a chain on a toothed sprocket encircling the unit, and the whole unit rests on two or more rings on

solid rubber or polyurethane trunnions. Today, a trommel is usually driven through pneumatic tires rotating on a shaft.

Trommels are almost autogenous (i.e., they rely on gravel, sand, and clay tumbling in slurry, and rubbing and rolling against each other to loosen and bring into suspension any silt or clay). The transport of material through these machines usually relies on the discharge aperture being greater than the feed aperture, as the fall between the two is usually only 5°. The dwell time for materials in the trommel is around 2 minutes, which is usually sufficient to clean the material to the required standard; for particularly dirty material a longer dwell time would be set. Trommels are often lined with wear-resistant rubber liners with rubber lifter bars installed longitudinally to assist in cascading the material in order to improve the cleaning action. The peripheral speed ranges from 16 m/min in washers to twice this speed in scrubbers. (Note: Scrubbers operate at about 60% of critical speed—that is, the speed at which the contents would cling to the sides by centrifugal force). Trommels use approximately 25 L of water per minute per ton.

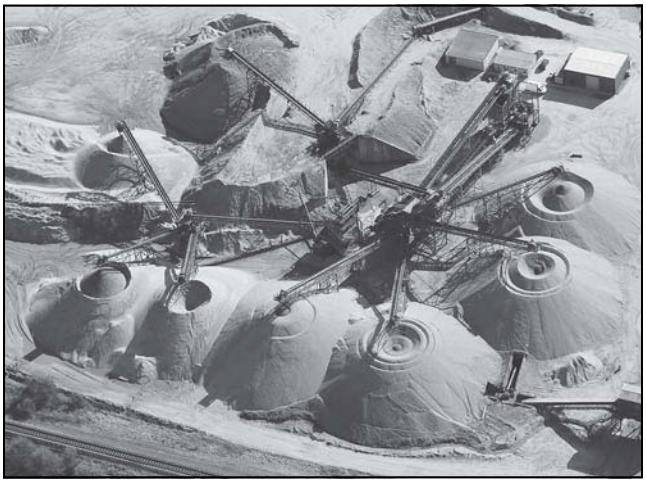
Log washers are used for particularly dirty material. They consist of two counter-rotating steel shafts (logs), fitted with many steel blades, which agitate and scrub the material, pushing the coarse fraction up the inclined tank, with the fines overflowing the weir at the back. The two shafts rotate inward toward each other so the material is forced into scrubbing contact. Blade mills work in a similar manner to log washers except they contain an Archimedean screw instead of the bladed logs.

The discharge from these machines is usually fed to another screen, which gives an opportunity (by using further spray bars) to rinse any remaining fines from the cleaned gravel. The clay, sand, silt, and water are screened out to a collecting sump from where they join the fines-handling process. Cleaned gravel is then fed by conveyor to a product-sizing screen or crusher if necessary.

During sand production, clay and high levels of silt in sand and aggregates used for concrete cause weakness and therefore have to be removed, usually by washing. Particle size definitions used to describe sand production are as follows:

- Sand: +75 μm to 4 mm
- Silt: +2 μm to 75 μm
- Clay: –2 μm

Methods of Processing Sand



From the collecting sump, a number of methods are available for separating the sand from the silt and clay and at the same time classifying the sand into different grades based on particle size (Littler and Millburn 2007).

Free Settling Classifiers (30% to 70% efficient)

Free settling classifiers operate on the principle that sand settles out of slurry into a sump by gravity and is then mechanically separated and partly dewatered by rakes, bucket wheels, or screws. From there, it is often carried by a radial stacking conveyor for further dewatering by gravity. The silt and surplus water overflows a weir adjacent to the bucket wheel or screw and is then pumped to settling lagoons or mechanical thickeners.

Horizontal Current Classifiers (<50% efficient)

Horizontal current classifier machines are commonplace in North American sand and gravel quarries but rarely seen in Europe and other parts of the world. These classifiers provide consistently graded products from a varying feed and allow enough flexibility to achieve the required specification. The long horizontal tank typically consists of 11 compartments, known as stations. Slurry enters at the feed end, where the coarser (i.e., larger) particles begin to settle out. Settling continues along the length of the tank, with the particles that settle out in each station being smaller than from the previous. Because horizontal classifiers rely on free settling, a large amount of fines, unfortunately, are entrained in the early coarse sand stations. This can be overcome by introducing (through slatted plates) a rising current of water, which pushes particles farther down the tank. The required grade of sand can be obtained by blending the material from a number of different stations, each of which has three outlet pipes discharging at 60% to 70% solids by weight into three separate flumes. Each flume runs the length of the tank, picking up material from all stations and transferring it to a dewatering system, which often involves a fine-material screw classifier.

Courtesy of Lafarge.

Figure 10.11-7 Alrewas sand and gravel washing plant

Hindered Settling Classifiers (80% to 90% efficient)

Hindered settling occurs when the settling rate of a particle (within the sand slurry) is increased. The transition from free settling to hindered settling occurs as the concentration of the solids in the slurry increases. This reduces the distance between particles sufficiently that the drag force created by the settling particles affects the movement of nearby particles. However, if the concentration of solids in the slurry is too high, then entrapment and misplacement of particles will dominate. One of the most common hindered settling machines currently in use is the hydrosizer, which works in the following way:

1. The slurry is fed through the top opening of the hydrosizer with additional feedwater (if required).
2. The upward current of water is created by introducing more water through the teeter plate, at the bottom.
3. The upward flow of water counters the settling velocities of the solids.
4. The remaining solids build a high-density fluidized bed until a desired height (or bed thickness) is achieved.
5. After the desired bed thickness is reached, an automatic controller is used to discharge the product at the bottom.
6. Surplus water and silt are discharged from a weir at the top.

Elutriators (<50% efficient)

An example of this group of equipment is the S-type classifier, which is designed to take a continuous feed of up to 25% solids by weight. Feed is passed down a central tube until it meets a deflector plate and is turned radially outward. At this point the flow is split, with fine sand and silt tending to move upward to the overflow, while the coarser particles move downward to the underflow. Which particles move in which direction is determined by the velocity of the upward current, with inevitably some fine particles becoming entrained with the coarser particles and passing downward. A second classifier is often required to further separate the overflow into fine sand and silt.

Hydrocyclones or Hydroclones (60% to 80% efficient)

The hydrocyclone is a simple machine with few, if any, moving parts. It consists of an upper cylindrical section over a lower downward-tapering conical section, the bottom of which is known as the spigot and is 20% of the upper section's diameter. A hollow pipe, the vortex finder, extends through the top of the cyclone and is usually around 30% of the upper section's diameter. Hydrocyclones are usually constructed in sections for ease of maintenance and are lined with polyurethane or rubber to minimize wear. The feed of slurry, sand, and water enters the unit tangentially via a pipe and onto an involuted feed well, which, in effect, wraps around the top of the cyclone. This process pressurizes the feed, which is forced onto the cyclone walls under centrifugal force. The relatively density of sand is 2.5 times that of water and as such forces its way to the walls of the cyclone, pressing out the less dense water, which moves toward the central axis of the cyclone. The partially dewatered sand spirals down the inside of the cyclone and discharges through the spigot. Dirty water exits through the vortex finder into a lower pressure zone. The purpose of the vortex finder is to stop the sand in the feed shortcutting to the overflow.

After sand exits any of these machines, it should be dewatered prior to stockpiling. The most efficient machine for this task is the dewatering screen, which usually accepts sand at 60% to 80% solids by weight and discharges it at greater than 90% solids. Dewatering screens are often horizontal or inclined slightly up at the discharge end. The decks can be stainless-steel wedge wire or slotted natural rubber. However, by far the most common screen media is modular polyurethane. The underflow water is usually fed back to the sand plant in order to recover any remaining fines.

Management and Disposal of Silt

The waste from sand and gravel washing is a suspension of silt and clay in water. By far the most economic way of dealing with this material is to allow it to flow by gravity to settling ponds, which are usually excavated in the floor of the quarry where the sand and gravel has been extracted. The ponds should be geotechnically engineered to ensure they are stable and do not leak. The silt and clay settle out by gravity usually in the first of a series of ponds, the water in each pond becoming successively cleaner. This cleaned water is often pumped back to the washing plant for further use. Ideally, the silt ponds remain where they are and (when they are full) form part of the quarry restoration.

However, in a number of cases, settling ponds are not practical because of, for example, lack of space, severe shortage of water, no planning consent, high silt content, environmental issues or proximity to local amenities, or the airspace/quarry void has been allocated for landfill. If any or a combination of these factors apply, then the silt-laden water has to be mechanically and chemically (with flocculent) thickened prior to discharging to the silt pond. This will provide recycled water for immediate reuse in washing, thereby reducing the size of the silt pond. If no space exists for a silt pond, the thickened silt has to be made into a semidry cake using a filter press.

The conventional silt thickener consists of a large tank containing a slowly revolving rake mechanism. The dirty water is fed in at the top of the tank where a measured amount of flocculent is added. This causes the silt particles to coagulate together, which makes them heavier, and they sink toward the bottom of the tank. The clean water overflows at the top of the tank, usually to another adjacent tank for immediate use in the washing process. The thickened silt is drawn to the center of the tank by the revolving rake, from where it is pumped to a silt pond or filter press.

The filter belt press is one of a number of systems available that will create a semidry filter cake. The thickened silt is treated with more flocculent and is forced between two filter cloths that are pressed together with mechanically driven rollers to remove the surplus water. The water is reused, and the semidry cake is usually stockpiled by the conveyor, to be disposed of by haul trucks.

A more efficient method of filtering is the plate press, made up of a number of recessed plates forming chambers into which the thickened silt is pumped. The plates are supported in a fabricated steel frame and are pushed together by the force of a hydraulic ram. Each plate is covered by a filter cloth, which retains the solid particles but allows the water to pass through. The solid particles gradually build up on the surface of the filter cloth to form a solid cake. After a predetermined period of time, the pressure is released, the filter plates separate, and the cake falls into a stocking bay to be disposed of later.

Removing Lignite from Sand

Some sand and gravel deposits contain small amounts of organic matter and/or lignite, which will cause damage in concrete if not removed. Several ways to separate these deleterious materials rely on the principle that these materials are less dense than sand. One of the more common methods of lignite removal uses an upward current of water in a tall cylindrical tank, which collects the much lighter lignite particles that overflow from a weir at the top of the tank. This mixture of lignite, fine sand, and water often flows over a sieve bend, or curved steel fixed screen. The water and fine sand return to the product, while the lignite is removed by a separate conveyor or chute. If lignite is still present in the sand, the process is repeated in a second adjacent set of equipment.

Dry Screening

In many cases natural sand can simply be dry screened straight from the quarry face without the need for complicated and expensive washing equipment. This is typically done with a mobile screen fed from the face by a wheel loader into a hopper. Sand then passes up an inclined conveyor to a double-deck screen, the top deck of which, having 20-mm apertures, is used simply to protect the bottom deck, which is often a series of longitudinal piano wires. The oversize and the product are usually stockpiled separately with conveyors. The productivity of a dry screen will depend on the feed size

and moisture and clay content, and in some cases has to be processed twice.

Manufactured Sand

In certain parts of the world, no local deposits of sand are available, or, if present, they are unsuitable for use in construction materials. In such areas, the only solution is to manufacture the sand.

From a normal crushing and screening process, making sand for producing concrete is quite difficult. Often, too many coarse or gritty particles or too many fines exist, and sometimes particle shape is a problem, especially if the fines have been scalped without crushing.

Manufactured sand can be made from surplus 20-mm or 10-mm aggregate by reprocessing it through a vertical shaft impactor. With a high proportion of stone-on-stone crushing in these machines and with high rotor speeds, well-graded sand with good particle shape is achievable. However, as always, this is often dependent on the geology of the feed material. Further fine screening may be needed to fine-tune the particle size grading of the manufactured sand. The Mogensen sizer is a multideck dry screen that is capable of making a cut between different sizes of fines. If manufactured sand is made dry, it should be stored in a building to avoid being windblown, causing an environmental problem.

An air classifier can be used to remove surplus fines from sand made from crushed rock; this operates in a similar way to the cyclones used, except that pressurized air is used instead of water.

SPECIALIST QUARRYING OPERATIONS

Super Quarries

Typically, aggregate quarries are relatively small, especially when compared to mines. This is primarily due to the relative abundance of suitable geology for the raw materials and the need for the operation to be close to market because of high transport costs, as aggregates are heavy and of relatively low value. On average, sand and gravel quarries are smaller than rock quarries, as the deposits are fairly shallow (i.e., between 3 and 10 m below the ground level) and consume huge areas of land.

Most quarries in Europe produce less than 1 Mt/a, and many generate much less than half this amount. However, a number of large super quarries (>3 Mt/a) have significant reserves, large processing plants, automated plant control systems, and fewer but larger items of mobile equipment, and can take advantage of economies of scale when distributing by rail or water. The United Kingdom, for example, has eight super quarries (out of a total of about 1,500). Taking advantage of these economies of scale, they produce approximately 15% of the nation's requirements for primary aggregates.

The typical quarry in North America is usually larger than those found in other parts of the world, because land is relatively cheap, aggregate consumption per head is higher, and fuel costs are lower. A number of super quarries in the United States and Canada have been established for various reasons over the years:

- Remote location with massive reserves
- Special properties for cement or lime production
- Close proximity to the rail network for aggregate distribution to rapidly growing urban areas
- Innovative plant designs using large-scale equipment borrowed from the mining industry
- Large ships (30,000 t or more) that have proved cost-effective for transporting aggregates on the Great Lakes and along the West Coast

Underground Quarries

The overwhelming majority of quarries operate as open-pit mines. However, sometimes a rare combination of circumstances makes it cost-effective for aggregates to be mined from underground. These include

- Favorable geology;
- High-strength rock structure to allow room-and-pillar operation;
- Relatively scarce, high-specification material;
- Extension to an existing quarry so a quarry face to tunnel into and other infrastructure are in place;
- Significant environmental constraints that prevent further surface quarrying; and
- Large depths of overburden.

Marine Aggregates

The European continental shelf is relatively shallow and contains similar sand and gravel deposits to those found on land. The reserves are considerable, but a complex system of permitting is required to ensure that the rules governing a country's territorial waters and international waters are respected. Additionally, possible damage to the marine habitat, which could affect fish stocks, and the potential of an increased risk of coastal erosion are concerns, although no evidence currently exists to substantiate either of these claims.

Marine sand and gravel is dredged from the seabed by large, specialist ships, which operate 24 hours per day, 7 days per week. The dredging areas are clearly defined, and the ship's efficiency and compliance with the permit are monitored closely by sophisticated Global Positioning Systems. Suction pumps attached to steel pipes are lowered from the ship during dredging. Up to 10,000 t of sand and gravel may be extracted in one sailing. Most ships have the facilities to screen either surplus sand or gravel from the as-dredged cargo.

When the ship is full, it returns to port (i.e., Amsterdam, London, or Antwerp), where the cargo is discharged at a marine aggregate wharf, which is just like any other wharf except it has a sand and gravel processing plant, usually with a high capacity, 250 to 500 t/h. There is a ship-to-shore conveyor and a stocking area capable of holding at least two ships' worth of material. The sand and gravel is washed (in fresh water) and screened in much the same way as land-won material. The main differences are as follows:

- The salt content will corrode the plant quickly unless galvanized and well maintained.
- Fresh water must be used in the washing process.
- The aggregate products have to undergo extra testing to ensure no deleterious effect from the extra seashell content or chlorides.
- The risk of dredging unexploded munitions left from World War II exists, and suitable precautions need to be in place.
- Marine-dredged aggregate has a low silt content, which minimizes waste. However, a wharf has no place to put traditional settling lagoons, and therefore silt thickeners and filter presses will be necessary to handle this difficult material.

Dimension Stone

Prior to the invention of concrete, many buildings were made of natural stone quarried for that purpose. Many castles, mosques, stately homes, banks, and government buildings are built with dimension or building stone. Historically, every town needed its local building-stone quarry, which were often small and labor intensive.

Since concrete has become one of the world's most heavily consumed materials, dimension stone production has fallen dramatically and is used now only for the cladding of some prestige buildings. Quarries supplying these materials are few and, as such, support a niche market.

As ever, the local geology is critical. A dimension stone quarry must have massive, unfractured rock strata that are strong enough for a building but not too strong to extract in blocks. Overburden will be stripped by conventional methods, but a variety of different systems will be used to extract the blocks of stone:

- Slow-burn explosives in small-diameter holes
- Diamond-toothed saws
- Ultra-high-pressure water cutters
- Traditional wedge and feather system
- Hydraulic version of wedge and feather
- Large hydraulic backhoe excavator with a ripping tooth and/or bucket
- Wire ropes (impregnated with sand or industrial diamonds), which are looped through drilled holes and cut the rock as they travel at high speed against the rock

When the large blocks have been removed from the quarry face, they are moved to a plant for further processing by various combinations of wheeled loaders, cranes, and haul trucks. Processing of the blocks into paving slabs or walling stone is carried out either by automated diamond-toothed saws or workers with hammers and chisels.

REHABILITATION

In old quarries, all the effort was put into the task of winning material from the ground, converting it to a product, and selling it. No plans were made to rehabilitate the land, either during the quarrying process or at the end when the reserves were exhausted. Nevertheless, nature has done a reasonable job in rehabilitating some of these old quarries over many years, and indeed some are now protected areas for flora and fauna (Smith and Watkins 2007).

Modern quarries in many parts of the world will not receive an operating permit without a rehabilitation plan; this must be included as part of the mine plan. In some circumstances, the rehabilitation result is designed first, and the quarry is planned to achieve it. Many quarry rehabilitation projects have been carried out in the United Kingdom during the last 20 years or so, and it is difficult to identify where the quarry was located because of the continuously improving techniques of the quarry industry, vis-à-vis postextraction planning.

Sand and gravel quarries are usually easier to rehabilitate than rock quarries because they are shallower and often operate quickly over a large area of land, in which case the rehabilitation can be progressive. The overburden stripped from one part of the quarry is directly placed as backfill onto another part of the quarry that has already been worked. This is good rehabilitation practice and economic, because the material is only excavated and transported once.

Rock quarries are much more difficult to rehabilitate progressively, as they are often worked to a greater depth than sand and gravel sites. It is not uncommon for rock quarries to be exhausted before they undergo any rehabilitation process. Also, the number of options is limited in designing rehabilitation schemes for rock quarries, especially if they are deep.

Examples of types of rehabilitation for worked-out quarries are discussed in the following sections.

Lakes

To create a lake, the margin of the worked-out quarry is graded to a shallow slope, trees and aquatic plants are planted, and the water table is allowed to rise. The lake could be used as a nature reserve with shallows for wading birds or reed beds for other species and blinds for bird watchers. There are many spectacular examples of former quarries that have been converted into some excellent wildlife habitats (Goodquarry 2009a).

Lakes can also be used for fishing, sailing, rowing, diving, and other water sports. These activities will usually require a means to enable public access, such as roads and parking lots, as well as buildings for cafes and washrooms or the storing of equipment. The rowing lakes in Sydney (for the 2000 Olympic Games) and in London (for 2012) were both constructed following sand and gravel quarrying.

Agriculture

Many quarries are rehabilitated back to agriculture, which is often what the land was used for prior to quarrying. In some operations it is a simple matter of leveling the quarry's base and replacing the soils at a low level, usually with a pump-operated drainage system (Goodquarry 2009b).

In other circumstances the quarry void is backfilled with construction and demolition waste to the original level and the soils put back on top. Some quarry voids are backfilled with household waste, although this requires the construction of an impermeable seal to prevent the leaking of unwanted pollutants into the water table. This type of quarry landfill usually needs a large dome of material to allow for settlement, but after this process, the land can be converted back to agriculture.

Other Uses

Quarries, either rock or sand and gravel, can be valuable as landfill sites. If the waste is from households, it will emit methane as the waste degrades, which can be harnessed through pumps and pipelines and used to generate electricity. Some quarries are converted back to open land or forestry for wildlife and later the harvesting of timber. Other rehabilitation projects include residential housing, industrial and commercial premises, golf courses, and shooting ranges.

MARKETING

The production of quarried aggregates can be a complex, time-consuming, and expensive business. The sales and marketing of quarry products is a specialist field but essential to ensure a good return for the operator. Unlike metals and coal, no international market exists for such commodities, nor are aggregates (in the normal course of events) worth extracting and storing until they can be sold and used.

A quarry's location is determined primarily by the local geological conditions and the numerous environmental conditions necessary to secure a permit. The distance to the market is important because the cost of transport, whether by road, rail, barge, or ship, ranges from high to very high in

comparison to the value of the product. Most quarries usually serve a market within a radius of approximately 50 km.

Many quarries are operated by vertically integrated companies which sell the aggregates internally for the production of ready-mixed concrete, and asphalt and precast concrete products, such as blocks, roof tiles, curb stones, and paving blocks. For many years, these products were seen as basic with little or nothing to choose between them. However, the 21st century has seen changes in concrete and asphalt technology. The major producers now heavily promote their brand of self-leveling, colored, or crack-resistant concrete. Similarly, asphalt producers focus their marketing on skid resistance, low traffic noise, and high-durability materials.

The most significant user of aggregates and aggregate products is the construction industry. Most of the materials used in civil engineering are seen as commodities. Because price is usually the most important factor, the nearest quarry to the construction project has an advantage in terms of transport costs. Sometimes other factors will give an operator that is farther away from the site the opportunity to supply a project with superior or more consistent quality materials or a better service by delivering the correct quantity of material on time, every time.

Because the market for aggregates can be quite variable, operators have to be able to react to significant changes in sales volumes. In the northern hemisphere, for example, extreme winter weather can reduce the production season to 8 or 9 months a year. If material has to be washed, only a 5-month window of operation may be available. Quarries adapt to these climatic conditions by operating a night shift in the summer and building up stocks for the winter. Concrete production can continue at low temperatures by using hot water and/or special additives, thereby giving the operator a competitive advantage.

Quarries located close to major railway lines, navigable rivers, or the sea enables them to compete in markets a considerable distance from the site by using low-cost bulk transport by rail or water. Local distribution is then carried out by short-haul road deliveries. Quarries with rail access are also in a good position to supply ballast for maintaining the railway infrastructure.

A large construction project in a particular area can also affect the sales and marketing strategy of local quarrying companies. New roads, railways, airport runways, dams, power stations, or ports consume huge quantities of materials, usually over a 2- to 3-year time period. Sometimes luck will give a quarry an advantage simply by being the closest to the project.

The structure of the quarrying industry in a country or a region can also influence how aggregates are sold and distributed to the construction sites. In the United Kingdom, 80% of the quarries are operated by five global companies. Peaks in demand give a national operator the ability to back up material supplies from other sites. In Italy most quarries are operated by different companies competing in different local markets.

As in every other aspect of quarrying, geology plays a part in marketing as well. Some quarries produce aggregates with special qualities simply due to the rock type. This means the product has a higher value, often due to scarcity, and can be distributed effectively over a much larger area. For example,

- The ideal geology for the manufacture of cement is a deposit that is near the market and contains limestone and shale.
- High-purity calcium carbonate is required for flue gas desulfurization in large volumes, and distribution by rail is essential.
- The aggregate for high-friction road surfacing can be quite rare and often located long distances from the market, so the costs will be much higher.

PART 11

Hydraulic and Pipeline Mining

CHAPTER 11.1

Hydraulic Mining

Mark Richards

The use of water plus energy to mine unconsolidated material has a long history. In recent years, however, the most popular techniques have been based on either water-jet cutting or dredging. Water-jet cutting is used for the mining of unconsolidated materials, alluvial deposits, freshly blasted ores, and for the recovery (or remining) of dewatered tailings dams. Dredging is used for the recovery of unconsolidated materials in rivers, lakes, in other extremely wet environments, and for the recovery (remining) of fluid tailings dams, see Chapter 11.2.

HISTORY

There are many claims for the invention of the hydraulic method. With the basic principles so obvious, however, it is thought that there was concurrent development of similar mining operations around the world in the 18th and 19th centuries. Certainly its use was heavily championed by the gold miners in North America; by gold, diamond, and possibly rutile miners in South Africa; and by china clay miners in Cornwall, United Kingdom. (Numerous sources regarding the history of hydraulic mining are available through the Internet.)

In North America, the heavy industrialization and scaling up of this mining method led to millions of tons of waste materials flowing down major rivers. The uncontrolled release of this debris led to one of the western world's first environmental action laws as the authorities forced the miners to capture the waste on the mine site and reuse the water.

Uncontrolled hydraulic mining and the use of rivers for high-volume waste removal continued in many countries well into the early 20th century and indeed still occurs today in some South American and Far Eastern countries. Now, in a more environmentally conscious age, this method is largely restricted to operations that can successfully contain the waste and reuse the water at an acceptable cost, such as the current china clay industry (where rheological parameters apply) and some tailings dam recovery operations.

The initial development of the technology concentrated on *monitors*—high-volume and relatively low-pressure output water jets. These were very effective but quite inefficient in energy terms. The monitors of the time had nozzles that ranged up to 200 mm (8 in.) in diameter, with feed pipe work being much bigger. This led to a fairly static operation, which was fine for the denudation of hillsides and thick alluvial operations. The technical considerations of balancing the resultant thrust vectors and steering the monitor were solved by "brute-force" applications using big counterweights, thrust vanes, and so forth.

At the end of the 19th century, the "easy pickings" were beginning to disappear in both the gold and china clay operations. The need to wash blasted material and less easily sorted material resulted in the need for a higher-pressure, more robust, and more transportable monitor. The technology for this was freely available in the parallel development of fire-suppression systems. The early 20th century saw the introduction of higher-pressure and lower-volume systems, loosely based on fire-industry designs. From that moment on, design diverged to match the mining method.

HYDRAULIC MINING TODAY

Today, after the factual features (i.e., grade, size, structure, depth, and location) of a deposit are taken into account, the energy costs associated with hydraulic mining are probably the most important factor influencing the viability of this mining method. To minimize the water pumping requirement, the liberation of ore from country rock using water must be carried out at the highest fluid density possible.

Low fluid density liberation means that a great deal of energy is required for

- Pumping the water to the production face,
- Pumping the resulting ore streams away from the production face,
- Recycling the water and separating the ore, and
- Setting aside a great deal of space for large settling ponds or investing in high-cost dewatering systems.

Mark Richards, Mines Manager, Imerys Minerals Limited, Cornwall, UK

Figure 11.1-1 Hydraulic monitor

Water-Jet Cutting

Water-jet cutting is normally achieved by using a water canon or hydraulic monitor (Figure 11.1-1).

Water-jet cutting technology has been developed regionally to match the specific mining requirements of the ore bodies. Alluvial gold mining, for instance, and china clay mining use quite different designs. The basic principles remain consistent, however, and there is starting to be a convergence of design based on significant step changes introduced by the fire-suppression industry.

Design Parameters

Conditions that will maximize the efficiency of hydraulic mining include the following:

- A reliable source of water, high above the washing faces, that minimizes pumping energy
- Pumps that are energy efficient and in the correct location
- A ready supply of large-diameter pipe to feed water to the monitors
- Monitors that do not need to be moved very often to maintain their optimum position at the mine face
- A mine face drifting into a hill with a gravity runoff that will direct the ore stream toward the processing plant
- No need to recycle the water

In today's operations, however, the mine designer may have to cope with many suboptimal parameters, probably the most crucial of which will be the requirement to recycle the water. This reflects on the energy use most of all and has been the reason that many hydraulic mining efforts have been replaced with mechanical make-down systems, such as washer barrels and water-sprayed vibrating screens.

Whatever these parameters may be, the task is exactly the same: to maximize the efficient use of the energy available.

SYSTEM DESIGN

Water-jet mining projects require a pumped water supply. It is essential that the pump and pipe-work system be designed to make the most efficient use of the electricity supply. More energy efficiency gains are possible from pump and pipe-work optimization than from monitor optimization.

Pumps

In an ideal project, a single pump would be preferred; however, most pressure pumps have a fairly narrow efficiency curve. If there is a requirement to move monitors between benches (thus varying the head requirement of the pump) or if there is a need to run varying numbers of monitors, then a multiple-pump setup should be considered. A single pump can be used for varying loads if the pump has a very flat efficiency curve and if it can be driven by an inverter-controlled motor. Large inverters (above 200kW) are also very expensive, and in certain circumstances they can cause unwanted harmonic effects back to the grid. For this reason, some electricity utilities place limits on their use. A complete cost analysis should be carried out, therefore, to determine which system is more appropriate.

The ideal pump arrangement is based on one pump per monitor, where the head and volume requirements are matched. If the water is free of suspended solids and has a neutral pH, consideration should be given to hydrophobic pump coatings which will definitely improve pumping efficiency, sometimes by up to 5%. If suspended solids are present, they should be minimized by the use of a large settling pond, which can also be used as a water storage lagoon. The presence of even small amounts of suspended solids or adverse pH conditions will significantly alter the choices regarding pump construction materials. In these cases, it is recommended that duplex stainless steel be used.

Modern pressure pumps need a net positive suction head in order to run efficiently, and therefore the pumps should be gravity fed with a minimum of least 1 m (3.2 ft) of head. Consideration needs to be given to stone traps, isolation valves, servicing room, crane access, and most importantly pipe friction; it is always good practice to oversize the pump pipe work on the suction side.

On start-up, a lot of damage to the pumps can occur through cavitation, especially if they are required to pump into an empty and unpressurized pipe-work system. It is therefore advisable that the pressure-side isolation valve be designed so that it can be partially closed during the start-up sequence, allowing the pump to be "throttled" during the start-up phase. Many installations have a timer sequence built into this valve for automatic throttling during start-up and shutdown.

It is advisable to have some facility for pump health checks that does not necessitate pump dismantling. Many modern diagnostic systems need pressure tappings before and after the pump, as well as on the pump casing, and also a facility to measure the bearing temperatures.

On high-power installations, it is always advisable, even with flexible couplings, to use laser alignment techniques between the motor and pump. Misalignment will mean heat buildup and bearing damage in the long term.

Finally, pressure pumps can have very high starting currents. It is therefore prudent to consider this when designing the power supply and also when designing the control panels. It is wise to have these control panels linked in some way to prevent operators from turning pumps on simultaneously.

Pipelines

Multiple-pump systems should be fed via a well-designed manifold for efficient distribution to the pipe-work system. If the manifold has not been well designed and properly aligned, a great deal of energy can be needlessly wasted at this stage. Ideally there should be a swept bend off each pump into the manifold, and the manifold itself should be at least large enough and long enough to reduce the turbulence of the water before it is fed into the pipe-work system. Manifolds without

Figure 11.1-2 A typical multipump arrangement in the Cornish clay industry

swept bends can be used if they are considerably oversized. The manifold will need drain and inspection points.

Figure 11.1-2 shows a four-pump (duplex stainless steel) arrangement with 355-kW motors. Of particular note are the oversized suction and delivery manifolds, the suction isolation valves, and the motorized delivery valves for throttling the start-up. The stone traps are out of view to the right.

It is all too common to build a system based on a "Christmas tree" approach to pipeline design, where sections are added over time with little thought for either isolation or friction losses. Where possible, the entire pipeline system should be designed to have a pipe friction of less than 1%. Many free on-line calculators for pipe friction and other pumping parameters are available on the Internet.

Because collisions between mobile plant and the pipeline network are inevitable, having the ability to isolate a section without losing production is a necessity. The use of *ring mains* with multiple pathways and isolation points will allow the friction losses to be kept to a minimum. Multiple pathways enable smaller-diameter pipes to be used, thus saving money and making pipe handling, maintenance, and movement considerably easier. The location and inclusion of both drain points and air bleed-off points should be considered during the design process.

If there are a variety of pipe sizes in the system, it is obviously wise to put the biggest diameters where the highest flows occur. Any large pipe, however, wherever it is located in the main feed system (before a branch occurs), will always reduce the friction losses.

It is normal to use steel pipes with rubber-lined steel wraps for pipe jointing; this allows a slight give for ease of fitting, movement under varying pressure, and some flexibility in alignment. Some industries have experimented successfully with high-density polyethylene pipes, which can be constructed in convenient lengths for dragging around the mine (typically 100 m [328 ft]). These longer lengths of pipe suffer proportionately less from the friction associated with the pipe joints and short bends.

MONITOR DESIGN

Historically, the major centers of hydraulic mining have tended to develop their own style of monitors with little concern about what was happening in other industries or areas. This has resulted in specialized designs that have given rise to an "evolutionary fit" for the hydraulic mining industry.

The basic principles are universal, and the overriding principle of jet cutting is to maximize the energy per unit area exerted by the water jet impacting the face. Therefore, the water jet should hold its shape and coherence for as long as possible, which means that the main efficiency driver for a monitor is the nozzle. To perform efficiently, the nozzle must be provided with nonturbulent water.

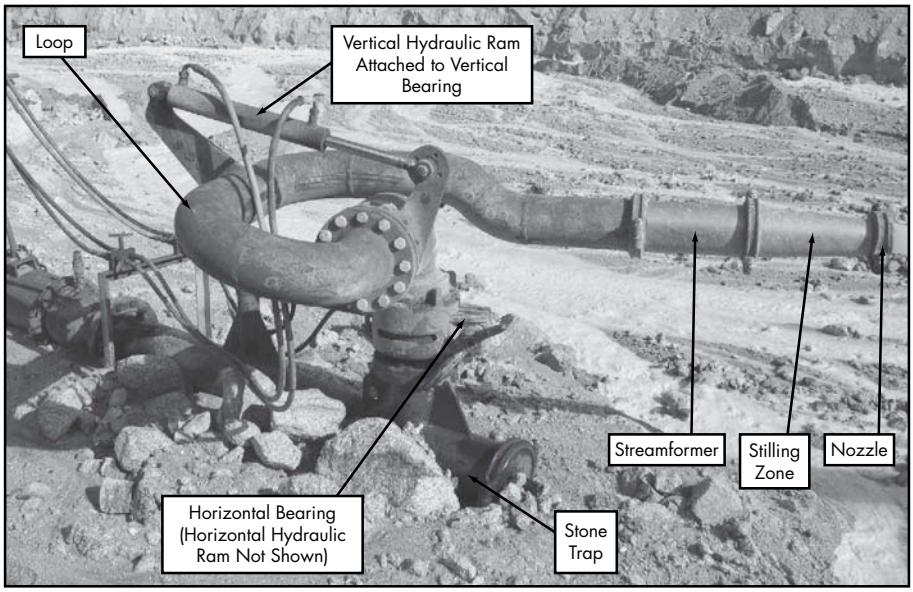
To steer the water jet in two dimensions, it is necessary to have two axes of maneuver and therefore at least two sets of bearings in the monitor. To balance the forces involved, a loop arrangement is needed where the bearings cross over. Figure 11.1-3 shows a monitor in operation in the Cornish clay industry. The thrust is in excess of half a metric ton (5,000 N), and therefore the forces must be balanced. Other approaches to this balanced-forces issue are shown in Figure 11.1-4.

A monitor is built of the following components:

- A base to counteract any overturning moment
- A stone trap
- A loop for balancing the forces as much as possible
- A multiple bearing assembly for two-dimensional movement
- Hydraulic rams, hydraulic ring motors, or electrical actuators for steering the jet
- A barrel that contains a streamformer, a stilling zone, and a nozzle

The nozzle needs to have a quick-change facility (normally using steel pipe wraps) for varying the volume and pressure in order to keep the pressure pump(s) on the peak efficiency point.

All of these elements must work together to minimize any turbulence before the water hits the nozzle. To facilitate this,



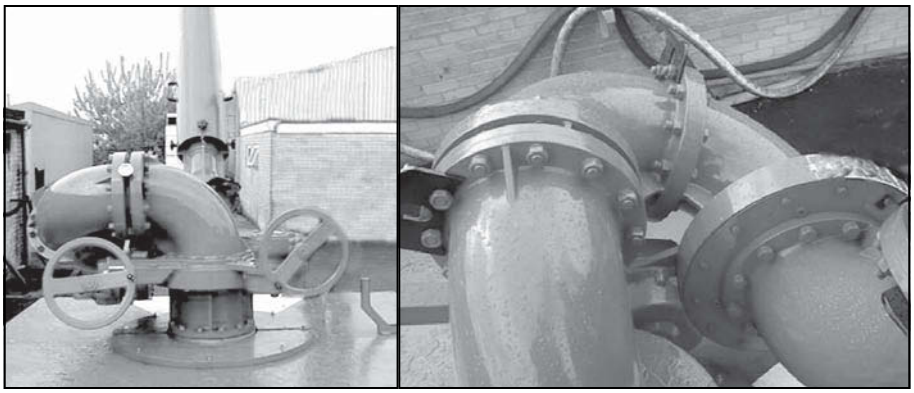


Figure 11.1-3 Close-up, showing bearing arrangement and hydraulics

Note: The long barrel is for foam generation, which would not be used for hydraulic mining.

Figure 11.1-4 Latest designs from the fire-suppression industry

there must be minimum friction all the way through the unit, which calls for large-diameter pipes, swept bends, constant diameter, and a low-friction streamformer. There is a trade-off among all these elements as, for instance, large-diameter pipes will require much tighter bends, while an efficient streamformer will cause friction. Current design cues coming from the fire-suppression industry, however, indicate that large diameters are more important than tight bends. As shown in Figure 11.1-4, the latest thinking suggests that the bends be approximately two pipe diameters with the pipe indexed downward off the top flange to keep the turning moment as low as possible.

The streamformer is to some extent dependent on the operating conditions. Since even the most efficient streamformers can be blocked or damaged by foreign bodies in the water, a degree of pragmatism has to be used in this case. The Cornish china clay industry, for instance, uses a streamformer that has no center at all (Figure 11.1-5); the fins are mounted on the circumference of the barrel and point inward. The fire industry uses a much more delicate honeycomb design because their water tends to be much cleaner.

The nozzle construction material is dependent on the water quality and ranges from aluminium-backed polyurethane to brass and gunmetal (Figure 11.1-6). The industry is converging, however, on a fire-hose-type design of a simple cone with some variations in angle. Many other designs have been tried, but ultimately the original fire-hose type has tended to be the most efficient.

Of major importance is the surface roughness of the nozzle. It is essential that the nozzle be free of nicks and gouges. As a general rule, no roughness should be felt when a fingernail is passed over the surface. The water emerging from a good nozzle setup should appear as a straight bar for at least 50 nozzle orifice diameters and should degrade slowly but steadily on its path to the mining face. Any sign of instability, expansion, or pulsing in this critical area should be seen as a sign of excessive turbulence within the monitor.

Actuation

In most monitor designs, the actuation, or steering, is accomplished by the use of hydraulic rams, although some designs use hydraulic ring motors or electric actuators. In smaller

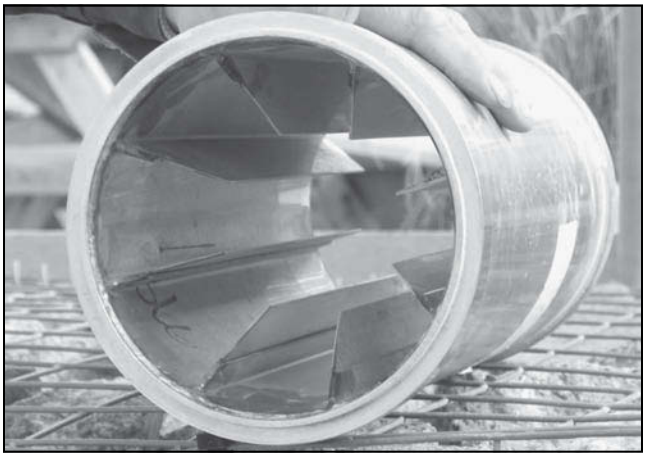

Figure 11.1-5 Self-cleaning streamformer

Figure 11.1-6 Polyurethane nozzle with aluminum backer

operations, or where the risk level is low, monitor steering may be a manual task by means of a yoke on the back of the monitor. In cases like this, it is normal to have a small tray on each axis where weights can be added to fine-tune the balance.

Respectively, motive power has to be supplied in the form of a hydraulic power pack or a generator. In all of these cases, it is common for a Pelton wheel to be used to supply the raw energy. The Pelton wheel is essentially a high-pressure water wheel that takes a small amount of water from the pressure line prior to the monitor to provide the motive force (Figure 11.1-7). Operation of the actuators is normally via pilot hydraulics from levers operated from the control hut (Figure 11.1-8).

In some instances, a secondary Pelton wheel has been used to supply lighting, although this is an inefficient use of pumping energy. In most cases, diesel-powered mobile lighting units or fixed lighting are preferred.

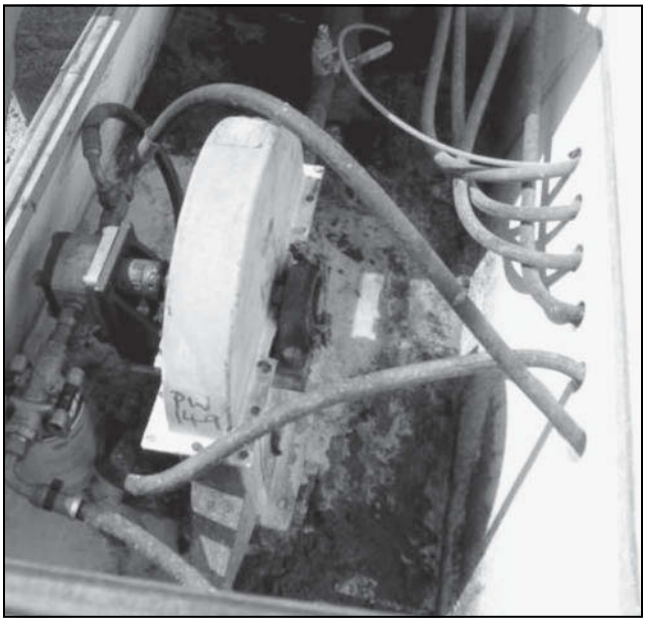

Figure 11.1-7 Pelton wheel

Control Hut Design

A demonstrable and significant increase in productivity, and therefore efficiency, can be achieved if the worker is able to maintain concentration on the production task, with eyes focused on the work face. Holding this attention span is difficult, however, if the worker is uncomfortable or having to work in a badly designed environment. Ergonomics, therefore, is the main driver for control hut design.

Obviously the prevailing climatic conditions will have a bearing on the control hut design; however the main design elements can be split into two categories: operator comfort and safety.

Operator Comfort

It is essential to treat the operator's seating position as if it were a workstation (similar to that for someone who uses a computer routinely) and to allow for the posture associated with operation of the levers. In other words, the controls should be designed to prevent repetitive strain injuries, and their positioning should prevent musculoskeletal stress. Other important considerations for operator comfort include the following:

- Soundproofing
- A draft-free operating environment
- A door design that can be kept open, shut, or anywhere in between, without being caught by the wind

Figure 11.1-8 Monitor control hut

- An ability to control glare if working at night or when the sun is low on the horizon
- A means of preventing windscreen dirt or, failing that, an efficient windscreen cleaning system
- The need for the mobile plant drivers that move the huts (normally small wheeled loaders) to be able to see through the hut while carrying it

Safety Considerations

Stones can be flung a long way by a working monitor, and it is therefore necessary to have a basic understanding of this process:

- Stones get ejected when the monitor jet hits a reflector, such as a flat stone or a hole, where the majority of the jet is reflected back toward the monitor.
- The vertical angle of the monitor jet is crucial; when pointing down, it is much more likely to reflect.
- Stones falling through the reflected jet pick up acceleration only while they fall through the jet.
- The accelerated stones are self-limiting on the distance they can be thrown. The small ones are accelerated quite rapidly but slow down rapidly because of air resistance; the larger ones are difficult to accelerate and thus do not travel as far. Overall, the small stones travel the farthest but do the least damage.

It is wise, therefore, to have a parking rule and a distance rule for avoiding ejecta where possible and to have regard for the safety of others where it is not possible. Recommended precautions include the following:

- The monitor should be "parked" when the wheeled loader is operating in front of the monitor position.
- A minimum distance should be established (the Cornish clay industry recommends a minimum distance of 80 m [262 ft]) requiring that
  - People not involved in the act of jet washing be kept out;
  - All individuals use a safety helmet and eye protection within the zone;
  - Vehicles without safety guard glass (i.e., service vehicles) be advised to park outside the zone until they have the attention of the monitor operator, who will then carefully park the monitor to allow safe entry.
- Because it is obviously difficult to physically put a cordon around the monitor in an ever-changing mining environment, education and warning signs are vital.

If the host rock consists largely of stones, then some armoring of the glass in the hut may well be necessary to prevent breakage. This can be achieved through metal mesh guards or with a ballistic film (a polymer sheet coating similar to laminated glass). In the case of a hand-operated monitor, the energies involved are so low that ejected stones should not be a problem.

OPERATION

The following series of steps provide an overview of the water-jet mining process:

1. The monitor jet washes the material to separate the ore and fine contaminants from the host rock.
2. The resulting ore stream should be tightly channelled to ensure that there is no dropout en route to the processing area or to the gravel pumps which then transport the stream to the processing area.
3. A wheeled loader is normally employed to remove the washed host rock from the mining area.
4. Subsequent removal of the waste host rock can be by haul trucks being loading directly, or the waste can be stockpiled for later removal. Economies of scale may favor stockpiling.

Monitor and Control Hut Placement

The optimum distance from the monitor to the washing face is commonly considered to be 100 nozzle orifice diameters. This will maximize the energy per unit area of the water jet impacting the face. However, from an operational (health and safety) point of view, this is very close and, depending on the scale of the operation, may well compromise the reach in terms of the overall washing area. What is not in doubt is that the monitor should be as close as is safe and practical to the face, and that the control hut should be situated out of harm's way. This distance obviously has to be tempered by the fact that the operator needs a clear view of the jetting and washing process.

It is very easy to bury a monitor with debris runoff from the washing face. Although the operator should be able to prevent this by periodically cleaning the area in front with the monitor jet, it is sensible to place both the monitor and the control hut on small platforms made from local debris. This removes the equipment from the ore stream and makes it much more visible to any mobile plant working in the area.

Rewashing of consolidated tailings and other materials may result in a collapse of the face when liquefied. The operation must be risk assessed according to local conditions. Nevertheless, certain points are common to these operations:

- The control position must be substantially distant from the monitor.
- The control position should be placed on a high bank or mound of material that is not likely to be washed away.
- Washing face heights should be much lower than normal.
- Frequent checks of the washing face should be carried out by a suitably qualified person.

Monitor Operation

With due regard for safety, the operator should use the water jet in a horizontal action at the base of the ore pile in order to undercut the pile. Gravity will then bring unwashed material into the washing area. There is little need to raise the water jet into the higher reaches of the pile unless there is a need to dislodge a hanging rock. Washing from the higher reaches will mean that washed debris comes down to cover unwashed ore near the bottom, making the process inefficient. In addition, this practice tends to reduce the overall slope angle of the ore pile, which means that the optimum monitor position is quickly compromised as the ore pile is washed away.

To dislodge a hanging rock, a technique known as *doubling the stream* can be employed. The operator will direct the water jet to the top of the face above the rock for long enough that the face is covered with a falling cascade of water. The operator will then lower the water jet to the bottom of the hanging rock and take advantage of the weight of the cascade.

With the monitor centrally placed in front of the ore pile, the operator can wash one side until the density begins to drop off and there is a buildup of cleaned host rock or debris. At this point, the operator can move to the other side of the target

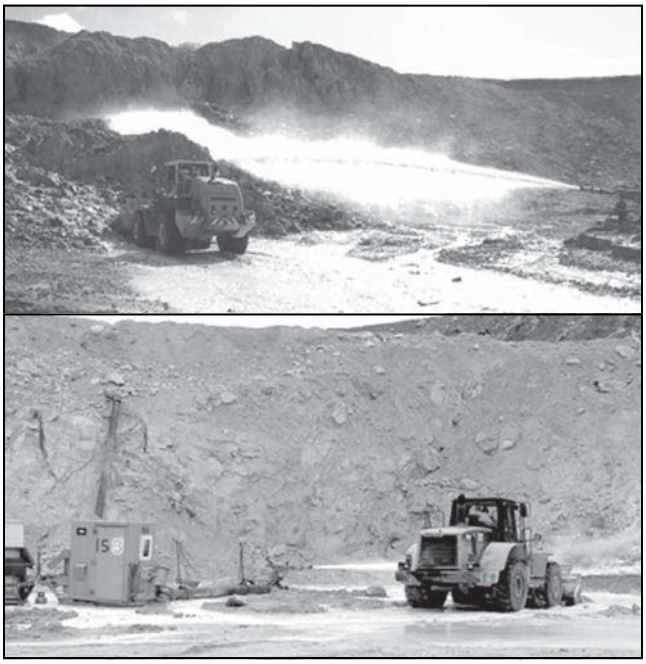

Figure 11.1-9 Wheeled loader removing washed host rock

area, thus allowing the wheeled loader access to load out the waste (Figure 11.1-9). When the wheel loader is forward of the monitor position, the jet should be parked so that flying stones are minimized.

It is at this point that good communication between the monitor operator and the wheeled loader driver is essential. At the beginning of their period together, they should agree on a set of signals or actions so that each can clearly understand the other's actions and intentions. It is normal, therefore, for each side of the ore pile to be worked in turn, allowing the wheel loader to be sufficiently available to remove the debris on demand and thereby keeping the density of the ore stream as high as possible.

Mobile Plant Operation

In most operations, the wheeled loader is sized to allow one machine to be fully occupied by one monitor. Additionally it is normal practice to stockpile the debris so that a fleet of trucks dedicated to waste removal can take advantage of the economies of scale.

The efficient interaction of the wheeled loader driver and the monitor operator is paramount to maximizing productivity and minimizing accidents. That the two must work as a team at all times cannot be stressed enough.

Ore Stream Pumping Versus Trucking

The method of mining used depends to a great extent on the debris ratio and the method of its removal. Across all industries the debris percentage can range from 90% down to 20%. Thus, it is wise to consider the cost of waste removal and the cost of ore stream removal as a whole.

If the debris ratio is very high, it may be appropriate to dispense with ore stream removal costs and carry the raw ore to a central washing point with a gravity run into the processing system. Conversely, if the debris ratio is very low, then electrically pumped ore stream removal is the most efficient. In addition, some ores degrade quite rapidly with too much energy input or shear. Thus, a high degree of pumping may do damage, and trucking may again be more appropriate.

In recent years, there has been a trend toward centralized hydraulic mining, and in some cases its abandonment, in favor of wet mechanical separation. In every new case, however, a comprehensive total costing of the ore stream *and* the waste stream will indicate the preferred process.

CHAPTER 11.2

Placer Mining and Dredging

Richard L. Bullock, Michael J. Cruickshank, and Ian Sherrell

PLACER MINING METHODS OTHER THAN BY DREDGING

The Spanish word *placer* means sand or gravel bank or shoal where gold can be obtained by washing. As it is defined for this chapter, a placer is any area of unconsolidated rock fragments or particles that may also contain minerals potentially of economic value. Placer mining involves the extraction of these unconsolidated materials without the use of explosives or any other significant means of rock-breaking force. This chapter contains a classification of placer deposits and describes the mining and processing of these deposits, which requires the application of mining and metallurgical engineering.

Many placers of economic value can be and have been mined by hand; indeed, the famous gold rushes of the American West and Klondike were in this category. Although it is fascinating history, such mining does not require the engineering methods described in this handbook. For individual prospecting and hand mining, as well as processing, see Wells (1973) and Peele (1945).

Classification of Placers

The many types of placer deposits described in this chapter all have four things in common:

1. A source of the original mineral existed.
2. Some mechanism released the mineral from its original location.
3. The valuable mineral must be resilient enough to survive transport and remain commercially recoverable.
4. A reason existed for the placer being located and concentrated where it was found.

Breeding (1985) describes the steps involved in the formation of a commercial placer as follows:

> The formation of a commercial placer requires a source of valuable minerals. Above primary deposits, eluvial deposits may exist that were formed by the erosion of gangue minerals and the concentration "in-situ" of valuable minerals. Down slope from these deposits are the hillside or colluvial deposits, and below them are the alluvial deposits of redeposited material. Most of the great placer fields of the world are the result of several generations of erosions and deposition. Well-known examples are in California and Colombia.
>
> Gold is a very resistant and malleable matter, and gold placers may extend for 40 to 50 mi (64 to 80 km) along a river system. Platinum is less malleable, but is very resistant to disintegration. Diamonds are extremely hard, and (especially gem diamonds) may be found over great lengths of a river system. Cassiterite (i.e., tin crystals) are less resistant to disintegration, and such placers seldom extend more than 2 mi (3.3 km) without resupply from an additional source or sources of mineralization. Tungsten minerals are generally more friable, and within a few hundred yards (meters) of the source disintegrate to the point that they are uneconomical to recover. Rutile, ilmenite and zircon placers generally result from the weathering of massive deposits and may be encountered over extensive areas; most are fine grained and durable.

Source of Mineral

Sometimes the source material is a mineralized vein (lode) containing high-grade mineralization that is attacked by the release mechanism. Sometimes the source material is a more massive mineralized rock containing disseminated bits of low-grade mineralization. In both cases, the matrix rock and the mineral are broken down into smaller particles that may or may not then be transported by the release mechanism. Portions of the original vein or host rock may remain, or it may all have been removed by the release mechanism.

Michael J. Cruickshank, Consulting Marine Mining Engineer, Marine Minerals Technology Center Associates, Honolulu, Hawaii, USA
Ian Sherrell, Business Development Engineer, Outotec, Jacksonville, Florida, USA

Release Mechanism

Physical release. The more common types of placers are those whose release mechanism is by flowing water. It may be normal stream movement, very rapid seasonal stream movement, flooding rivers or streams, or intermittent streams. When the water is moving fast enough to pick up the small particles, it will carry them to the point where a loss in velocity causes the stream to drop its load. Another release mechanism is the movement of ice as a glacier. This can be followed by streams flowing from the glacier, which then transport the material to a point where it will drop its load. Finally, wind erosion can also wear the rock particles down and separate them from the mineral particles.

Hydrothermal alteration and weathering. Both vein and massive types of mineral deposits can be broken down into smaller rock particles by hydrothermal alteration or by weathering. In these cases, the mineral usually stays in place and may have little chance of physical displacement other than by rolling down an adjacent slope, so there may be little chance for concentrating the mineral.

Deposit Type Formation

Several placer-building mechanisms can take place over long periods of geologic time and form the various types of deposits discussed in this chapter. The mechanisms are

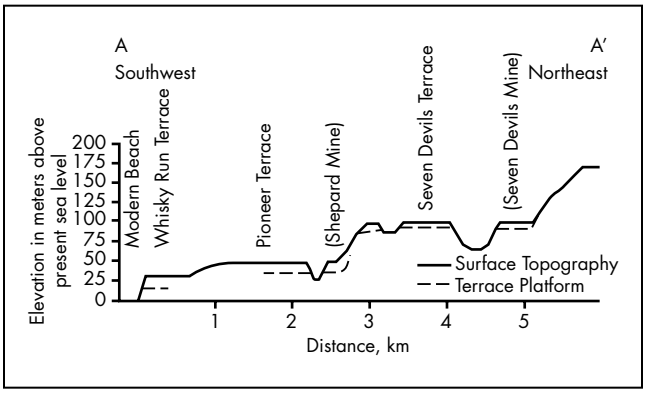
- In-situ residual building,
- Eluvial and gravitational creep movement,
- Stream transport, and
- Steam transport and the wave action of a sea or ocean.

Residual Placers

Residual placers form when the remaining eluvials, consisting of mineralized rock, decompose in situ principally by chemical weathering or in some cases by hydrothermal alteration, often with little or no change in volume (Daily 1973).

Eluvial Placers

Eluvial placers, also termed *colluvial* or *hillside placers*, are transitional between disintegrated rock and stream gravel. They are formed on slopes where smaller particles are removed by rilling, wind, and dissolution (Daily 1973).



Various Stream Placers

Stream transport is a mechanism for forming placers.

Gulch placer. Creek placers, river placers, and gravel plain deposits (Wells 1973) are forms of the gulch placer. The differences are the volume, water force, and areas of deposit attributable to the water's action. McCulloch et al. (2003) classifies these deposits as colluvial, debris flow, pulse placer, and alluvial fans.

Debris flow, pulse placers. These deposits form when the original lode deposit has been sufficiently weathered so as to be weakened. Then, because of above-normal precipitation, the strong rush or pulse of water carries the debris from its original location down and across the valley. Coarse and fine material will flow with the pulse; fine material could be transported farther by normal precipitation.

Alluvial fan placers. When the normal stream flow carries its load down the narrow mountain valley to meet a wider valley or plain, the water fans out, whereupon it drops its load. It fills the current channel to the point that the stream is forced to find a new channel. In this manner a fan deposit is gradually created.

Source: Drew and Lessard 2009.

Figure 11.2-1 Schematic section depicting the relationship between terraces

Eolian placers. Eolian placers are concentrations resulting from the removal of lighter material by wind action (Daily 1973).

Bench Placers

When streams cut downward through a previously deposited alluvial deposit, a bench placer is developed. The economic bench placers are characteristically larger in volume than stream placers. These types of placers were typically mined in 1850 in California (United States) by hydraulicking.

Beach Placers

Where mineral-bearing streams reach the sea or ocean before they drop the transported mineral load, the wave action of the sea tends to concentrate the heavier minerals and forms bands or layers of the concentrated mineral or gem. These types of deposits are extremely important around the world for concentrating heavy minerals such as ilmenite, chromite, rutile, zircon, garnet, diamonds, and so on. It is important to understand that frequently such "beaches" are no longer by the seaside and are at elevations much higher than sea level. They may now be miles from the sea—for example, the Oregon chromite sands (Figure 11.2-1) or the deeply buried deposits of ilmenite/rutile sand east of Nashville, Tennessee (United States).

Desert Placers

Desert placers are found in arid regions where erosions and transportation of debris depend largely on fast-rising streams that rush down gullies and dry washes following summer cloudbursts that fall at higher elevations. These are typical in the southwestern United States and in other desert regions of the world. In these areas, the deposits can be quite large in extent, but erratic in location and mineral grade.

Glacial Placers

Glacial placers are mineral deposits that have been associated with a moving glacier that scraped off loose rock debris, soil, and sometimes minerals. The mineral is later concentrated either in glacial moraines or the streams forming from these glaciers. The gold deposits that have been worked along the foothills of the Sierra Nevada (United States) and the placer

deposits of Fairplay and Breckenridge, Colorado (United States) are examples of glacier-related placer deposits (Wells 1973).

Marine Placers

Any of the placers just described may be found submerged offshore on the continental shelf, which extends at its outer edge to a water depth of about 150 m (500 ft) and as much as several hundred kilometers (nautical miles) from the current shoreline. All coastlines have been subjected to frequent changes in sea level over geological time and during periods when existing placers were subjected to high-energy surf or ocean currents. As the shoreline advanced or retreated, they may have been dispersed, reconcentrated, or buried. Occurrences have been reported of placer gold in Alaska (United States) carried off the shelf by turbidity currents in submarine canyons to depths of approximately 4,000 m (13,000 ft).

Placer Exploration and Sampling Techniques

Before an exploration program is undertaken, it is important to understand what type of placer deposit is being prospected for. The type of deposit will have to be addressed to judge how the mineral concentration took place, how far the mineral may have been transported, where the larger particles of the mineral are likely to be, and where the finer particles will probably be. The normal range of thickness of the deposit will also have to be judged.

In performing exploration and sampling of a potential placer deposit, it is necessary to be aware of the mining and recovery method likely to be used to extract and recover the valuable mineral. To perform exploration and sampling effectively, it is necessary to understand the limits of the mining and recovery methods. This same philosophy also applies to assaying: If the mineral cannot be recovered by the concentrating methods being applied in the mining and processing, then fire assaying of the total mineral content of the material sampled does not make much sense, since recovery may not be possible.

As to the sampling technique, sampling tools that are normally used for hard-rock minerals or coal are simply not adaptable to most placer deposits. What is needed is a sampling tool that extracts a sample large enough to be processed to determine what is recoverable and to assay that which is recoverable.

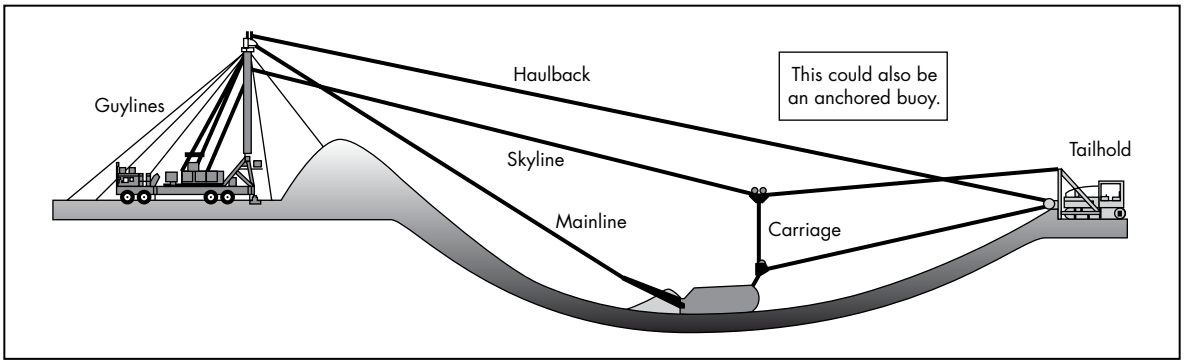
The many methods of extracting samples from a placer deposit vary from being highly prone to error to fairly accurate. They are

- Hand grab samples gathered from existing terrain,
- Hand-dug pits or trenches,
- Backhoe trenches,
- Bulldozer trenches,
- Churn drill holes,
- Auger drill holes,
- Reverse-circulation drilling,
- Vibratory drilling,
- Other types of drills that case and capture the entire sample within the hole, and
- Large-area bulk sampling.

One method of capturing a large sample for bulk sampling and still cover a wide area of a deposit is with a drill. Between 1979 and 1984, a subsidiary of St. Joe Minerals Corporation (Missouri, United States) combined a measuring hopper, a portable jig plant, and the drilling of large bulk samples for sample testing. The jig concentrate was panned and amalgamated to recover the gold. This system was used to prospect 28 holes in the tertiary gravels of the San Juan gold property of the North Columbia area of California. The drill first sank a 915-mm (36-in.) casing and used a cactus-grab bucket to muck out the sample. Where the gravels were cemented, they had to be broken with a chopping bit. The advantage of the total system was that it minimized the possibility of unintentional salting, and it only sampled and assayed that which could be recovered by the pilot processing.

If the gravels are re-cemented, it is also possible that a diamond drill can be used. One such case was reported (Stone et al. 1988) in which a 100 $\times$ 140 mm (4 $\times$ 5.5 in.) diamond drill bit was used very successfully on the cemented gravels described previously.

The problem with the majority of the drilling methods is that a typical alluvial placer deposit contains boulders that are too large to be broken down on the surface by a drill bit or auger flights. This is why for most placer deposits, a bulk sample extracted with mining tools that can handle the boulders is more accurate. However, for a desert placer deposit that is likely to have only a few boulders, an auger drill is the best option. Another problem with drilling holes for the sample is that unless the hole is cased, or unless the deposit is a cemented conglomerate, caving of the hole will occur. If the sampling horizon passed a high-grade lens, the samples below this lens are likely to be unintentionally salted. The resulting sample values will be elevated and thus inaccurate.



Probably the biggest problem is trying to sample the highly erratic nature of the precious-metal placer deposits. It will take many holes over a large area to statistically even out the nugget effect, which often occurs. In fact, with enough drilling and sampling, the outliers should be discarded from the sample collection.

Bulk Sampling Advantages and Disadvantages

The advantages of bulk sampling include a good view of the gravel in place and knowledge of the amount of force required to excavate it. Some of the same digging machines used in bulk sampling are used in production. The large samples obtained minimize the nugget effect and errors. On the other hand, a serious disadvantage is the fact that pits or trenches may not reach bedrock in all cases. Other disadvantages include the following. Curves often make it difficult to accurately measure a pit if the excavation is by a backhoe, because of sloughing from the sides. If groundwater is encountered, sample integrity is lost. Larger samples require larger transport and processing equipment, and the situation becomes more complicated. As unit costs of each sample are high, the exploration cost to delineate reserves is very expensive (Cope and Rice 1992).

Drill Sampling Advantages and Disadvantages

Historically, drilling has been the sample method of choice and has been proven by operation in most cases. Drilling gives greater coverage than bulk sampling in developing gravel grade and reserves at less unit cost, the profile of bedrock, and indications of enriched and barren areas. A disadvantage of drilling is that it gives a small sample, which aggravates the nugget effect. Other disadvantages are that at times boulders

Courtesy of Ramsey Company, Inc.

Figure 11.2-2 Sand or gravel being mined by Ramsey scraper bucket

will necessitate abandonment of uncompleted drill holes, vibration from driving casing or from a reverse-circulation hammer drill may cause gold to migrate downward into the gravel, and drill rigs require at least minimal access roads and drill pads (Cope and Rice 1992).

Other Mining Methods

Although the most common method of large-scale mining of placers is by dredging, several other methods of placer mining have been used over the years, and they are discussed in this section.

Drift Mining

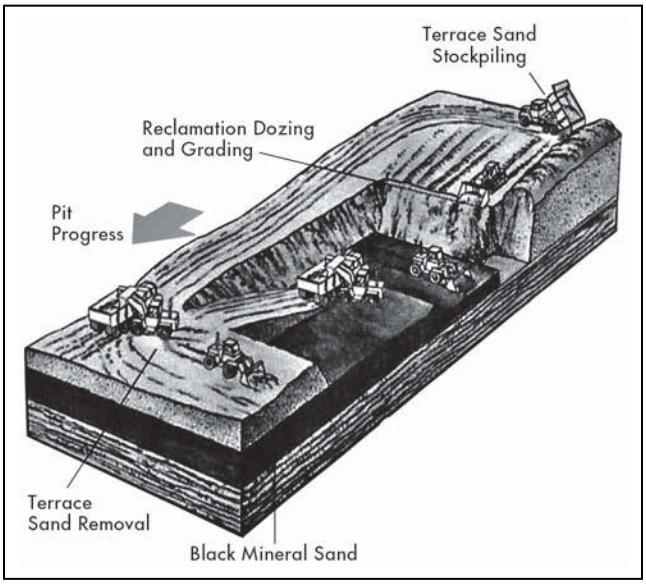
Frequently, the precious metals of a placer deposit are located in relatively thin lenses on or very close to bedrock or some other impervious material, and they may be covered by many feet of worthless gravels and debris. The economic value does not warrant the removal of all of the overburden; in such cases, if the mineral is above the valley floor, adits may be driven into the hillside and the high-grade placer mineral extracted by drifting wherever the deposit exists. Usually, these adits or drifts must be timbered to maintain stability. Occasionally, the rock has re-cemented itself into a conglomerate and drifting could take place without timbering. Typical deposits that have been mined extensively for both gold and platinum are remnants of ancient channels now above groundwater in California, British Columbia (Canada), and Alaska; frozen stream-valley and bench-type placers in the Yukon (Canada) and Alaska; and deep lead deposits in gutters in the bedrock below the groundwater table in southwestern Australia and British Columbia (Daily 1973).

Conventional Equipment for Dry Unconsolidated Placers

The term *conventional equipment* refers to the same type of equipment that is used in various types of standard earth moving in surface or open-pit mines. It includes

- Front-end loaders and trucks;
- Tread-mounted power shovels or hydraulic excavators and trucks;
- Bucket-wheel excavators and trucks;
- Draglines combined with some other materials-moving system;
- Diesel-powered scrapers, which are excellent for large-area and desert placer deposits; and
- Bulldozers and a truck-loading chinaman chute (a colloquial term for a loading ramp that carries material to a truck parked below it).

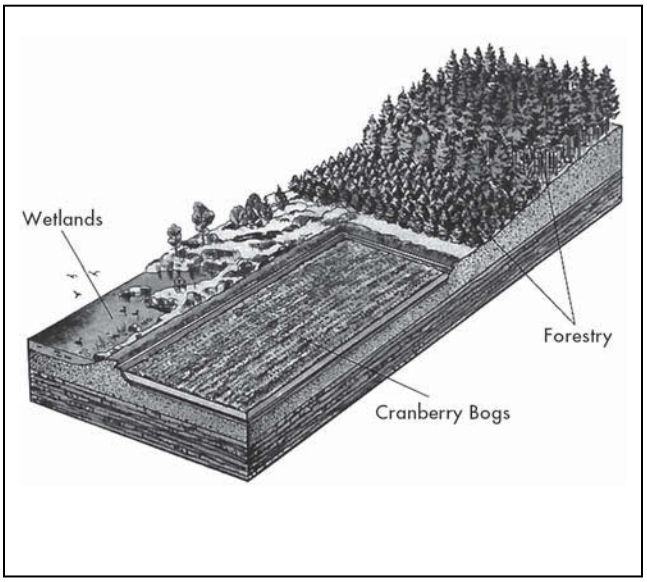
Also included are various types of wire rope scrapers (tuggers), which move loose material by bucket to a truck- or hopper-loading system. These systems having curved-type buckets are used for mining diamond placers off the coast of West Africa. Another example of a scraper that can be used in deep water is the Ramsey bucket, shown in Figure 11.2-2.



It is unnecessary to describe the many combinations of mining sequence for each of these pieces of equipment, since their use is current practice in hundreds of sand-and-gravel, quarry, and open-pit operations around the world. However, how to mine the placer and reclaim it at the same time is worth at least one example.

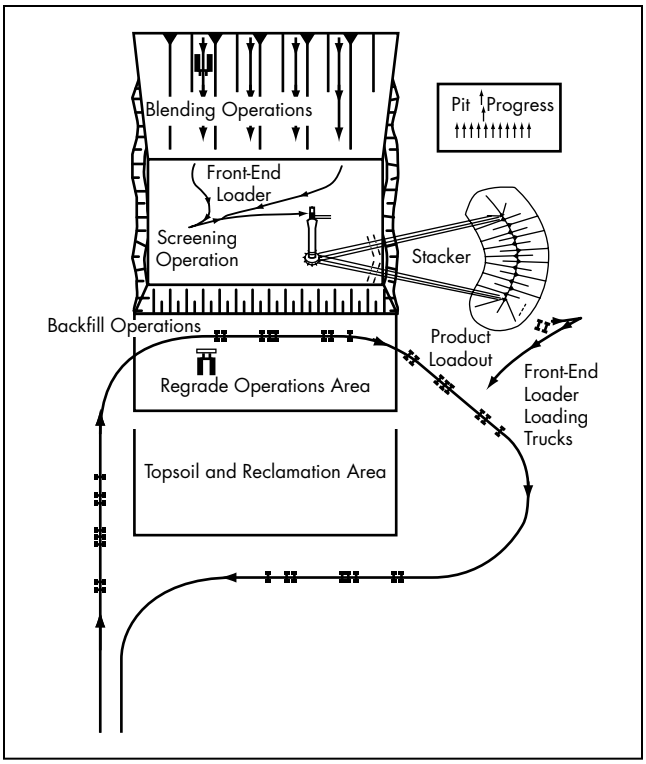
At the Oregon Resources Corporation Coos Bay mine, the material to be mined is a series of deposits of dry black sands containing commercial chromite, zircon, and garnets located on ancient beach terraces. In some ways, the mining will be more like a sand-and-gravel operation than an open-pit mine. Two mining systems were proposed (Figures 11.2-3 and 11.2-4), both ending in reclaiming the strip as shown in Figure 11.2-5.

After the small amount of waste overburden (averaging only 6 m [20 ft]) is removed, the mining method is simple front-end-loader/dozer, truck-operation strip mining. The process is similar to coal strip mining in the Midwestern United States, but on a much smaller scale. That is, they immediately mine and reclaim a series of parallel pits across the deposit. After the stripping has taken place for that pit for a length of 91 to 122 m (300 to 400 ft), the mining can commence. Most of the pits are not level, and they will be worked from the lower elevation upgrade.



The mining is a simple process of bulldozing the black sands down a slope to the pit bottom, where a front-end loader loads the material to a portable scalping-screening plant hopper, which removes the deleterious materials and transfers the heavy mineral sands to a stockpile. From the stockpile, the material is loaded into bottom-dump trucks and hauled to the plant in Coos Bay, approximately 33 km (20 mi) away. When developed, the mine is expected to produce an annual average of 977,810 t/yr (metric tons per year) (1,077,840 stpy [short tons per year]) for the first 8 years and an average of 850,000 t/yr (936,935 stpy) for at least the next 12 years.

The trucks returning from the plant carry cleaned and dewatered sand from which the ore has been extracted. This



Source: Smith 2008.

Figure 11.2-4 Mining with dozers and front-end wheel loaders with reclamation being accomplished concurrently

is dumped at the edge of the pit, and a dozer pushes the material into the pit and fills it. The backfill pace keeps up with the mining extraction, so that no more than about 30 m (100 ft) of pit bottom is ever exposed. The disturbed swell of the material being brought back will fill the pit within about 81% of the original elevation.

The dozed backfill is then graded to the approximate contour of the original ground or is restored to a contour requested by the landowner to be reclaimed or to satisfy environmental regulations.

Frozen Placers

Mining the frozen placers of the earth's Arctic regions poses special problems. The following summarizes the problems connected with the mining of frozen placers (McLean et al. 1992):

> Practically all the auriferous gravel deposit north of the Alaska Range in Yukon and Alaska were frozen and had to be thawed for mining by all methods other than hydraulicking (Daily 1973). Gravel deposits to about 15 ft (5 m) in depth often could be thawed by solar action after removal of all vegetation and muck. The early drift miners used wood fires to sink shafts, and steam was delivered to pipe points driven into the face of drifts. During earlier years, ground was thawed for dredging by the use of steam introduced through pipes driven into the ground, which was inefficient and expensive. The fact that frozen gravel could be thawed best with cold water was discovered in 1918–1920, and that method was developed to a high level of efficiency as a result of research of the United States Smelting, Refining and Mining Co. The method consist of delivering water at ambient temperature, under low natural or pump pressure, through special pipe points either driven into the ground to bedrock or set in predrilled holes. Water temperature was seldom over 50°F (10°C). Flow was continued until the ground was thawed, which required six weeks [for] two or more seasons, depending on the depth of ground and character of deposit.
>
> The total volume of ground thawed with cold water at the three major properties in Alaska and

> Yukon from 1924 until termination in 1964 was more than 360 million yd^3 (330 million m^3). Average water duty was approximately 11 yd^3 (10 m^3) per MID (miner's-inch-day) of water (1 MID = 1.5 cfm per 24 hours). Average rate of thaw in stream gravel to depths of about 45 ft (14 m), using ¾-in.- (19-mm-) diameter pipe points driven in an equilateral triangle spacing of 16 ft (4.9 m), was 1½ days of water under pressure.

In the mid-1970s, the University of Alaska performed a research project demonstrating that drifts could be driven through frozen ground using drilling and blasting techniques. Likewise, frozen fractured rock is often drilled and blasted in mine sites like Polaris on Little Cornwallis Island near the North Pole.

Hydraulic Mining of Placers

The term *hydraulicking* as applied to placer mining describes the excavation of gravel banks by streams of water under pressure from nozzles. Thrush (1968) defines it as follows:

> The process by which a bank of gold-bearing earth and rock is excavated by a jet of water, discharged through the converging nozzle of a pipe under a great pressure, the earth of debris being carried away by the same water, through sluices, and discharged on lower levels into the natural streams and watercourses below.

This practice was at one time (the late 1870s through 1984) a very efficient manner by which to mine the auriferous (gold-bearing) gravels in northern California, Alaska, and the Yukon. These early mining techniques brought about the first antimining environmental laws in the United States (the 1884 Sawyer decision), which prohibited any further discharge of waste material into the Sacramento and San Joaquin rivers. The mining method that was applied—well documented in Peele (1945)—has few applications in "enlightened" countries with environmentally restrictive regulations. However, hydraulic mining is also applied to nonplacer mining, namely coal and tailing reprocessing, neither of which is covered in this chapter.

Subgrade Hydraulic Mining

Places in Thailand and Malaysia for many years were mined by subgrade hydraulic mining (Daily 1973). The following conditions favor this type of mining:

- Many deposits of limited areal extent exist that are unsuitable for mining with dredges.
- An abundance of clay is pulped satisfactorily by water action.
- Extremely irregular limestone bedrock has deep channels in many places, which become exposed in the bottom of the pit.
- High-grade concentrations of mineral are often present in recesses in the top of the bedrock, which can be cleaned effectively only by handwork.
- Water is available in sufficient quantity during all or most of the year.
- Electric power is available at a reasonable rate.

Table 11.2-1 Estimated cost for dryland placer mining (2009 U.S. dollars)*

	Stripping Ratio			
Daily Production	**1:1**	**2:1**	**4:1**	**6:1**
Per metric ton of ore				
500	6.40	7.70	10.55	13.25
1,000	6.00	6.65	7.20	7.85
2,000	5.60	6.10	6.75	7.30
Per short ton of ore				
500	5.80	7.00	9.55	12.00
1,000	5.45	5.95	6.55	7.10
2,000	5.10	5.55	6.15	6.60

*Estimate includes wages/benefits, operation of equipment, fuel, power, and supplies. It covers stripping, mining, waste replacement, and minimum reclamation. Long haulage is not included. It does not include processing except for a scalping screen on-site. Assumes 1,672 kg/m^3 (104 lb/yd^3) material.

- Space is available for slime-settling ponds sufficient to permit compliance with regulations.
- An adequate supply of labor at acceptable cost is available; many operations are conducted by a type of cooperative or family organization.
- Security can be provided. Security is a constant problem, especially protection from roving individuals or groups at night.

Estimated Placer Mining Cost

The average cost of a timbered drift in consolidated ground is estimated to range from approximately \$219 to \$390/m^3 (\$6 to \$11/ft^3), depending on the size of the drift.

Table 11.2-1 shows the range of mining costs using wheeled front-end loaders or hydraulic shovels, bulldozers, and trucks to mine a dry placer deposit above the water table in mild terrain and in a location where the weather allows work year-round. The cost also includes in-pit scalping or screening but not mineral concentrating. The accuracy is no better than ±30%–40%.

PLACER MINING BY USE OF DREDGES

Placer mining is the removal of alluvial material of economic value. Traditional placers were gold deposits found in active or paleo and buried river courses. More recently, the term has come to include alluvial deposits containing economic values of gold, platinum, or silver (rare); heavy minerals of tin, titanium, rare earths, or iron; diamonds; and commercial aggregates. These deposits may be concentrated beneath an overburden of alluvial material some hundreds of meters thick, or they may be disseminated throughout the material or exposed on or near the surface. They may be in small concentrations or cover very large areas, and they may be deep beneath the oceans. The mining of unconsolidated materials such as manganese nodules and metalliferous muds from the deep oceans will be touched on only briefly.

Dredging is the recovery of mined materials from under water. The two basic types of dredge, mechanical and hydraulic, are distinguished by the method used to lift the material to the surface. Many variations and combinations of these types are available. The final selection of a dredge for a mineral deposit, however, is based on many factors

including, but not limited to, the natural and social environments in which the deposit is located, the characteristics and current value of the deposit, the depth of the water, transportation distance, the efficiency of recovery, and the cost of the dredging system.

The decision to dredge or use other means of excavation depends on factors relating to the presence or availability of water and the characteristics and tenor of the deposit. With rare exceptions the dredge is used only in alluvial material, and the type of dredge chosen may be strongly influenced by the presence or absence of coarse materials, boulders, or other obstructions. Mining dredges for gold and heavy minerals are generally self-contained; the concentration plant is an integral part of the dredge or floats in close proximity. When there is a considerable overburden and little water, dry excavation employing large bulldozers, scrapers, or draglines may initially be used to remove the overburden and expose the ore, much like strip mining for coal. Offshore the depth of water may be paramount, but the nature of the deposit may call for specially designed systems for the platform and for excavation and recovery of the minerals.

Preparations and Planning the Dredging Operations

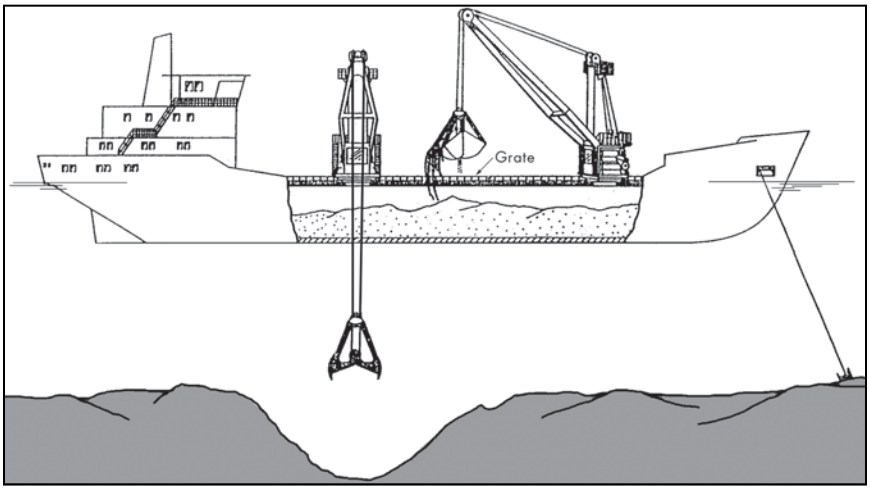
Dredging preparation begins with accurate evaluation of the area by sampling on an appropriate grid and preparing a three-dimensional representation of the deposit. Reverse-circulation or churn drills suitable for sampling are normally used. More modern methods of downhole sensors are sometimes employed. In lacustrine or coastal areas, continuous surveys with seismic or acoustic penetration may be preferentially used to develop the dimensions of the deposit in place and to select appropriate sites for drilling. The grade of the ore and characteristics of the deposit determined from the sampling data are used to select a dredge of the appropriate type and capacity.

The initial placement of large mineral dredges on land may typically involve the excavation of a pit in which the dredge is constructed. On completion, the pit is flooded and the dredging proceeds according to plan. In offshore or coastal areas, dredges may be towed directly to the site, but many more modern dredges have ship-type hulls and are self-propelled.

Crew sizes will vary considerably depending on the size and type of dredge and the social environment in which the deposit is located. The offshore tin recovery bucket ladder dredges in Indonesia typically had crews of 80 or more. Modern dredges are more automated but each shift needs a dredgemaster, an engineer, surface crews to maintain the control lines, and mechanical crews to conduct constant maintenance on all moving parts. Including shore, office, and transportation crew, the operation usually employs about 70 during the dredging season and 30–50 during the winter months. Fully automated systems require fewer personnel on-site (Garnett 1999a).

Dredge Location and Grade Control

Mining and grade control are determined from the sampling data. The sampling data will be treated in the same way in lakes as on land, although it may be necessary to adapt the sampling equipment to the environment. In northern latitudes, drilling may be carried out from an ice cover during the winter. Control in ocean beach environments is difficult, particularly where heavy surf or high tides are prevalent, and draglines may be used to mine in bulk without regard to whether the recovered material is high or low. In other situations, notably the diamond operations in southwestern Africa, the ocean may be held back by specially constructed massive berms or dikes so deposits can be worked in the dry.



Sampling equipment varies considerably in its methodology and cost. The more valuable the economic material, the more accurate and difficult the sampling will be. Sampling of beach sand may require only a determination of the depth of the sand to bedrock. Sampling of alluvial gold deposits requires extreme accuracy because of the value of the grains, and a "rich" deposit may contain only a few parts per million of gold. Because the specific gravity of gold is approximately 19, the strong tendency of gold grains is to migrate to or away from the sampling device when it penetrates and disturbs the ground. This effect can create significant sampling errors. An alluvial diamond deposit may contain only one part per billion of diamonds; these areas are generally sampled by very large bulk samplers that may be prototypes of the proposed mining device (Garnett 1999b).

An important aspect of determining the efficiency of the dredging operation is the R/E factor, a measure of actual recovery divided by the recovery estimated from the sampling data. This number may vary between 0.5 and 2.5 depending on the accuracy of reserve estimation and the recovery of the gold by the dredge and in the beneficiation process. A factor of 1.04 was recorded by the Alaska Gold Company, averaged over a period of 4 years (Garnett 1991).

Natural Hazards, Waste Disposal, and Environmental Controls

Natural hazards in minerals dredging may include severe winter conditions in Arctic environments, the inclusion of large boulders in river gravels, buried trees in tropical areas, or deeply gullied bedrock in other areas. The overcoming of these problems may be expensive and must be factored in to the unit costs of the operations. In the Arctic, it may be possible to keep a dredge pond open by sawing the ice and removing it from around the dredge, but more often the dredge may be put on a maintenance basis during the winter months. If large boulders are present, the dredgemaster may be required to mine around them, thus losing time and pay dirt, or it may be possible to lift them out of the way. Some large bucket-ladder dredges have such a capability. Buried trees, commonly found in the tin fields of Southeast Asia, may be circumvented in similar fashion. The problem with gullied bedrock can be quite severe if the rock is too hard to disintegrate with the dredge. In the diamond placers on the southwest African coast, massive berms have been built to keep out the sea, and the overburden and surficial waters are completely removed. The gullies where many of the diamonds are retained are swept by hand with small brushes. Offshore, new dredge heads have been developed that have the capacity to disintegrate the bedrock incorporating the gullies.

Discharge of tailings from a dredge may be the result of overburden removal, or the separation of the pay dirt from the gangue material. In either case the waste materials may be a significant part of the dredge output, and they must be disposed of in a manner that does not interfere with the recovery of the pay dirt. This may be done by hydraulic or mechanical diversion of the waste to an area normally located behind the dredge. If the mined ground must be restored, the soil cover may be removed separately and stockpiled away from the dredged area for later replacement over the mined area by earthmoving equipment.

Source: MMS 1993.

Figure 11.2-6 Hopper dredge using clamshell for both loading and unloading

Environmental controls may preclude the use of certain areas for tailings disposal because of the runoff from the waste. However, most primary treatment at the dredge site involves only sizing and separation by physical properties such as specific gravity, color, or magnetic susceptibility. Chemicals are rarely added and the environmental problems may not be paramount. However, the issuance of permits is generally a political matter highly influenced by local and subjective feelings and can result in much frustration and delay. Waste-disposal permits must be secured at a very early stage in the planned development process. It should be recognized that all forms of placer mining are extremely cost sensitive. As such, dredging operations cannot withstand imposed expenditures on generic environmental research programs that are geographically located well outside the zone of influence of the dredging operation (MMS 1993).

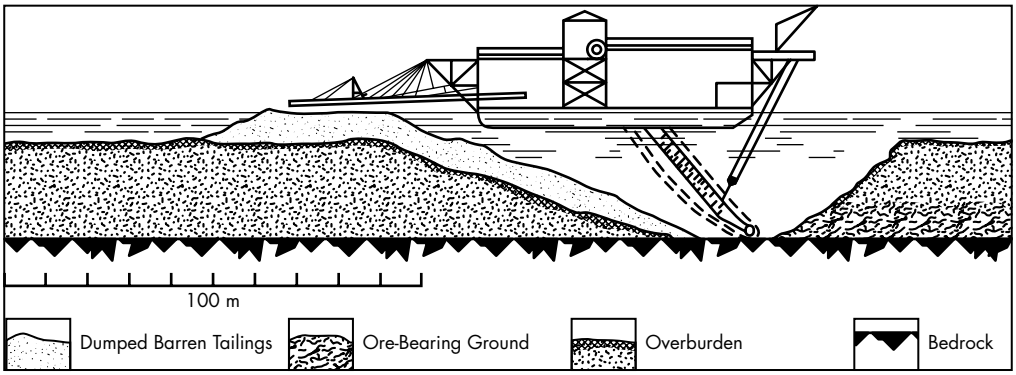
Silting of watercourses can be prevented or lessened by containing and recycling the wastewater using cyclones or other dewatering devices. Containment or settling ponds may also be installed in appropriate areas. Offshore, some hydraulic dredges have used an antiturbidity system that allows the major solids to settle in a holding tank before discharge.

Types of Dredges

Mineral dredges may be generally classified as mechanical or hydraulic, depending on the means of transporting the dredged material from the dredge head to the dredge platform (Duane 1976).

Mechanical Dredges

Mechanical dredges transport the material from the deposit via moving buckets or moving belts. Major types of dredge buckets include the dragline, grab bucket, fixed arm, bucket ladder, bucket wheel, and continuous line.



Dragline. The dragline is a simple excavating bucket attached to a cable on a cranelike ladder structure. The bucket may be drawn back and forth until the required depth is achieved. Excavated materials are swung aside on the crane for dumping. Normally used in the mining of nonmetallics such as phosphates, aggregates, coal, or overburden, the dragline has the advantage of simplicity and comparatively low cost. Bucket size may vary from 0.76 m^3 (1 yd^3) or less to more than 38 m^3 (50 yd^3) for some mega-draglines.

Grab bucket. The grab bucket is commonly used for the mining of aggregates or overburden. The bucket or clamshell is manipulated by a crane-type ladder to dig vertically into the material. The open bucket is dropped onto the material and its two halves automatically close on the load when the bucket is raised and swung to the point of discharge. Normally limited in capacity and depth of excavation because of multiple cables, the grab bucket is, however, frequently used in coastal marine environments for reef coral sands (see Figure 11.2-6.)

Fixed arm. The fixed-arm bucket is a more rigid machine that can dig into a deposit using an upward and forward force applied to a toothed open bucket on the digging arm. It is normally used for dry excavation but has been adapted for underwater use on submersible platforms with the addition of a bucket wheel or a rotating cutter feeding in to a suction line.

Bucket ladder. The bucket ladder, a heavy and sometimes ponderous dredge, has been traditionally and widely used for the mining of gold and tin placers throughout the world. Bucket ladders are generally capable of handling heavy ground containing coarse materials and boulders. On land they may be constructed on a barge in a dry dredge pond that is flooded after construction is completed. Bucket ladders use a continuous rotating loop of heavy steel buckets on the ladder, cutting into the forward face of the pond and discharging into a washing and concentrating plant on the dredge. Waste materials are discharged well behind the dredge from chutes or belt conveyors as the bucket ladder moves forward. The concentrates are gathered onboard and shipped by local means to the smelters on shore.

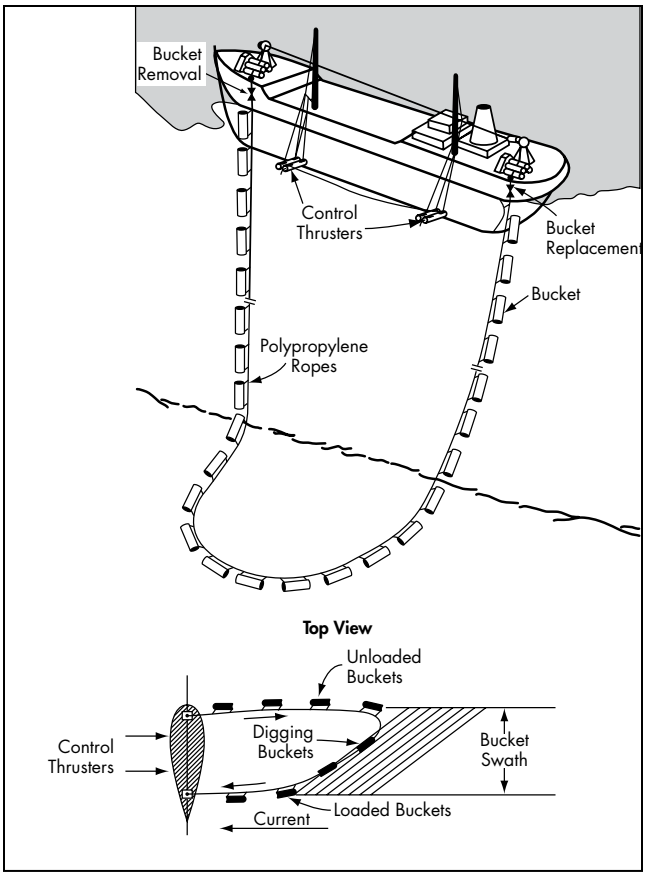
There are two basic types of bucket-ladder dredge. The New Zealand type is moved forward on a headline anchored several hundred meters ahead of the barge and controlled laterally by anchored lines on each side. The more common California or spud type is propelled forward by a walking effect using two widely separated spuds at the stern of the barge and alternately raising and setting them as the ladder is swung from one side of the cut to the other, also using lateral anchored lines (see Figure 11.2-7). Bucket ladders are limited in the depth of cut by the length of the ladder. When

Source: MMS 1993.

Figure 11.2-7 Bucket ladder dredge with head line and anchors for estuarine or offshore operations

the bucket-ladder dredge is used offshore, the barge hull is modified to oceangoing standards, and headlines and multiple anchors are used for control. The dredge may be towed directly to the site, but many of the more modern ones have ship-type hulls and are self-propelled.

Bucket wheel. The bucket-wheel system consists of a rotating wheel with digging buckets on the periphery that discharge into a ladder-mounted belt conveyor or a hydraulic pipeline. The wheels may vary in diameter from a few meters to 10 m (30 ft). The bucket wheel is very adaptable, and with the major advantage of a powerful digging torque, it is now commonly preferred over the heavier and less mobile bucket ladders.

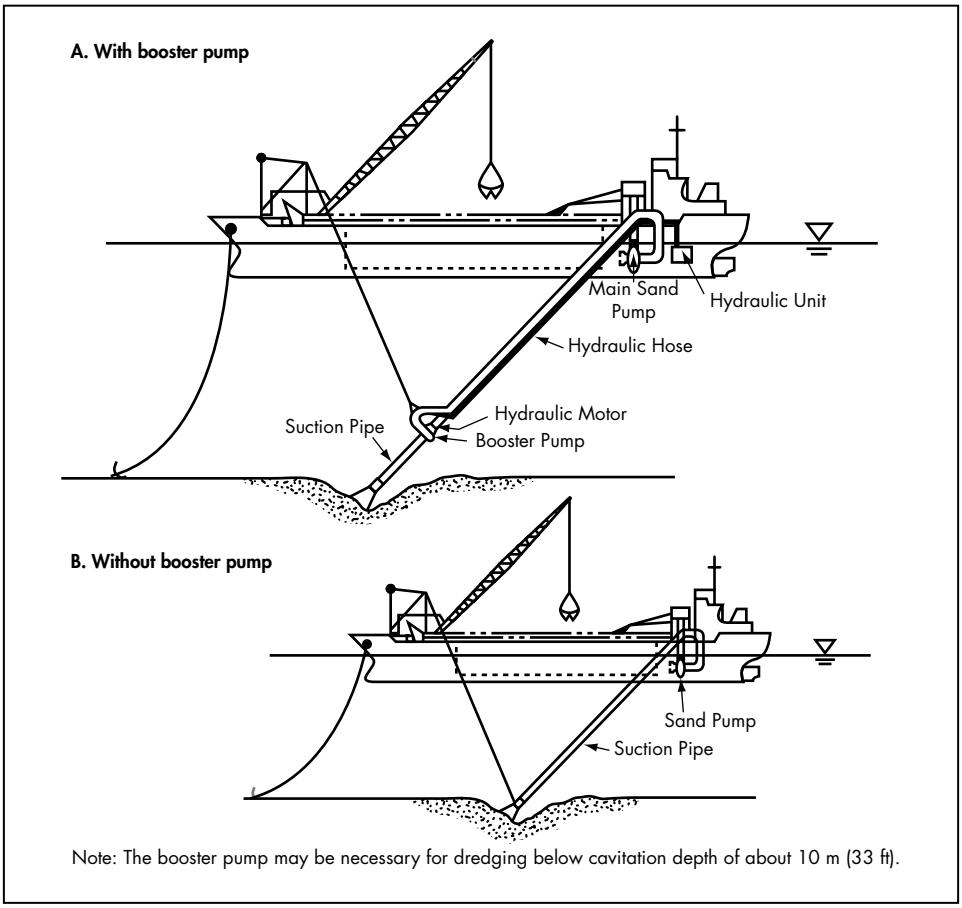


Continuous-line bucket. The continuous-line bucket is based on a system for unloading bulk granular materials from stockpiles or ship cargo holds (Figure 11.2-8). The bucket may be bell shaped or flat and attached to a continuously rotating flexible line. Its advantage when excavating loose materials such as sand is its capability to adapt to water depths. The system has been modified and tested for undersea mining of surficial deposits such as manganese nodules in water depths of 4,000 m (12,000 ft).

Hydraulic Dredges

Hydraulic dredges transport the dredged material from the dredge head to the surface in a slurry through pipes that may form, or be contained in, the dredge ladder. The dredge pump, usually a specially designed solids-handling centrifugal pump, may be on the dredge or submerged on the ladder. Submergence of the pump or addition of a submerged booster pump eliminates cavitation in the suction and may be necessary when the dredging depth exceeds cavitation depth (Figure 11.2-9). In special cases, air lifts or Venturi suction may be used in place of centrifugal pumps. The pump may discharge directly to a hopper, a treatment plant, or a sidecasting device on the dredge or it may be piped to a remote treatment plant or directly (in the case of a beach reclamation) to a fill area.

Variation in Dredge Heads



Straight suction heads are commonly used for removing sands or mud in harbor maintenance or for back-of-the-reef collection of carbonate sands for beach maintenance or cement manufacture. Small diver-operated suction devices are sometimes used for prospecting for river alluvials or in archaeological work for the recovery of artifacts.

Source: MMS 1993.

Figure 11.2-8 Continuous-line bucket dredge tested in 4,000-m (12,000-ft) water depth. Note the bucket swath width controlled by the separation of the lines and the transverse movement of the vessel.

Trailing drag heads are commonly used from seagoing hopper dredges to mine commercial aggregates or for the clearance of river channels for commercial shipping. They are also adaptable for the mining of some seabed surficial mineral deposits such as heavy mineral sands or manganese nodules (Figure 11.2-10). They have a shallow but strong digging capability because of the momentum of the moving vessel.

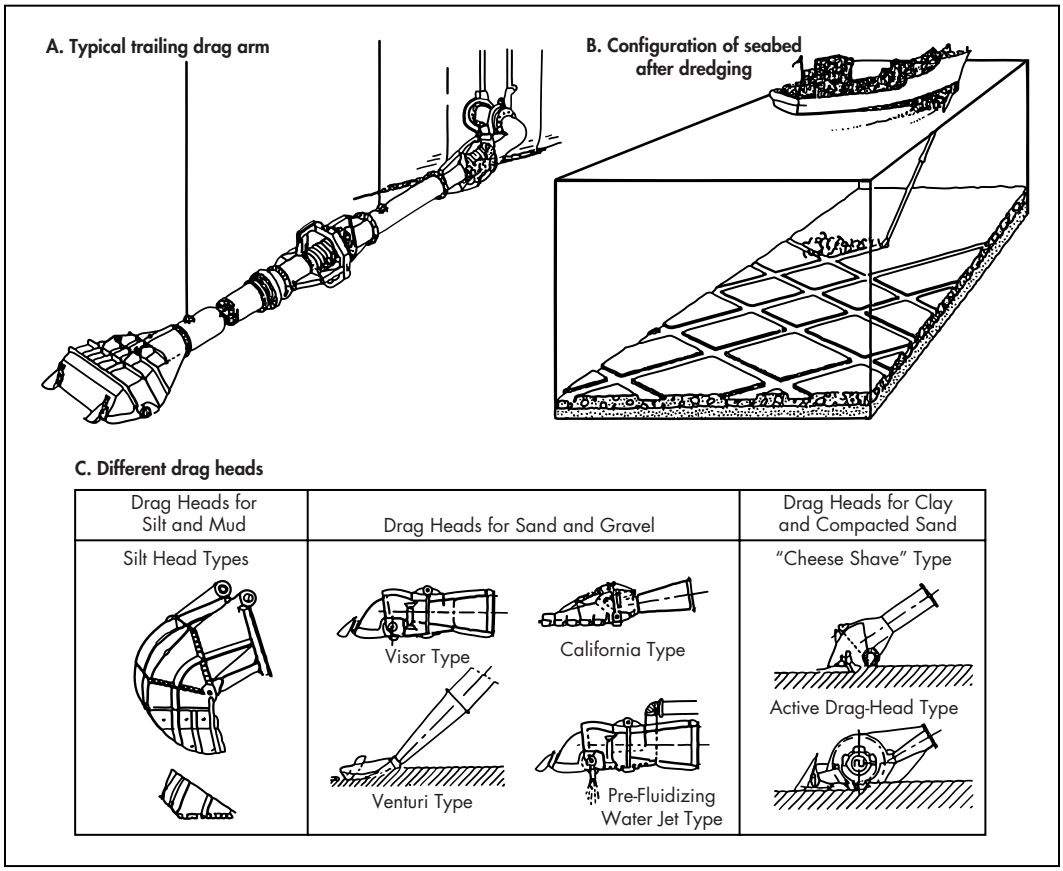
Source: MMS 1993.

Figure 11.2-9 Suction hopper dredges

Rotary-cutterhead dredges are commonly used in heavy ground where considerable energy is required to penetrate the material being mined. The material at the working face may be extensively disturbed, and use of these heads for the recovery of heavy minerals may result in significant losses of pay dirt, particularly if the underlying bedrock is very hard, rough, or gullied (Figure 11.2-11).

Horizontal auger heads are used in soft material that may be passed from a wide cut into the suction pipe opening. They are more often used for maintenance work in harbors than for mining. However, their use has been proposed for the recovery of surficial unconsolidated mineral deposits such as manganese nodules on deep seabeds.

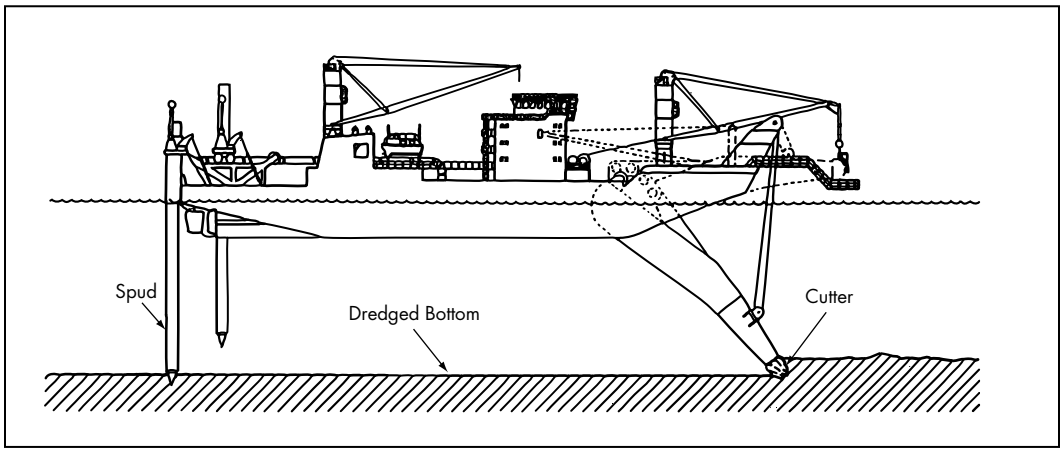
Bucket-wheel cutterheads are a relatively recent innovation that has proven to be ideal for mining dredges. Digging buckets similar to those on a bucket-ladder dredge, but generally smaller, are mounted on the periphery of a rotating wheel attached to the digging end of the ladder. The buckets have tremendous torque and are capable of removing weathered bedrock. They can be designed to discharge directly into a suction pipe or conveyor without spillage of materials. For the mining of precious metals and heavy minerals, the bucket-wheel suction dredge has capabilities similar to those of the bucket-ladder dredge, and they generally cost less to operate. They have also been used in the form of remotely operated vehicles for sampling of gold placers and deepwater marine metalliferous sulfides.



Dredge Manufacturers

Mining dredges of all kinds are manufactured throughout the globe. *Dredgers of the World* (Clarkson Research Services 2009) lists 233 backhoe, dipper, grab, and clamshell dredges; 18 barge-unloading dredges; 53 bucket-ladder dredges; 412 cutterhead suction dredges (including bucket-wheel dredges); 32 types of special equipment including agitation, water-injection, and wormwheel dredges; and 39 suction and 481 trailing suction hopper dredges. The reader should refer to appropriate Web sites such as www.westerndredging.org or www.worlddredging.com for additional information. Manufacturers of pumps are listed on the Internet at www.dredgepumps.com.

Dredging Costs



Costs vary widely depending on many factors, as outlined previously. Economies of scale may provide a significant cost advantage for dredging over many other forms of earth moving and transportation (Correia 2005).

Other data have been presented by Garnett (1999a, 1999b) for gold placers and diamonds. These include costs of $\$1.10/m^3$ ($\$0.87/yd^3$) for Indonesian bucket-ladder tin dredges offshore and $\$7.00/m^3$ ($\$5.51/yd^3$) for gold dredging offshore in Nome, Alaska. The latter cost was similar for an experimental remote-controlled underwater miner bucket-wheel excavator with a higher R/E factor. Offshore diamond recovery in Southern Africa was reported in the same sources to be

Source: MMS 1993.

Figure 11.2-10 Trailing suction hopper dredge and various configurations of drag head

Source: MMS 1993.

Figure 11.2-11 Cutterhead suction dredge with rigid boom and spuds (cutterhead could be replaced by a bucket-wheel cutter)

about \$1/m^3 (\$0.79/yd^3) in the ore stratum and \$1.25–\$1.50/m^3 (\$0.98–\$1.18/yd^3) in the overburden. In the same location, costs for the underwater miner (Namsol) were reported to be \$10–\$20/m^3 (\$7.87–\$15.75/yd^3).

Recent costs for beach replenishment sands from immediately offshore at Waikiki Beach in Hawaii (United States) in 2007 were stated to be about 59/m^3 (47/yd^3) using barge-mounted flexible-line submersible pumps piped directly to shore.

The average costs for all dredging carried out by the U.S. Army Corps of Engineers for 2008 ranged from \$3.00 to \$17.85/m^3 (\$2.37 to \$14.06/yd^3), more than doubling their reported costs since 2000.

Obviously, dredging costs are highly variable, and extreme care should be taken in preparing cost estimates for any future operations.

Future of the Dredging Industry

The technology for placer mining on land will continue to improve as new materials and automation are applied to earth moving in general. This will bring down costs and improve the capability to work sustainably within the natural and social environments involved. The worldwide demand for heavy minerals is increasing, and operations are prevalent in newly industrializing countries such as India, People's Republic of China, and Mongolia (Yernberg 2006).

An even brighter future is likely to be associated with the deeper waters of the world's oceans, where applicable technology from other industries is already being applied. Placer diamond mining off the coast of southwestern Africa was instigated in the early 1960s (Cruickshank et al. 1968) and has since been developed into a significant industry involving several companies and countries. See also www.diamondfields.com/s/Namibia.asp and www.theartofdredging.com/peaceinafrica.htm.

In July 2008, Neptune Minerals (www.neptuneminerals.com), a leading explorer and developer of seafloor massive sulfide (SMS) deposits, lodged its first mining license application over the Rumble II West seamount within the exclusive economic zone (EEZ) of New Zealand. The application represented a key milestone in that company's progress toward commercialization and pilot mining by 2010. Neptune also successfully received prequalification proposals for its first seafloor mining contract. Leading international dredging and subsea engineering companies were invited to undertake a build-own-operate contract mining system for the commercial development of the deposits.

Nautilus Minerals, Inc. (www.nautilusminerals.com), has reported that the company was following the lead of the oil and gas industry to tap into the vast marine resources in deep waters offshore. Nautilus was the first company to commercially explore for deposits of SMSs and potential sources of high-grade copper, gold, zinc, and silver in water depths of approximately 2,000 m (6,000 ft). Its initial project, Solwara 1, under development in the archipelagic waters of Papua New Guinea (PNG), utilizes technologies from the offshore oil and gas, mining, and dredging industries, as well as current technologies from marine scientific exploration and positioning. In December 2009, the company reported eight new discoveries in the area, secure port capacity for its operations at Rabaul, and the grant of an environmental permit from PNG authorities. Farther afield, high-grade SMS systems were discovered during a Tongan exploration cruise. Long-term plans include an increase in tenement licenses and exploration applications in the EEZs and territorial waters of PNG, Fiji, Tonga, the Solomon Islands, and New Zealand.

Commercial dredging for deep-seabed nodules, crusts, or other mineral deposits has not yet been carried out in the United Nations area beyond the EEZs. Significant research has been conducted, however, on the potential technology available for their mining at water depths from 3,000 to 5,000 m (9,843 to 16,404 ft) and for the environmental sustainability of proposed operations. Extensive documentation may be accessed at the headquarters of the International Seabed Authority in Jamaica at www.isa.org.jm/en/home.

The future of placer mining by dredging is obviously changing and matching the global needs of the 21st century. Many other useful data may be accessed at www.OneMine.org.

PLACER MINING PROCESSING

When placer ores are mined, they must be upgraded to produce salable product(s) by either a wet or dry process. This section describes the most common upgrading processes and equipment. A heavy mineral sands example shows how processes can be combined.

Placer Ore Beneficiation Methods

Wet Versus Dry Beneficiation

Beneficiation of placer ores generally involves wet processing, with further downstream dry processing necessary for certain mineral assemblages and markets. A majority of the deposits (i.e., tin, phosphate, precious metals) can be upgraded purely by wet processes, but ilmenite, rutile, zircon, and other minerals found in heavy mineral sand deposits almost always require some sort of dry processing.

When compared with dry processing methods, wet processing offers the benefit of easy ore movement (pumping versus dry conveyance) and typically cheaper operating/maintenance costs (per ton treated or transported). For these reasons, combined with the common placer mining method of dredging, wet processing is used at the beginning of placer ore beneficiation flow sheets. The wet separation equipment may not always achieve the product grade and recoveries that are needed. In these instances, dry processing can be used.

In dry systems, the circuit always includes a dryer, which can require an equivalent of 8+ L/t (2+ gal/st) of diesel fuel per metric ton dried. The cost of drying, almost entirely made up of fuel costs, only allows further downstream equipment to achieve the desired separation. Drying does not increase the value of the ore itself and should always be minimized. When dry processing is required, a cost reduction may be obtained if it is preceded by a partial upgrade of the ore by wet processes. The partial upgrading will reduce the amount of material that must be dried and can drastically reduce drying costs. This process is decidedly different than minerals processing that requires flotation, in which the drying that takes place is primarily to meet customer specifications or reduce shipping weight of the concentrate.

Even when wet processing equipment obtains acceptable grades and recoveries, dry processing equipment may be able to achieve higher grades and recoveries. To determine if dry processing is required, lab testing should be performed. Each upgrading process has advantages and disadvantages, and specific mineral assemblage separations can only be determined by testing. The benefits and drawbacks of each type of processing must be weighed in full before a processing flow sheet can be finalized. The performance of the equipment and the overall capital and operating costs of the circuit should also be taken into consideration.

Sizing

Unlike most mineral processing, in which comminution is required to achieve a specific liberation size, particles generally have already been liberated by the time placer deposits are being processed. However, a wide range of particle sizes, from rocks (centimeters/inches in diameter) to clay (microns in diameter), must be properly handled. Trommel screens are used to remove the large waste rock and organic matter and are a last place to break up or remove large clay conglomerates. Cyclones are commonly used to deslime (remove clays and ultrafines) and remove the fine fraction of the ore that cannot be economically upgraded.

The nature of placer deposits may make it necessary to remove clay coatings on the minerals to allow proper separation and improve grade. These coatings are not typically seen in hard-rock operations in which comminution has been used to reach the liberation size. To clean the particle surface, attrition scrubbers are used. These scrubbers mix the slurry at high percent solids, which results in multiple particle–particle collisions. These collisions remove the softer surface coating of clay, which can then be easily washed away.

Vibrating screens are also used to either remove uneconomic size ranges of the ore or to separate the feed into multiple size fractions that can be upgraded using separate circuits. The resulting tighter size range will increase the separation efficiency of physical separation equipment since the size effect of the particles does not come into play as much. Generally wet screens are used on the higher-tonnage initial feed portions of the circuit, whereas dry screens can be found in later portions of the flow sheet or on final product sizing.

Hydraulic classifiers can also be used to size material. They can achieve excellent size separation given a mono-density feed, and they offer the benefits of high throughput, low operating cost, and very low maintenance cost when compared with wet vibratory screens.

Gravity Separation

In general, the greatest upgrading in placer ore beneficiation occurs with spirals. They are typically the first separation devices that the ore encounters after the initial sizing operations. The ore must be sized prior to spiral feeding, with oversize and slimes removed. Particles outside of a separable size range (that varies from mineral to mineral) do not separate well on spirals and can even hinder the separation of particles of more acceptable size. Initial wet concentrator spiral plants are generally installed on a barge that trails the mining dredge. Having the concentrator in the mining area reduces transportation cost of the raw ore and tailings.

In addition to their use as sizing devices, hydraulic classifiers can also be used as density separators. Denser particles report to the underflow and lighter particles report to the overflow. Because hydraulic classifiers combine density and sizing separations, coarser light particles may be misplaced to the underflow while finer heavy particles report to the overflow. To remedy the problem that this poses, both the underflow and overflow can report to separate spiral circuits. The misplaced coarse lights and fine heavies, the result of processing by the hydraulic classifier, must be separated from their respective streams, and feed that has undergone the sizing process lends itself to easier spiral separation than a raw mixed feed would allow (Benson 2005). Because of this phenomenon, newer flow sheets are incorporating hydraulic classifiers into spiral plants at the beginning and middle of a spiral circuit, whereas they traditionally were incorporated at the end (Elder et al. 2001).

Centrifugal jigs are another common gravity separator for placer ore. These enhanced gravity separators use a ragging material that can be varied to change the apparent specific gravity of the separating medium. Both product and tailings streams are screened to remove the ragging material, which can then be recycled. The adjustability of the apparent specific gravity of the separating medium and the centrifugal action of the jig allow for efficient separations. The drawbacks to these separators include the cost of the ragging material and the high maintenance required for the enhanced-gravity portion of the separator compared with other common placer ore gravity separators. Maintenance can include daily (or more frequent) shutdown and cleaning, and yearly rebuilds that can be costly and incur extensive downtime. Typically, centrifugal jigs are used in difficult specific gravity separations to recover higher-valued minerals. For example, they can be used in a scavenger stage of zircon wet gravity circuits.

Wet shaking tables can still be found in placer ore beneficiation, generally where near-specific-gravity separations are required at low throughputs. They provide excellent gravity separations but do have big drawbacks such as low feed rates and large size. Because of these drawbacks, wet tables are typically only used for higher-priced products (e.g., gold and zircon) that have already been at least partially concentrated. Their low feed rate (0.5–2 t/h [0.55–2.2 stph] per industrial-size table) and capital and operating expense must be economically justified before introduction into a flow sheet.

Magnetic Separation

Magnetic processing can be done both wet or dry, and so it lends itself to all aspects of a placer deposit flow sheet. In wet magnetic processing, a low-intensity magnetic separator (LIMS) is used to remove magnetite or other ferromagnetic minerals. In most placer deposits, the magnetite is usually a tailings stream, but in the case of iron sands, it can be a product. In general, medium-intensity wet magnets are not used for placer deposits. However, wet high-intensity magnetic separators (WHIMSs) are widely used. They offer the advantage of high throughput and wet processing (coinciding with the common wet mining methods), and they excel when used at the beginning of circuits where product grades are easy to achieve or extra tailings can be removed prior to drying, resulting in cost savings. As an example, in a typical ilmenite/rutile/zircon deposit, a WHIMS can be used to remove ilmenite that does not meet grade (e.g., low percentage of TiO_2).

Dry magnets have ranges of field intensities similar to those of wet magnets, and they are used to remove similar minerals. Some common dry magnets used in placer beneficiation include the rare earth drum (RED), induced-roll magnet (IRM), and rare earth roll (RER). REDs are medium-intensity dry magnetic separators and are commonly used to remove, as product or tails, more highly paramagnetic minerals such as ilmenite. Higher-strength dry magnets are available as both permanent rare-earth magnets, which are found within RERs, and electromagnets, which are used for IRMs; each has its advantages and disadvantages (Dobbins and Sherrell 2009). The higher-strength magnets are typically used to remove the middle to weakly paramagnetic minerals such as staurolite and leucoxene or to reduce the final $\%Fe_2O_3$ grade of a non-magnetic product (e.g., zircon).

In general, wet magnets are a little less selective than dry because the liquid medium adds a restrictive drag force. On the other hand, dry magnets are not as tolerant of fine material and generally can only effectively treat down to 75 μm, whereas wet magnets routinely treat material finer than –45 μm (although that fine size is not very common in placer ore deposits).

In placer deposits where iron-bearing minerals are present, magnetite can be found. If enough ferromagnetic material is fed to higher-strength magnets, the ferromags cannot be effectively released, and wearing of shells and belts or plugging of matrices become issues. In these instances, low-intensity magnets can be used as scalpers for both wet and dry processes.

Electrostatic Separation

The typical separation equipment that coincides with the dry magnetic separators are the electrostatic separators. These can be found before (standard for heavy mineral sands) or after the magnets in placer ore beneficiation plants. They are mostly found in heavy mineral sand separation plants where the added physical property of conductivity is used to separate and upgrade the various products. Because the surface conductivity is so important for this type of separation, mineral surfaces must be clean (see information about attrition scrubbers previously in the "Sizing" section). All electrostatic separators either require minerals to be heated for a separation to occur or separate more effectively when minerals are heated. Some minerals, such as titanium-bearing sands, change conductivity at higher temperatures. The heat (+100°C [+212°F]) also removes the surface moisture that may be present, which can mask the true conductivity of a mineral.

The two common types of electrostatic separators are high-tension rolls (HTRs) and electrostatic plates (ESPs). The HTR has a higher capacity per unit length than the ESP (e.g., for heavy mineral sands 2 t/h/m of roll length versus 1 t/h/m [2.2 stph/m versus 1.1 stph/m]) and are generally the first stage of electrostatic separators. Because of the nature of HTRs, coarser nonconductive particles can report with the conductive material, and finer conductive particles can report with the nonconductive product stream. The opposite is true for ESPs. The misplacements associated with these machines make it possible to place ESPs within or after an HTR circuit to achieve effective separation of all particle sizes.

A much less common third type of electrostatic separator is the triboelectric separator. These can separate two nonconductive minerals based on the pre-charge that the minerals receive before they are introduced to the separation chamber. These may be used in place of flotation where water or environmental concerns are an issue. The greatest potential for these within placer ore processing plants is upgrading of phosphate by removal of silica sand and fine zircon cleaning by removal of undesirable nonconductors such as sillimanite and kyanite.

Other Processing

Flotation is not that prevalent in most placer ore upgrading but is frequently found in phosphate operations to separate silica from phosphate. The phosphate flotation circuits are generally large, with feed rates in excess of 1,000 t/h (1,100 stph). The flotation circuits are generally located after hydraulic classifiers that split the feed into tighter size ranges to allow for better separation efficiencies of the flotation cells. Circuits can be set up as rougher-cleaners, where the rougher flotation uses fatty acids as collectors for the phosphate. Because the phosphate floats very quickly, silica is usually entrained within the phosphate concentrate. To clean up the phosphate further, a cleaner flotation is used with amines as collectors to float the silica.

A placer ore beneficiation process generally limited to zircon sand is hot acid leaching. This process removes iron staining on sand grains with the addition of a high-concentration sulfuric or hydrochloric acid. This would only be incorporated where low $\%Fe_2O_3$ grades are needed for final product specifications that cannot be accomplished by other means and where the value of the treated mineral can pay for the addition of this type of circuit. A hot acid leach circuit would include a dryer for heating, reactor vessels, rinsing equipment, acid storage and distribution systems, and an effluent treatment plant. Effluent treatment plants are generally simple and include addition of a base to neutralize the acidic effluent and a thickener to remove precipitated solids from the effluent system. The effluent water would be recycled back to the acid leaching circuit so that no off-site discharge would have to occur.

Tailings Handling

Tailings from the floating concentrators are immediately pumped off the barge to backfill the pond or cut (in the case of offshore tin mining). In pond-dredging operations, clays can be pumped into the operating pond when they quickly drop out of suspension or are not much of an issue. If they build up in concentration and hinder separation, clays can be pumped to settling ponds where they dewater and are eventually mixed with the top sand layer during reclamation.

With dry mining there is no working pond, so all tailings from the concentrator must be deposited into settling ponds. These ponds allow reclamation of water as well as settling of clays. In some instances, mixing the clay and sand (which come from different tailings streams within the concentrator) speeds overall dewatering rates.

When mineral separation plant tailings streams are not pumped directly back to a mining pit, they are generally sent to a stacker. The stacker includes a dewatering cyclone with some type of distribution mechanism for the underflow of high-percentage solids. The distribution mechanism (e.g., swinging chute or movable cyclone) allows the underflow tailings to stack because of their high percentage of solids and to become partially dewatered (5%–10% moisture) over time. The dewatered solids can then be trucked back to the mine to backfill mining areas or to create berms for dewatering ponds. Clays report back to process water ponds or thickeners, where they are allowed to settle.

General Heavy Mineral Sands Flow Sheet

Heavy mineral sands operations use nearly all of the processes mentioned previously. For this reason, an example of a typical heavy mineral sands processing flow sheet is given to illustrate how the previously mentioned equipment would be incorporated into one flow sheet (Figure 11.2-12). The overall flow sheet is broken up into a wet concentrator section that produces a heavy mineral concentrate and a mineral separation plant that produces the final products. The wet concentrators are mostly found on floating barges located behind the mining dredge. Mineral separation plants (MSPs), on the other hand, are always land based and are located away from the mine site so concentrate can be easily transported from any location within the mine plan and so that multiple mine sites can feed a single MSP. The central-location concept can move the MSP far from the mine site(s); 50+ km (31+ mi) can still be economical.

When feed is introduced to a wet concentrator, it is first sized by trommel to remove oversize and then treated with hydrocyclones to remove clays and fines. The feed is then sent to a gravity circuit that includes spirals (Reichert cones can be found but are rare) and may include hydraulic classifiers. Typically, the classifiers would be placed at the end of the spirals circuit to help remove any misplaced silica and any fine material that would not be recoverable within the MSP. An attritioning step would be included between the spiral circuit and classifier to clean the sand surface and allow washing of clays if they are present. Spiral circuits have multiple stages; the final product usually passes through four spiral stages

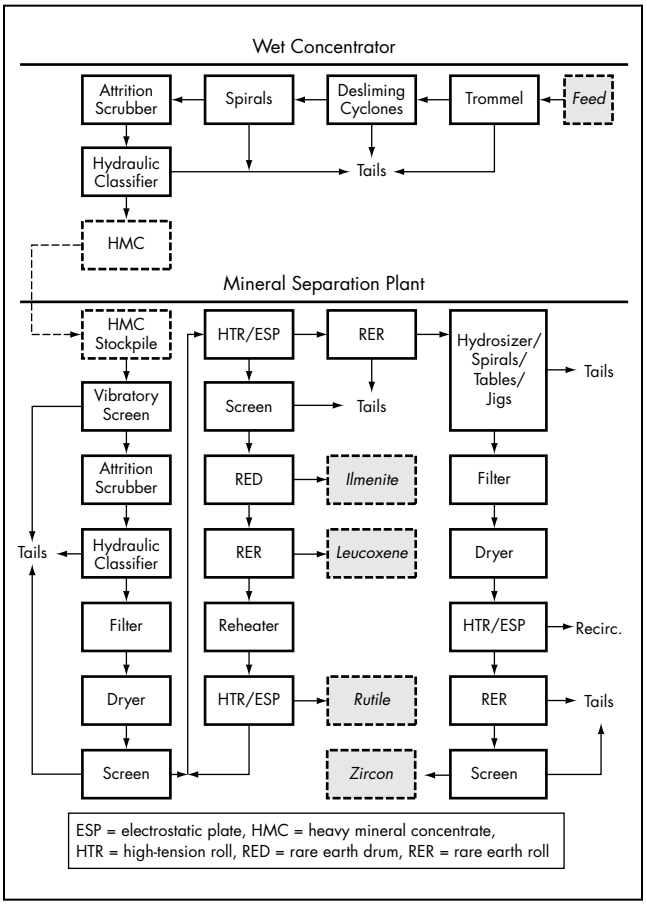


Figure 11.2-12 Generic heavy mineral sands flow sheet

including at least one scavenger step. The final product from the wet concentrator is referred to as heavy mineral concentrate (HMC).

After the HMC is produced, it is transported to the MSP. Blending may occur from multiple mine sites to achieve consistent product grades and mineral assemblages in the feed. Consistent mineral assemblages can reduce bottlenecks in the MSP that may occur at low feed rates if too much of one mineral is present in the feed.

The first circuit of an MSP would generally be a feed-preparation step that may include wet screens to remove oversize as well as attrition scrubbers and hydraulic classifiers to guarantee clean grain surfaces and minimal silica. The feed would then be filtered and dried. High-tension separators are used after the drier to utilize the inherent heat from that process to ensure efficient separation of conductors from nonconductors. Conductor minerals would then be run through various magnets (RED and RER magnetic separators) to remove ilmenite and leucoxene as products. The resulting conductor/nonmagnetic minerals would be reheated and passed through more electrostatic separators to produce a rutile product.

The nonconductor stream from the first high-tension separator circuit is run through a separate magnet circuit to remove nonconductive/magnetic minerals such as monazite and staurolite. Depending on market conditions, monazite and staurolite may be marketable products. The resulting nonconductor/nonmagnetic minerals have a high percentage

Table 11.2-2 Heavy mineral beneficiation cost example

Area	Ore, US$/t	Heavy Mineral Concentrate, US$/t
Mining (dredge)	0.60	5.10
Wet concentrator	1.40	13.45
Mineral separation plant	0.60	6.50
Product handling and delivery	0.95	10.95
General and administrative	0.35	3.75
Concurrent reclamation	0.10	1.05
Total operating cost	4.00	40.80

Courtesy of Outotec (USA), Inc.

of zircon but also an upgraded silica content. To remove the lighter silica, this stream is rewetted and run through wet gravity separators that include a combination of spirals, hydraulic classifiers, wet tables, and/or centrifugal jigs. The heavy concentrate from the MSP wet gravity circuit has a high zircon content but generally does not meet product specifications on $\%TiO_2$, $\%Fe_2O_3$, and potentially $\%Al_2O_3$. To clean up this zircon stream, it is dried and passed through high-tension separators and RER magnetic separators. Based on customers' product specifications, a final screening stage may be needed to remove any oversize or to size the zircon appropriately.

Cost for Mineral Processing of Placer Deposits

Table 11.2-2 shows typical costs for beneficiation of a heavy mineral sands placer deposit. The data assume a 1,000-t/h (1,100-stph) feed rate to the wet concentrator and ore containing an average total heavy mineral (HM) grade of 12.5%. The heavy mineral concentrate produced by the wet concentrator contains 95% heavy minerals; the valuable heavy minerals are ilmenite (65% of HM), rutile (5% of HM), and zircon (5% of HM). Recoveries in the wet concentrator are on the order of 95% for ilmenite, 90% for rutile, and 95% for zircon. Recoveries in the mineral separation plant are 98% for ilmenite, 90% for rutile, and 80% for zircon.

CHAPTER 11.3

Heap Leaching

Travis J. Manning and Daniel W. Kappes

HISTORY

The method of heap leaching has a long history in the mining business. In the mid-1500s, mines in Hungary recycled solutions bearing copper through waste rock for additional copper recovery. Around that same time, Georgius Agricola wrote about piling rocks in heaps and sprinkling them with water for alum recovery in his book *De Re Metallica* (Agricola 1556). At the original Rio Tinto mine in Spain, acid solutions were added to large heaps of copper oxide ores circa 1750. In the 1950s, heap leaching was used for uranium extraction from ore. It was not until 1967 that heap leaching was developed for precious metals by the U.S. Bureau of Mines; the first large-scale gold heap leach project was at Cortez, Nevada. Fewer than 20 years after heap leaching of gold was first developed, it accounted for 30% of all gold production in the United States. In parallel with gold heap leaching, the last 40 years have seen a tremendous expansion of copper dump and heap leaching (Scheffel 2002). Uranium ores have been heap leached with both acid and alkaline solutions since the 1950s. A list of current and historical uranium heap leach operations can be found on the Web site for the World Information Service on Energy: Uranium Project (WISE 2007). Heap leaching of nickel laterites is still in its infancy with only one project near production, the Çaldag project in Turkey.

HEAP LEACHING EXPLAINED

In a simplistic sense, heap leaching involves stacking of metal-bearing ore into a "heap" on an impermeable pad, irrigating the ore for an extended period of time (weeks, months, or years) with a chemical solution to dissolve the sought-after metals, and collecting the leachant ("pregnant solution") as it percolates out from the base of the heap. Figure 11.3-1 is an aerial photograph showing the typical elements of a heap leach operation: an open-pit mine is shown on the left; on the right is a 2-Mt heap of crushed, conveyor-stacked ore on a plastic pad. Pregnant and barren solution storage ponds are located downslope from the heap. Buildings include a solution process facility for recovering metals from the pregnant solution, a laboratory, a maintenance shop, and administration offices. For a small operation such as the one illustrated here, very limited infrastructure is required.

In a more complex sense, heap leaching should be considered as a form of milling. It requires a nontrivial expenditure of capital, and a selection of operating methods that trade cost against marginal recovery. Success is measured by the degree to which target levels and rates of recovery are achieved. This distinguishes heap leaching from dump leaching. In dump leaching, ores are stacked and leached in the most economical way possible, and success is measured by any level of net positive cash flow.

WHY HEAP LEACHING?

Options for recovering metals from ore are many, including agitation leaching, gravity separation, magnetic separation, flotation, and vat leaching. If the ore can be heap leached (which requires good metals recovery by leaching and a rock type that allows the construction of permeable heaps), this technique offers some significant economic benefits. Recent large-scale, very simple heap leaches (40,000+ t/d) have been constructed for a total project capital cost as low as $3,000 per daily metric ton of ore processed, whereas the total capital costs for an agitation leaching plant are often $15,000–$35,000 per daily metric ton. The capital costs of a flotation plant are $10,000–$25,000 per daily metric ton. Another advantage of heap leaching is that it is a chemical process and the product of the leach operation is usually a metal. For gold and silver ores, the primary product at the mine for a leaching operation is an impure gold/silver (doré) bar that can be sold for 95% or more of the quoted price for the metals recovered from the ore. For copper ores, the primary product is usually copper metal that can also be sold for a high percentage of its value. In comparison, flotation plants, which are the primary competitor to the chemical leaching processes, produce a concentrate of the main value mineral(s), which often carries lower-value components and must be sold to a smelter so that the realizable value of gold, silver, and copper is often only 60% of the quoted metal price of the recovered metals.

A number of factors will determine whether heap leaching is the best fit for a project:

Travis J. Manning, Metallurgical Engineeer, Kappes, Cassiday & Associates, Reno, Nevada, USA
Daniel W. Kappes, President, Kappes, Cassiday and Associates, Reno, Nevada, USA

Source: Kappes 2002.
Figure 11.3-1 Heap leach installation at Mineral Ridge, Nevada

- **Risk.** An increasing number of mining projects are being developed in exceedingly remote locations or places with political and social upheaval. It can be a wise choice to select heap leaching in these situations where a mill, with higher capital costs and more complex equipment systems, would be harder to maintain (or stop and restart) as social and political changes occur.
- **Lack of sufficient reserves.** In many underground and some open-pit mining situations, it is difficult (occasionally even impossible) to develop a large ore resource early in the project. Heap leaching offers a very quick, low-cost avenue for treating such ores. As an example, the Sterling mine in Beatty, Nevada (Imperial Metals Corporation) began life as an underground mine with a reserve of 100,000 t (metric tons) of ore at a grade of 11 g Au/t but eventually heap leached nearly 1 Mt.
- **Differential recovery is not sufficient to justify the added investment.** The operating cost plus debt service for a medium-sized mill (3,000 t/d) will typically be $34/t of ore treated, whereas the comparable cost for the heap is $12/t (year 2009 cost basis). Since the heap leach typically gets 25% less recovery than the mill, the gross value of the ore would typically have to be greater than $85/t in order to justify the mill.
- **Capital is very difficult or expensive to raise.** Heap leaching can give a small company a project that can catapult it into the "big league" from a relatively small investment. Often early-stage capital can be raised only by excessive equity dilution or acceptance of onerous bank covenants. The heap leach also gives the management of a small company more time to build up an experienced operational staff before it tackles more complex processes.

HEAP LEACHING CONFIGURATIONS

Configurations of heap leaching available include dynamic heaps, permanent single-lift and multilift heaps, and valley-fill heaps.

Dynamic Heaps

Dynamic heaps reuse the same lined area by loading the ore onto the pad, leaching, washing, and then removing the ore from the pads. They are also referred to as "on/off heaps." The advantage of an on-off heap is that a large amount of ore can be leached in a limited area in relatively thin layers. For ores where the permeability of thicker layers cannot be maintained, which is typical of oxidized copper ores, dynamic heaps often offer the only option. One factor often overlooked is that the leached ore is still an environmental liability and must be moved to another lined area. However, the water balance is easily manageable because of the limited area of the pads. The small area also makes it possible to cover the heap if necessary. Dynamic heaps are applicable to low-grade, precious metal ores containing sulfides that will start to oxidize to form acid within 1 to 3 years. The benefit of using a dynamic heap for this type of material is that the values can be recovered during the short leach time associated with the dynamic heap and the generation of acid would occur in the waste dump, not affecting the leach process.

The pad below a dynamic heap needs to be of sturdier construction than that for a permanent heap because there is more traffic at elevations close to the pad. Pads for dynamic heaps are frequently made of concrete or asphalt for this reason, though with careful ore removal a geomembrane (plastic liner) could be used. Slowly leaching ore can be re-treated by simply restacking it along with the new ore, but this will reduce capacity. Typically the maximum recovery is not reached with dynamic heaps because of the limited time frame for leaching. Before the ore can be removed from the pad, it is usually washed to recover any dissolved values and detoxified if necessary.

Permanent Heaps

In permanent heaps, the ore is stacked on a low-permeability surface and never removed. While this definition also applies to valley-fill heaps, the term *permanent heap* is usually reserved for a heap that is stacked on a relatively tabular ground surface where solution can exit at multiple points across the face of the heap. To expand the available volume for stacking ore, the pad is either expanded or additional lifts are added on top of the ore already stacked. The primary advantages of permanent heaps are that operations are less expensive than dynamic heap operations, and they allow for much longer leach times (up to several years).

Multilift heaps have been built as high as 200 m with successive lifts stacked on top of previously leached lifts. Single-lift heaps are appropriate for some ore types or leaching situations where, for example, the ore is high grade and not very permeable. For single- or multilift permanent heaps, the initial capital cost is relatively low because the liner does not need to be as robust as for a dynamic heap, and a small area can be lined at first with expansion in subsequent years. As multilift heaps grow taller, there are added operating costs for pumping solutions and transporting ore to higher elevations. Permanent heaps require a large area with gently changing topography. The large area required often leads to issues with the water balance in high-rainfall environments, but permanent heaps can be effectively used where rainfall exceeds 2.5 m/yr.

Valley-Fill Heaps

A valley-fill heap leach is just as it sounds: the ore is dumped at the bottom of a valley and is built up, "filling" the valley. Valley-fill heaps are built in areas that do not have enough level terrain to build an expanding permanent heap. Valley-fill

heaps can accommodate long leach times well. A valley-fill expands upward and outward as the valley widens near the top. The necessity for multilifts means that the ore should be strong and maintain high permeability under high loads. The pregnant solution is often stored inside the bottom of the heap and a small pond is used to collect the solution for recovery. This has advantages of less cost in liner, less precipitation collection, and it can keep the solution from freezing in cold climates. If solution is stored within the heap, a better liner needs to be in place because of hydraulic head on the liner. The front slope of the heap needs to be thoroughly designed and very stable to prevent any catastrophic failure. Frequently a retaining structure, or dam, is used to support the toe of the heap.

GEOLOGY OF GOLD DEPOSITS

Carlin-Type Sedimentary Ores

These ores consist of shales and "dirty" limestones containing very fine (submicroscopic) gold. Oxidized ores leach very well, with low reagent consumption and production recovery of 80% or better being achieved. Ores are typically coarse-crushed (75 mm) but may show recovery of 70% or better at run-of-mine (ROM) sizes. The largest of northern Nevada's heap leaches (Carlin, Goldstrike, and Twin Creeks) treat this type of ore. Unoxidized ore contains gold locked in sulfides (typically 1%–3% pyrite) and also contains organic (carbonaceous) components, which absorb the gold from solution. This ore shows heap leach recovery of only 10%–15% and is not suitable for heap leaching. Because of the different ore types, the northern Nevada operations (for instance, Barrick's Goldstrike mine) may employ roasters, autoclaves, agitated leach plants, and heap leaches at the same mine site. Crushing is usually done in conventional systems (jaw and cone crushers) and ores are stacked by trucks.

Low-Sulfide Acid Volcanics or Intrusives

Typical operations treating this type of ore are Round Mountain (Nevada) and Wharf mine (South Dakota, United States). Original sulfide content is typically 2%–3% pyrite, and the gold is often enclosed in pyrite. Oxidized ores yield 65%–85% recovery but may have to be crushed to below 12 mm. Usually the trade-off between crush size and percent recovery is a significant factor in process design. Unoxidized ores yield 45%–55% gold recovery and nearly always need crushing. At Round Mountain, approximately 150,000 t/d of low-grade oxide ore is treated in truck-stacked ROM heaps, 30,000 t/d of high-grade oxide ore is treated in crushed (12 mm) conveyor-stacked heaps, and 12,000 t/d of unoxidized ore is treated in a processing plant (gravity separation followed by leaching in stirred tanks). Primary and secondary crushing is done using jaw and cone crushers; finely crushed ore contains enough fines that conveyor stacking is preferred over truck stacking.

Oxidized Massive Sulfides

The oxide zone of massive sulfide ore deposits may contain gold and silver in iron oxides. Typically, these are very soft and permeable, so crushing below 75 mm often does not increase heap leach recovery. The Filon Sur ore body at Tharsis, Spain (Lion Mining Company) and the Hassai mine in Sudan (Ariab Mining Company) are examples of successful heap leaches with this type of ore. Because the ore is fine and soft, the ore is agglomerated using cement (Hassai uses 8 kg cement/t), and stacking of the heaps is done using conveyor transport systems.

Saprolites/Laterites

Volcanic- and intrusive-hosted ore bodies in tropical climates typically have undergone intense weathering. The surface cap is usually a thin layer of laterite (hard iron oxide nodules). For several meters below the laterite, the ore is converted to saprolite, a very soft water-saturated clay, sometimes containing gold in quartz veinlets. Silver is usually absent. These ores show the highest and most predictable recovery of all ore types, typically 92%–95% gold recovery in laboratory tests, 85% or greater in field production heaps. Ores are processed at ROM size (which is often 50% minus 2 mm or 10 mesh) or with light crushing. Ores must be agglomerated and may require up to 40 kg of cement/t to make stable, permeable agglomerates. Many of the western African and central American heap leaches process this type of ore; good examples are Ity in the Ivory Coast and Yatela in Mali. When crushing is required, one or two stages of toothed roll crushers (Stamler-type feeder-breaker or a mineral sizer) are usually employed. Conveyor systems are almost always justified; ore can be stacked with trucks if operations are controlled very carefully.

Clay-Rich Deposits

In some Carlin-type deposits and volcanic-hosted deposits, clay deposition or alteration occurs along with gold deposition. These ores are processed using the same techniques as for saprolites, except that crushing is often necessary. Because of the mixture of soft, wet clay and hard rock, a typical crushing circuit design for this type of ore is a single-stage impact crusher. Truck stacking almost always results in some loss of recovery. Agglomeration with cement may not be necessary, but conveyor stacking is usually employed.

Barneys Canyon (Utah, United States) uses belt agglomeration (mixing and consolidation of fines as it drops from conveyor belts) followed by conveyor stacking. The La Quinua operation at Yanachocha, Peru, employs belt agglomeration followed by truck stacking.

Silver-Rich Deposits

Nevada deposits contain varying amounts of silver, and the resulting bullion may assay anywhere from 95% gold and 5% silver to 99% silver and 1% gold. Mexico also has multiple silver-rich deposits, like the Dolores and Ocampo projects. Silver leaches and behaves chemically in the same way as gold, although usually the percentage of silver recovery is significantly less than that of gold. Examples of nearly pure silver heap leaches are Coeur Rochester and Candelaria mines in Nevada, and Comco in Bolivia.

GEOLOGY OF COPPER DEPOSITS

Copper occurs in three basic assemblages: oxides, secondary sulfides, and primary sulfides. Porphyry deposits produce the bulk of the world's copper, and if these outcrop, they usually contain all three mineral assemblages (Bartlett 1998). The secondary sulfides are often the highest grade because of the oxidized cap leaching naturally and depositing copper in the secondary sulfide zone. If acidic conditions are not sufficient, the copper is not transported and an oxide deposit is formed.

Normally, there is no distinct zoning and there is frequently a transition zone from oxides to sulfides. The varying chemistry of copper makes the chemistry of copper heap leaching more difficult and complex than that of gold or silver. Adding to the chemical issues, feldspar minerals in copper ores often break down over several weeks of leaching to form clays, which reduce the permeability of the heap. Dump leaches—where uncrushed low-grade mine waste is leached with dilute acid—are fairly common at copper mines because extra copper can be recovered at a very low cost.

Oxide Copper Ores

There is a wide range of copper oxide minerals. With the range of minerals comes a range of metallurgical responses. Most copper oxide minerals leach relatively quickly although some, especially the silicates (like chrysocolla), may be only partially soluble because of the formation of impermeable coatings.

Sulfide Copper Ores

There are primary sulfides, like enargite and chalcopyrite, and secondary sulfides, like chalcocite, bornite and covellite. The secondary sulfides usually leach faster and more completely than the primary sulfides. All sulfides need an oxidant present for dissolution, and the slow introduction of oxygen or oxidizing chemicals can result in a significant lengthening of leach times over what was predicted by laboratory tests. Within the heap, oxygen is usually converted by bacteria into oxidized (ferric) iron, and it is this ferric iron that reacts to oxidize the sulfides, so the heaps must be built in such a way as to encourage the growth of bacteria.

GEOLOGY OF URANIUM DEPOSITS

Sedimentary Uranium Deposits

Oxidized uranium is readily soluble and may be transported from granites or tuffs by groundwater to another location where it is concentrated. The uranium may precipitate in an area for a number of reasons, including lower temperatures and pressures, reduction, ion exchange, neutralization, and chemical replacement. Generally, for ore bodies, the uranium is deposited by reduction from the soluble, hexavalent uranium dioxide to an insoluble tetravalent state. The classic uranium deposits of the western United States are "roll front" deposits in which uranium is dispersed from sandstone and reprecipitated in a continually moving zone.

Granitic Uranium Deposits

Uranium may also be concentrated as large bodies of granite solidify. The initially low concentrations of uranium are continually forced into the remaining solution in the granite until small concentrated amounts of uranium-bearing solutions are left. The fluid can get into fissures in the surrounding rock and form veins of ore.

GEOLOGY OF NICKEL DEPOSITS

Nickel laterite deposits are created when a parent rock is weathered by high rainfall and elevated temperature, typically in a tropical or subtropical climate. The minerals that dissolve easily are removed by the rainfall, leaving behind higher concentrations of the less-soluble elements like iron and aluminum. Nickel is somewhat mobile and concentrates near the base of the leached zone.

CHEMISTRY OF GOLD DEPOSITS

The chemistry of leaching gold and silver from their ores is essentially the same for both metals. A dilute alkaline solution of sodium cyanide (NaCN) dissolves these metals without dissolving many other ore components (copper, zinc, mercury, and iron are the most common soluble impurities). Solution is maintained at an alkaline pH of 9.5–11. Below a pH of 9.5, cyanide consumption is high. Above a pH of 11, metal recovery decreases. A pH above 11 can also result in dissolving silica, which can cause problems with scale control and blinding of carbon.

Many heap-leachable ores contain both gold and silver. Deposits in western Africa and Australia tend to be very low in silver, while those in Nevada and Mexico are highly variable, ranging from pure gold to pure silver. Silver is usually not as reactive with cyanide as gold. This is because gold almost always occurs as metal, whereas silver may be present in the ore in many different chemical forms, some of which are not cyanide soluble. The consequence is that heap recoveries for gold typically range from 50% to 90% while silver typically ranges from 25% to 60%.

Recovery of gold from leach solutions is usually accomplished by adsorption of the gold cyanide complex onto granular activated carbon by pumping the solution through columns filled with the carbon. The leach solutions are recycled to the heap. Gold-rich solution from the heap usually contains only a few parts per million gold, whereas the carbon loads up to about 5,000 ppm. Gold is removed from the carbon by contacting it with a hot chemical solution that is then sent to an electrolytic cell for production of gold metal. This is usually melted on-site to produce a doré bar for sale to refineries (Marsden and House 2006).

The recovery of silver, and the recovery of both gold and silver from solutions high in silver, is usually accomplished using the Merrill–Crowe process. In this process the metal-rich solution from the heap is prepared by filtration and then vacuum treated to remove oxygen from solution. Zinc dust is added to precipitate the metals, and the precipitate is collected on filters. This precipitate is melted on-site to produce a gold/silver doré bar.

The level of cyanide in the heap leach on-flow solution typically ranges from 100 to 600 ppm NaCN, although some ores may require more than 1,000 ppm. Cyanide consumption via complexation, volatilization, natural oxidation, or oxidation by ore components typically ranges from 0.1 to 1.0 kg/t of ore. Cement and/or lime consumption ranges from 0.5 to 70 kg/t of ore. Several operations use cement for alkalinity control (instead of or in addition to lime) as well as for agglomeration.

Other leaching agents—thiosulfate, thiourea, hypochlorite, bromine—have been experimented with as an alternative to cyanide, but cyanide is by far the most effective and the most environmentally friendly leaching agent.

CHEMISTRY OF COPPER DEPOSITS

Copper ores are nearly always leached with a dilute sulfuric acid solution. Copper in heap pregnant solution is typically several grams per liter, whereas for gold/silver ores the solutions contain only a few parts per million of metals. With copper oxides it is not uncommon for the solution availability to the metals in the ore to limit the leach rate of copper. If a slow leaching rate is simply due to the avpplication rate, this can be remedied, but it is often due to the capillary action in the ore

particles, and this is difficult to speed up. Wetting agents have been used to overcome this, with limited success.

Depending on the ore, the natural production of sulfuric acid can be sufficient for the leaching process. The pH of the leach solution needs to be in the range of 2.0 to 2.8 or lower to prevent hydrolysis of the ferric ions. If other oxidizing sulfides (such as pyrite) are present, the acidity can drop to the point where gangue minerals react quickly to form clays, which plug the heap.

Recovery of copper from leach solutions is usually accomplished by processing the copper-rich solution through a solvent extraction plant where copper is extracted into an organic liquid and then back-extracted into concentrated acid for concentration and purification of the copper solution. The barren solution is recycled to the heap. The concentrated solution is sent to electrolytic cells for production of metallic copper. Copper cathodes produced from this process are normally of marketable purity and are sold directly to copper end users (Jergensen 1999).

CHEMISTRY OF URANIUM DEPOSITS

Uranium ores are typically leached with dilute sulfuric acid, often naturally generated, or ammonium carbonate. The tetravalent uranium in oxide minerals needs to be oxidized to the hexavalent state. This is normally done in an acid heap by natural bacterial oxidation, but use of chemical oxidants may be employed. For an alkaline heap, hydrogen peroxide, H_2O_2, is usually employed as an oxidant. The roll of the ferric ion in the oxidation in an acid uranium heap is the same as that in copper heaps. As a result of similar chemical processes, acidic uranium and copper heaps have the same issues to overcome (Merritt 1971).

If lime is present in the host rock, this can cause permeability issues as the leach solution dissolves and reprecipitates the calcium as gypsum. It is common to begin the leach process at a low sulfuric acid concentration and increase it after the gypsum has had a chance to reprecipitate throughout the heap instead of in a single layer, as would occur if higher initial acid concentrations were used. If the lime in the host rock causes excessive acid consumption, alkaline ammonium carbonate $[(NH_4)_2CO_3]$ leaching can be used.

Ammonium carbonate leaching is selective to uranium and as a result the uranium bearing minerals need to be exposed to wetting, possibly requiring finer crushing.

Recovery of uranium from both acid and alkaline leaching is typically accomplished by upgrading solutions with solvent extraction or ion exchange resins followed by a caustic treatment to precipitate "yellow cake" uranium, which can be refined to uranium dioxide (UO_2).

CHEMISTRY OF NICKEL DEPOSITS

Heap leaching of nickel has been proposed but rarely applied. Either hydrochloric (HCl) or sulfuric (H_2SO_4) acid may be used as lixiviants. Recovery of nickel from recycled heap solution requires expensive neutralization of the acid, and this is a barrier to application of the process.

LABORATORY WORK

As with any processing method, it is very important to base the design on the results of a comprehensive program of laboratory testing. For a proper heap leach laboratory program to be developed, it helps to know early on, preferably in the exploration stage, that heap leaching may be an option. To conduct representative column tests, the samples need to be coarse rocks that cannot be produced from reverse circulation drilling. Either large-diameter core diamond drilling (100–200 mm) or bulk sampling (tons) is required. It is common practice to drive a drift into the ore body to take a sample, but as the resource gets larger, this sample becomes less representative. The initial ore samples are seldom representative of the entire ore body; therefore, laboratory tests, including column leach tests, should be continued on a regular basis during mining.

After heap leaching is selected, there is a range of variables that need to be tested. These include crush size, heap stability, permeability versus heap height, solution application rate, reagent strength and consumption, the need for agglomeration, and the type (usually portland cement for gold/silver heaps) and the amount of agglomerating agent required, leach time, and percent recovery.

Heap leaching has inherent risks that can be largely eliminated if the design and operating practices follow the results of the initial and ongoing laboratory testing. The risks result from the nature of the operation. The results of the process are usually not known for several weeks or even months after the ore is stacked, and at this point it is not economical to reprocess the ore. Mistakes made in the initial plant design or incorrect operating practices (e.g., not crushing finely enough or not agglomerating or stacking properly) can result in cash-flow issues that might persist for up to a year after the problem is solved.

An on-site laboratory is an important part of the infrastructure at a heap leach operation. It should include an analytical section (for ore control) and a metallurgical testing section that regularly runs column leach tests on production samples. In addition to the standard production column leach tests, periodic test programs should be run to check the effects of chemistry, crush size, and agglomeration. For a small operation processing fewer than 5,000 t/d of ore, staffing should involve two or three technicians for sample preparation and assaying, and one metallurgist to conduct process tests. Large operations may have a laboratory staff of 10 to 15 people and around-the-clock operation.

HEAP PERMEABILITY AND FLOW EFFICIENCY

The key element in a successful heap leach project is a heap with high and uniform permeability. In any heap there are three zones of different flow regimes:

1. Coarse channels, which allow direct short-circuiting of solution from top to bottom
2. Highly permeable zones, in which solution is efficient at contacting the rock and washing the values downward in "plug flow"
3. Zones of low permeability where high-grade solution or unleached ore may be trapped

Efficiency of Solution Displacement

If the heap was "ideal" (i.e., moving in true plug flow), then when one displacement volume of solution was placed on top of the heap, it would fully replace the solution in the heap. This would be 100% wash efficiency. In practice, the "best" heap leaches exhibit a wash efficiency of about 70%. At 70% per displacement, three displacement washes are required to achieve a recovery of 95% of the dissolved metals. A fourth "displacement" is required, initially, to saturate the ore. Since a typical heap contains 20% moisture, 95% recovery (of the

dissolved value content) requires that 0.8 t of solution must be applied to each ton of ore. In gold heaps, typical practice is to apply 1.3 t of solution per ton of ore during a 70-day primary leach cycle. This suggests two things: (1) most heap leach operations are able to maintain reasonably good permeability characteristics, yielding at least 50% wash efficiency; and (2) a high percentage of the recoverables is solubilized early in the 70-day leach cycle.

Drainage Base

A drainage base of crushed rock and embedded perforated pipes should be installed above the plastic leach pad and below the ore heap. The importance of this drainage base cannot be overemphasized. Solution should percolate vertically downward through the entire heap and then enter a solution removal system with zero hydraulic head. If the drainage base cannot take the entire flow, solution builds up in a stagnant zone within the heap and leaching within this stagnant zone can be very slow.

To put this in context, a "typical" heap might run 500 m upslope from the solution collection point. All of the on-flow solution in a 1 × 500-m strip must flow out at the downslope edge of the heap through the drainage base, which is typically 0.65 m thick. The design of the horizontal percolation rate through the drainage base is therefore nearly 800 times the design rate of the heap itself. This is not a difficult engineering accomplishment since flow is carried in pipes within the base.

At one Australian copper heap leach operation, three adjacent leach panels were built. The two flanking panels had a good installed drainage base, but the center panel did not. Recovery in the center panel was depressed 20% by the poor drainage base. A similar effect has been seen but not quantified at some gold heap leach operations.

Recovery Delay in Multilift Heaps

As subsequent lifts are stacked, the lower lifts are compressed and the percentage of low permeability zones increases. The first solution exiting an upper lift may have a values concentration of up to three times that of the ore. If impermeable zones have developed in a lower lift, high-grade solution may be trapped, causing a severe reduction in recovery rate and possibly in overall recovery percentage. The highest heap leaches currently in operation are 200 m high, with about 10 lifts of ore. Hard ore, crushed or ROM, can withstand the resulting pressure without significant permeability loss. Many softer ores can be agglomerated with enough cement so that they can perform under a load of 30 m; some agglomerated ores perform satisfactorily to 100 m. These properties can be properly evaluated in advance in laboratory column tests, which are run under design loads.

The delay in recovery as lifts are added to the heap is partly a function of the impermeability of the lower lifts and partly a function of the wash efficiency discussed earlier. The net effect is that average recovery is delayed as the heaps get higher and overall pregnant solution grade decreases (requiring more solution processing capacity).

Intermediate Liners

If the permeability of lower lifts becomes a serious problem, it is possible to install intermediate liners, though this is not recommended. Two problems occur with installing an intermediate liner: (1) the heap below the liner is compressed as the upper lift is placed, resulting in differential settlement and possible tearing of the liner; and (2) the ore below the liner cannot be washed with water, which is sometimes required as part of final heap closure.

SOLUTION APPLICATION RATE AND LEACH TIME

With regard to sprinkling rate, the timing for metals recovery is a function of the following factors:

- The rate at which the metal dissolves. Coarse particles dissolve very slowly, and may not fully dissolve for several months in a heap leach environment.
- The percentage of the ore minerals that exist as free or exposed particles
- The rate of diffusion of the solution into rock fractures, and dissolved metal back out of the rock fractures. Where ore minerals occur on tight fractures or in unfractured rock, the rock must be crushed into fine particles to achieve target rates and levels of recovery.
- The effect of chemical reactions within the heap, or within rock particles, which consume the reagents needed for leaching
- The rate of washing the values off the rock surfaces and out of the lift of ore under leach. This is a complex issue that depends on the overall permeability of the lift and the local permeability variations due to segregation and compaction as the lift is being constructed.

These factors cause wide theoretical differences in the response of various ores to leaching. However, in practice, most heap leach operations apply solution to crushed-ore heaps within a fairly narrow range of flows. The typical range is from 8 to 12 L/h/m^2, though some heaps range far above or below these rates (Van Zyl et al. 1988). Some operations start at higher solution application rates to saturate the ore and decrease the application rate with time. Other operations will start solution application very slowly until the heap is thoroughly wetted, to prevent the formation of preferential channels of water flow and then increase the application rate.

Laboratory columns always respond much faster than field heaps. Generally the cause of this problem is reduced reagent-to-values contact in a production heap. Two major reasons for the reduced contact are: (1) the ore is placed in the laboratory column much more uniformly so that percolation is more effective; and (2) the solution-to-ore ratio (tons of solution per ton of ore in a given time frame) is generally higher in laboratory columns than in field heaps. Both small- (150-mm) and large-diameter (1,000-mm) column tests tend to leach similarly. For some field heaps, notably where the ore is fine crushed and the ore leaches quickly, the solution/ore ratio is a more important factor than overall leach time. However, for the majority of heap leaches, time seems as important as specific application rate. The general target for the solution/ore ratio is between 1:1 and 1.5:1.

For ores with very slow leaching characteristics, an intermediate pond and a recycle stream may be added to the circuit, so that each ton of ore sees 2 t of leach solution during an extended leach period. The process plant treats only the final pregnant stream—1 t of solution/t of ore.

The use of multiple cycles is good operating practice for single-lift heaps of high-grade ore. However, for multilift heaps this is not the case. Heap modeling indicates that after the heap attains a height of three lifts, the intermediate solution contains almost as much metal as the pregnant solution. Recycling results in a significant buildup of dissolved values

Figure 11.3-2 Heap leach installation at Brewery Creek. The open-pit mine is shown in the background. In the center of the photograph is an operating heap leach completely covered with snow.

within the heap, causing a slight overall recovery loss and a cash-flow delay. For multilift heaps, it is often possible to justify an increase in the size of the recovery plant so that only fully barren solution returns to the heap.

It is extremely important to design a heap leach system so that the ore can be leached for a very long time. Unlike an agitated leach plant where the ore can be ground to a fine powder and intensively mixed, heap leaching is not a very energy-intensive process. After a heap is built, one of the most significant variables the operator can employ to solve design or production problems is the leach time. Some operations use on-off leach pads to achieve rapid first-stage recovery and then transfer the ore to long-term heaps to complete the process (Kappes 2002).

SOLUTION APPLICATION

The primary goal in the irrigation of a heap is to apply the solution as uniformly as possible. Solution distribution to a heap is done by flood, spray, or drip irrigation. The choice of irrigation can vary greatly depending on specific heap conditions. In recent years, flood irrigation has become a rarity. Spray and drip irrigation are widely used and frequently both are used on the same heap, depending on the season. The following equipment has become standard in heap leaching.

Drip Irrigation

Drip emitters, which issue drops of water from holes every 0.5–1.5 m across the heap surface, are very common. Drip emitters are small in-line devices spaced along a tube that distributes the solution evenly by forcing the water through a complicated path at each emitter, creating an equal pressure loss for the first and last emitter in a line. Drip emitters are easy to maintain and minimize evaporation and cyanide loss. In very cold climates it is possible to bury the emitters to prevent freezing, as shown at Brewery Creek (Alaska, United States) in Figure 11.3-2. In the winter months, the solution flow is piped directly to the process facility on the lower right. The barren leach solution is heated prior to application on the heap and solution pipes are heat traced. The ponds in the foreground are frozen over but, if necessary, excessive flow may be directed into them. Drip emitters can be advantageous for some copper and uranium heaps because they conserve heat that may be required for biological activity. The main drawback to drip emitters is that they do not provide continuous drip coverage. Thus the top 1 m of the heap may not be leached very well until it is covered with the next lift. Other drawbacks are that emitters, due to their small channels, require intensive (and expensive) use of antiscalant, and the use of in-line filters.

Wobbler Sprinklers

Wobbler sprinklers are used at a large number of operations. Their main advantages are that they issue coarse droplets, which control but do not eliminate evaporation, and they deliver a uniform solution distribution pattern that ensures uniform leaching of the heap surface. The coarse droplet size has another advantage in gold heaps. Cyanide is readily oxidized by air and sunlight, and the wobbler-type sprinkler minimizes this loss (but not as well as drip systems). Wobblers are typically placed in a 6×6-m pattern across the heap surface. A disadvantage of all sprinklers is that they require continual servicing, and personnel spend extended periods working in a "rainstorm." Occasional skin contact with cyanide solution does not pose a health problem, but an environment that encourages repeated skin/solution contact is not recommended. Sprinkler maintenance personnel, especially on acid copper heap leaches, wear full rain gear to eliminate any exposure problem, but the working environment (especially in cold weather) is not as pleasant as with drip emitters. Because of the impact of the water on the surface of a heap, wobblers, or any sprinkler system, can lead to the breakdown of delicate agglomerates and migration of fines into a heap. In a tropical climate it may be necessary to use sprinklers because of evaporation issues, but they can cause permeability problems. The influence of the sprinklers on the breakdown of agglomerates and migration of fines can be minimized by placing screen material over the heap to dissipate the impact energy of the water droplets.

Reciprocating Sprinklers

Reciprocating sprinklers shoot a stream, typically 5–8 m long, of mixed coarse and fine droplets. They are not considered ideal for heaps but often find application for sprinkling side slopes since they can be mounted on the top edge to cover the entire slope. If emitters and wobblers are used on side slopes, they must be installed on the slope, which is a difficult and sometimes dangerous place for service personnel to operate from.

High-Rate Evaporative Sprinklers

High-rate evaporative sprinklers typically operate at high-pressures with an orifice designed to produce fine droplets and shoot them in a high trajectory. Evaporative blowers using compressed air to atomize and launch the droplets can also be used. The drifting of the fine particles with wind can cause a concern with chemicals entering the surrounding environment. This type of equipment is not normally used at heap leach operations, but it will become more common as more heaps enter the closure mode where rapid evaporation is needed.

Regardless of the systems used for solution application and management, capital and operating costs for solution handling are usually small.

WATER BALANCE

Since many heap leach operations occur in desert areas where water is scarce, and others occur in environmentally sensitive areas where water discharge is not acceptable, the balance between water collection and evaporation is important. Fortunately, by adjusting the method and scheduling of solution application, it is usually possible to meet the local conditions.

The evaporation of water, regardless of its mechanism, requires a heat input of 580 cal/g of water evaporated. A heap leach gets this heat input from three sources: direct solar heating on heap and water surfaces, latent heat in the shroud of air within the "sprinkler envelope," and latent heat in the air that is pulled through the heap by convection.

The average 24-hour incident solar radiation on a flat horizontal surface ranges from 3,000 kcal/m^2/d in the central United States to about 7,600 kcal/m^2/d in the equatorial desert, which could theoretically evaporate 5–12 L of solution/d/m^2. With a typical heap application rate of 10 L/m^2/h, incident solar radiation could account for an evaporation rate of 2%–5% of applied solution when using sprinklers. Evaporation would be somewhat less when using drip irrigation (1%–4%) because some of the solar energy is reradiated from dry areas on top of the heap. This same heat input would result in pond evaporation of 5–13 mm/d.

Overall evaporative losses include the sprinkler losses, convective loss from air flowing through the heap, and losses due to heating/evaporation from ponds and from other areas not sprinkled. These have been determined at several Nevada operations to be up to 20% of the total solution pumped in summer months, but averaging 10% annually. Thus, direct sprinkler loss accounts for about 60% of the total evaporation. Use of drip irrigation can reduce but not eliminate evaporative loss.

In tropical climates, noticeable losses occur even during the rainy season. On several tropical heap leach projects where rainfall is seasonal and up to 2.5 m/yr, the overall annual evaporative loss from all sources, when using wobbler-type sprinklers operated 24 h/d, is about 7% of the solution pumped. A typical heap application rate is 10 L/m^2/h, or 88 m/yr/m^2. Thus, evaporative loss of 7% is equal to 6.2 m/yr/m^2 on the areas actually being sprinkled. If the heap and pond systems are properly designed, the active leaching area can be up to 40% of the total area collecting rainfall; it is therefore possible to operate in water balance when rainfall is 2.5 m/yr. For these operations, very large solution surge ponds are required.

Where rainfall is high and evaporation rate is low, some operations cover the side slopes with plastic to minimize rain collection. Others have tried to cover the entire heap during the rainy season, but this has not worked very well because of the mechanical difficulties in moving the covers.

In western Africa and Central America, it is acceptable practice to treat and discharge excess solution during the rainy season. Typically, excess process solution is routed through a series of ponds where cyanide is destroyed using calcium hypochlorite [$Ca(ClO)_2$] or H_2O_2, followed by adjustment of the pH to near neutral. The INCO SO_2 system, using copper-catalyzed hyposulfite to destroy cyanide, is also employed for this purpose. Cyanide-free solution is further treated in controlled wetlands (swamps) to remove heavy metals prior to discharge.

The worst water balance situation occurs in cool, damp climates such as in high-altitude operations. In such climates, rainfall and snowfall may be significant and evaporation is minimal. Generally such heaps can stay in water balance with an aggressive program of summer sprinkling. Arctic heap leaches have been able to stay in water balance because precipitation is lower than the total water requirement needed to saturate the ore (Kappes 2002).

LEACH PADS

The leach pad below the heap is a significant element of a heap leach design. The ideal location for the heap is a nearly flat (1% slope), featureless ground surface. Usually some earthwork is required to modify contours, but it is not necessary to eliminate all undulations. It is only necessary that all the solution will flow across the surface toward the collection ditches on the base or the sides of the heap. Where the slope exceeds 3%, the front edge of the heap (30–50 m) should be graded flat to provide a buttress to prevent heap failure. In the western United States, where the water table is often far below the surface, the current practice is to construct the leach pad of 1.5-mm thickness high-density polyethylene or very-low-density polyethylene on a 30-cm-thick layer of compacted clay. A leak detection/water seepage system of pipes is installed below the liner.

HEAP HEIGHT

As discussed previously, for multilift heaps, there is a delay in the recovery and grade. This is not only true for multilifts but also for single lifts as the lift gets taller. A lower recovery grade means that either a larger recovery plant needs to be installed or a lower cash flow will have to be tolerated. The delay in cash flow caused by delayed recovery also needs to be taken into account for additional lifts or height. Depending on the permeability of the material and lift height, the delay per lift can range from 3 to 30 days. It is common to see a delay of 7 days per lift. As a single lift gets taller, there is the added concern of particle size distribution. As the ore is stacked, it rolls down the side slope of the heap. This cascading action naturally segregates the fine particles near the top of the lift, and the large particles near the bottom. The taller the lift the more stringent the controls on this problem need to be. On the other hand, the advantage of taller lifts is that there is less high-grade solution flowing through already-leached ore beneath it. The larger the quantity of high-grade solution flowing through leached ore, the more opportunity there is to lose values. For copper heaps there are additional factors that must be considered when choosing lift height. Copper oxide heaps are frequently limited in height to maintain the pH in the range that keeps the copper soluble. Copper sulfide heaps will create acid within the heap that may cause a pH problem, and these can also easily become oxygen deficient. Because of these issues and permeability problems, copper ores may be leached in "thin layer" heaps where the ore is stacked only 3–4 m high and leached for a relatively short period (weeks instead of months).

With harder ore and quality agglomeration, permeability is not always the driving factor in the ultimate heap height. It may be good operating practice to reduce the heap height in order to maintain a high, consistent solution grade, which is important for planning purposes, especially at very large operations.

MINING, ORE PREPARATION, AND STACKING

Mining of ore for heap leaching employs the same techniques and equipment as mining of ore to feed any other process

Figure 11.3-3 Agglomerating drum and conveyor stacking system with 6-m-high heap

method. Where uncrushed (ROM) ore is placed on the leach pad, ore may be blasted very heavily in order to reduce rock size and improve gold recovery. In high-rainfall environments when processing clay-rich material, it is very important to practice a mining routine that minimizes the amount of rainfall absorbed by the ore.

Ore preparation varies widely. ROM ore may be hauled from the mine and dumped directly onto the heap. At the other extreme from ROM leaches, some heap leaches crush the ore and dry grind it to more than 50% passing 150 μm (100 mesh) and agglomerate the fines (AusIMM 1991). At times, the high-grade ore will be ground and subsequently reblended with the coarse low-grade ore going to the heap. This process is called "pulp agglomeration" and is practiced at Ruby Hill in Nevada.

Ores high in clay (such as saprolites) are typically processed by two stages of crushing using toothed roll crushers, then agglomerated in drums and stacked using a conveyor stacking system. Many ores are crushed and then either truck-stacked or conveyor-stacked without agglomeration. For these harder ores, crushing is usually achieved by a jaw crusher, followed by one or two stages of cone crushing.

Agglomeration

The term *agglomeration* means different things to different operators.

The simplest application of agglomeration is practiced where the ore is hard but contains a large percentage of fines. Agglomeration means simply wetting the ore with water so the fines stick to the coarse particles and do not segregate as the heap is built.

A more involved form of agglomeration is practiced where the ore contains amounts of clay or fines that may begin to plug a heap of untreated ore. Belt agglomeration may be employed. In this technique, cement and water are mixed with the ore at a series of conveyor drop points, and the mixture tends to coat the larger rock particles. The primary goal is stabilization by mixing and contact. A typical conveyor stacking system involves 10 or more drop points, so belt agglomeration may occur as a normal part of the process.

Where ores are nearly pure clays, such as the laterite/saprolite ores in tropical climates, drum agglomeration is usually employed. Figure 11.3-3 shows a typical agglomerating drum. The ore is first crushed finely enough (typically 25–75 mm) to form particles that can be a stable nucleus for round pellets. For gold and silver ores, cement and water are then added and the ore is sent through a rolling drum. The fines and the cement form a high-cement shell around the larger particles, and the rolling action of the drum compacts and strengthens the shell. Copper ores cannot use cement because the sulfuric acid will break it down. Concentrated sulfuric acid is used as a binding agent instead, although the binding effect of sulfuric acid is not very good. Where copper ores are very high in clay or in minerals that decompose in the heap to clay, heap leaching may not be very effective. Drum size and throughput are a function of several factors, but typically a 3.7-m-diameter 10-m-long drum can process 750 t/h. A 2.5-m-diameter drum can process 250 t/h. At the Tarkwa mine in Ghana, two 3.7-m drums were installed to process up to 20,000 t/d of ore. For multilift gold heaps, it is often necessary to use a higher cement addition on the lower lifts, and this is usually determined by laboratory tests in which the ore is leached under the full heap load. Maintaining permeability of the lower lifts is extremely critical to the success of a multilift heap (Kappes 2002).

Truck Stacking

Where rock is hard and contains very little clay, it is possible to maintain high permeability even when ore is crushed and dumped with trucks (Figure 11.3-4). Truck dumping causes segregation, of the ore as it cascades down the slope. To control the degree of this segregation, the ore may be partially agglomerated (wetted to cause the fines to stick to the coarse material) prior to placing in the trucks.

Truck dumping can also result in compaction of roadways on top of the heap. Several studies have indicated large trucks noticeably compact ore to a depth of 2 m. To mitigate this problem, most operations rip the ore after stacking but prior to leaching. The number of ripper passes is important; usually

Figure 11.3-4 A truck is dumping an upper lift onto a lift that is actively under leach. The road formed by haul truck traffic on the heap can be seen on the right.

it is four passes in a crisscross pattern. Some operations practice building an elevated truck roadway that is later bulldozed away. However, this requires substantial bulldozer traffic on the heap surface, which can lead to permeability problems.

Stacking the ore with trucks can result in the tie-up of a large tonnage of ore below the truck roadways. This is a bigger problem for small operations than for large ones, because the roadway width is usually the same regardless of the daily production rate. For a heap leach of 5,000 t/d, the roadways on the heap can tie up one month's ore production. A conveyor system that stacks ore from the base of the lift can reduce the unleached inventory to a few days' production. Because of this inventory reduction, at smaller operations where the ore is crushed, it is usually less capital intensive to install a conveyor stacking system. Conversely, for operations of 100,000 t/d or more, truck stacking is more flexible and may be less capital intensive than a conveyor system.

Conveyor Stacking

Two major types of conveyor stacking systems are used on heaps: radial stacking systems and spreader conveyor systems.

Radial conveyor stacking systems commonly include the following equipment:

- One or more long (overland) conveyors that transport the ore from the preparation plant to the heap. Typically these consist of conveyors up to 150 m or longer.
- A series of 8–15 "grasshopper" conveyors to transport the ore across the active heap area. Grasshoppers are inclined conveyors 20–50 m long, with a tail skid and a set of wheels located near the balance point.
- A transverse conveyor to feed the stacker-follower conveyor
- A stacker-follower conveyor, typically a horizontal mobile conveyor that retracts behind the stacker
- A radial stacker 25–50 m long, with a retractable 5–10-m conveyor at its tip called a stinger. Wheels, discharge angle, and stinger position are all motorized and are moved continuously by the operator as the heap is built.

Radial stackers are usually operated from the base of the lift but may be located on top of the lift, dumping over the edge. Figure 11.3-5 shows a heap that is not only stacked with conveyors on top of the heap but is also stacked in a novel manner: a spiral of one continually climbing lift instead of multiple individual lifts. Inclined conveyors can be installed up the sides of the lower lifts, and the stacking system can be used to build multilift heaps. Stackers for this purpose should have very-low-ground-pressure tires and powerful wheel drive motors to cope with soft spots in the heap surface.

Radial stacking systems can be used for heaps processing up to 50,000 t/d of ore, but beyond that, the size of the stacker (and the bearing pressure that is exerted by the wheels) becomes prohibitive. For operations stacking very high tonnages, large stackers can be mounted on caterpillar tracks to reduce ground pressure.

Spreader conveyors can be used on very-high-tonnage heaps. On on-off (dynamic) heaps, spreader conveyors span the entire width of the heap and continually travel back and forth, distributing the ore on the heap. A bucket-wheel excavator can be installed to remove the ore after leaching is complete. Several recent dynamic heap installations have been built in the form of a ring or oval with a moving "slot" from which the ore has been removed. Ore is removed on the advancing face of a slot and new ore is placed on the trailing edge. The "slot" can be seen in Figure 11.3-6 between the new ore stacked by a spreader conveyor on the right and leached ore removed by a bucket-wheel excavator on the left. The slot between old and new material with a short distance into each face of the heap for the two conveyors to work is the only area of the heap that cannot be under leach.

Mobile spreader conveyors up to 400 m long, mounted on multiple caterpillar tracks so they can travel in any direction, are used on multilift, very-high-tonnage heaps, with notable examples being in the Chilean copper industry.

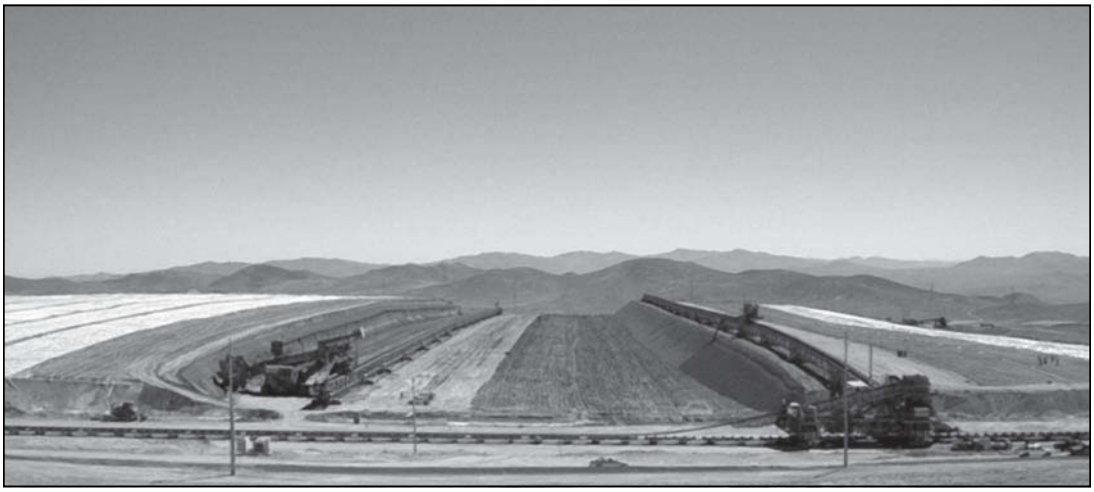
Figure 11.3-5 Valley-fill heap leach at Ocampo, Mexico

SOLUTION COLLECTION

After the values have been dissolved, it is necessary to collect the pregnant solution. A wide variety of arrangements are used to collect the solution and direct it to the pregnant pond. On some valley-fill heap leaches, all of the solution is drained to a single point on the pad and directly into the pregnant liquor pond. As mentioned earlier, a portion of the solution may even be stored inside the void spaces in the heap, thereby minimizing the need for a large pregnant pond. Pregnant solution is usually collected in lined ditches that run adjacent to the heap. More than one inlet to the ditch may be used if it is desired to observe the recovery of different areas on the heap. To further increase the ability to watch the recoveries of different parts of the heap, small ridges may run the length of the leach pad, perpendicular to the collection ditch, to separate the heap into "cells." It is common for a weir to be placed at the point where the pregnant solution exits from each cell, or from the entire pad, to measure the flow draining from the heap. With a heap designed with cells, it is possible to segregate solutions into an intermediate pond. Multiple ditches or pipes run parallel to the heap, one running to each pond. Figure 11.3-7 illustrates this process at the Tarkwa heap leach in Ghana. The three large gray pipes on the right distribute the barren and intermediate leach solutions to each cell of the heap while the black pipes collect the intermediate and pregnant heap runoff solutions. The box at the base of the cell is a solution control point to select which solution will be used for leaching and to which pond the runoff will go. There is also a weir in the distribution box for an instantaneous measurement of solution from the heap. The pad below the heap is commonly a single plastic liner above compacted clay, but the ditches and ponds (and flooded areas of valley-fill heaps) are usually constructed with a double plastic liner with intermediate leak detection.

METALLURGICAL BALANCE

If the values available are not well tracked, the amount of recovery will never be known. The following are some of the values that are important to obtain to be able to calculate a good metallurgical balance:



- Sampling of the ore to be stacked
- Knowing when, where, and how much ore is stacked
- Conducting quality column leach tests to monitor the continually changing ore, and modeling the test results to apply to the heap
- Sampling and flow measurement of the barren and pregnant solutions to and from the heap
- Good assay procedures employing fire assay of the ore samples for gold ores, and total and soluble copper assays for copper ores
- A good model that accounts for delays caused by adding lifts
- Patience

It is important to collect good grade, tonnage, and column test data from day one. It cannot be assumed that the entire ore body will act the same as the initial sample taken for design. To maintain a representative model, the recovery curves will change with the grade, ore type, variations of dilution from waste, and other factors that may affect the recovery. It is difficult to produce a stable and accurate metallurgical balance early in the life of a heap because of the slow reaction time. As a heap ages, the intricacies of how the permeability and leach rates of that particular heap will become easier to predict. A metallurgical balance is a continually changing tool for managing a heap and predicting the cash flow. A good model will keep bankers, stockholders, and your managers happy. A poor one can put a mine in dire straits when the predicted cash flow does not materialize.

DESIGN CONSIDERATIONS FOR RECLAMATION AND CLOSURE

After the heap leaching operation is completed, the facility must be closed in accordance with local environmental requirements. Closure activities are highly variable depending on the environmental sensitivity of the site and on the regulatory regime. In general, heaps are washed for a short period of time (commonly 3 years), during which time 1 t of wash water or recycled treated process solution per ton of ore is applied. Heaps are then capped, and ponds are filled and covered with suitable materials.

The easiest heaps to reclaim are single-lift heaps because the older heaps are abandoned early in the life of the operation and can be washed while production operations continue. In

Figure 11.3-7 Solution collection at the Tarkwa heap leach

valley-fill heap leaches, nearly all the ore ever placed on the pad is situated directly under active leach areas. Thus, washing of the entire heap must wait until operations are completed. Larger operations may have two or more valley-fill leach areas and can therefore appropriately schedule closure activities.

Environmental regulations usually applied in the United States call for reasonably complete washing of the heap to reduce pH, to remove cyanide, and to partially remove heavy metals. Cyanide is fairly easy to remove because it oxidizes naturally, but pH and heavy metals are more difficult to control. Regulators are recognizing that a better approach is to conduct a "limited" washing program and then to cap the heap with a clay cover and/or an "evapotranspiration" cover of breathable soil with an active growth of biomass. These covers are designed to prevent infiltration of water into the heap. After several years of active closure activities, the flow rate of the heap effluent decreases to a manageable level (or to zero in arid environments). After the flow rate has reached an acceptably low level, heap closure is accomplished by installing a facility for recycling collected effluent back to the heap. A relatively small "cash perpetuity bond" is maintained such that the interest on the bond covers the cost of maintaining and operating the intermittent pumping facility for as long as necessary.

Worldwide practices range from simple washing and abandonment to the more complex procedure described above. Environmental design is an industry unto itself, and the simplistic concepts discussed here may not be universally applicable. Heap closure needs to be addressed in the feasibility stage of the project.

TROUBLESHOOTING

As with most things in life, the best troubleshooting for a heap is to do it right the first time. One of the primary challenges in operating a heap is the delay in metallurgical response. With long leach times, the results of a change in operations will

not be seen for months. A common mistake people make is to watch a heap on a day-by-day basis, which is an insignificant amount of time. Arguably the most critical time in the construction of a multilift heap is the base lift of the heap, when operators are least familiar with the equipment and the characteristics of the ore. If the first lift is built poorly and has poor permeability or chemistry, this can have a lasting effect throughout the life of the heap.

Permeability

When permeability problems arise, there are few options to improve it. Often the first sign of low permeability is puddles of standing water on the surface of the heap, called ponding. Apart from ripping the top couple of meters, there are few viable options, although several have been tried. Some heaps are rehandled to improve permeability, which may be profitable on a higher-grade heap as pockets of ore will not have leached. Heaps have also been blasted to try to "fluff up" the ore, though with limited success. Allowing the water to pond might help to force the solution through. Efforts to improve the permeability of already-stacked ore are typically cost prohibitive.

Stability

Low permeability can also cause the ore to become saturated with water and lead to stability issues. The primary cause of stability issues in a heap is the complete saturation of a structurally significant portion of the heap. At the first signs of solution discharge from the side of the heap (more than 1 m above the base) or small blowouts, it is best to stop leaching that area immediately and assess the problem. The problem may be a general issue of poor permeability, or it may be that during stacking of an upper lift, the top surface of the lower lift was made impermeable. If this problem occurs, it usually implies that there will be an overall loss of recovery in the entire heap. To solve the immediate problem, the only practical solution is to reduce leaching near the heap edge, but it is possible to drill the area for installation of vertical drains. The problem indicates that the operation must do a better job of agglomerating new ore, or of ripping and then limiting traffic on the surface below a new lift.

Liner Leaks

Most pads have leak detection pipes below the pad, and leaks will report to the secondary containment sump. Some leakage through the primary liner is generally permitted, but excessive leakage will require abandonment of the heap. Several geophysical technologies have been developed to help locate a hole in a liner, but their accuracy is limited to a circle on the pad with a diameter equal to the vertical height of the heap. It is expensive to repair a liner under an operating heap, as the simple act of exposing it can complicate the issue by creating more holes. It is critically important to prevent liner leaks during construction.

Poor Recovery

A common problem that a heap leach will run into is that the ore takes longer to leach than predicted by the laboratory tests. To eliminate this risk, heap leach design must allow for total flexibility to extend leach times. Many heaps, especially in the copper industry, have achieved economically acceptable performance even though leach times were very long.

It is common practice to minimize the use of cyanide on a heap to save money. In reality this can lose money if done incorrectly. Initial laboratory tests can indicate starting concentrations and operators may periodically explore different cyanide levels to see the effects on recovery. The problem with this approach is that the results of any changes in a heap take a long time to notice. A better approach is to maintain an active production support laboratory and to periodically run a series of parallel column leach tests at different cyanide addition levels to find the best addition concentration. The cyanide concentration in a heap is controlled by the addition of cyanide to the leach solution, but the cyanide in the pregnant solution coming from the heap should also be monitored.

Acid Production/pH

For cyanide heap leaches, lime is usually used to maintain a pH above 10. For ores that generate acid slowly, limestone can be blended in with the ore as well. Caustic can be used but is normally not economic and can result in chemical reactions that plug the heap or are detrimental to the recovery process. If the pH of the pregnant solution flowing from the heap drops because of the oxidation of pyrite and other sulfides, there is generally no economic remedy. Such acid zones should be watched carefully as they can cause gold loaded in upper lifts to precipitate. That area of the heap may have to be abandoned. Future ore should be stacked with the correct amount of pH modifier.

For copper heaps, H_2SO_4 can be generated by the ore itself, but in most heaps, extra acid must be added. However, it may be needed in such quantities as to make the availability of this reagent the key economic issue in evaluating the project.

CAPITAL AND OPERATING COSTS

Heap leaching normally has significant capital cost advantages over agitation leaching. The capital costs for a heap leach can vary widely, from $2,500 to $8,000 per daily metric ton of ore treated depending on many variables including, but not limited to, process rate, location, infrastructure, and company policy. The capital costs of a typical agitated leach circuit per daily ton of ore treated is up to eight times that of a typical heap leach.

Operating costs for an agitated leach circuit may be several times that of a heap. In other cases where a large amount of cement is required for agglomeration or where the ore needs to be fine-crushed, the operating costs of agitation leaching are not necessarily higher than for heap leaching. Heap leach operating costs are not very sensitive to the size of the operation because as some things get less expensive (i.e., general and administrative expenses), other things get more expensive (recovery plant operation). This relationship can be seen in Table 11.3-1.

CONCLUSION

Although the concepts of heap leaching are simple, the practices have substantially evolved over the past 40 years. Early choices for pad materials, sprinkler systems, and stacker designs have been discarded under the pressure of operating experience and cost-reduction factors. Overall operating costs have continually declined as "superfluous" activities and controls have been eliminated.

In spite of the apparent simplicity of the heap leach process—or perhaps because of it—there were many failures in the early years. Now there is a large number of successful operations from which to draw the experience needed to optimize the process. Heap leaching is expected to maintain its

Table 11.3-1 Heap leach operating cost distribution

Operation	3,000 t/d	15,000 t/d	30,000 t/d

CHAPTER 11.4

Surface Techniques of Solution Mining

W. Joseph Schlitt

Most categories of solution mining represent alternatives to mechanical excavation of ore. For example, dredging is simply mechanical excavation from the bottom of a river or other body of water. Hydraulic mining uses a high-pressure jet of water to dislodge material from a working face and even transport it to the processing plant. In-situ mining extracts values chemically or by simple dissolution, leaving the host rock in place and essentially undisturbed. In contrast, surface (leaching) techniques are forms of ore processing not unlike milling and flotation. All rely on mechanical excavation of ore to provide the feed to be treated.

Most types of solution mining represent the primary method of production, including mine-to-leach operations. However, surface leaching can also provide a secondary or supplemental form of production, with leaching limited to sub-mill-grade mine waste. Usually such material is of too low a grade to justify the cost for some degree of crushing, even though crushing could improve recovery or at least the rate of recovery. Hence, leach material is typically truck-hauled in run-of-mine (ROM) condition and dumped in lifts on the leach pile. Supplemental leach operations are fairly common in the copper industry, where higher-grade ore is usually milled and floated. They also exist in the gold industry, where higher-grade ores are typically ground- and agitation-leached.

Cost accounting usually differs significantly for primary and secondary leach operations. In a primary mine-to-leach scenario, the leach operation carries the full cost of mining. This is not unlike typical milling and flotation operations, which also carry the full cost of mining. Conversely, secondary operations typically carry no mining costs, as the leach material must be mined anyway to expose mill-grade ore. In effect, secondary operation lowers the strip ratio and provides better utilization of the resource, as some production is derived from material that is otherwise wasted. However, some incremental costs may be assigned to secondary leaching. An example is the extra cost needed to construct one or more leach-lined dumps with profiles that optimize recovery, rather than simply dumping material at the shortest haul location.

Both primary and secondary operations must meet two general sets of criteria, one that focuses on the characteristics of the ore and one that involves the development of efficient operating practices.

Consideration must first be given to the characteristics of the deposit and the leach material itself. Parameters include location of the resource, extent of the mineral inventory, mineralogy and mode of occurrence of the metal values, and chemical and physical nature of the host rock. Nature must provide a sufficient tonnage of material with adequate recoverable metal values per ton; otherwise the leach project never reaches the point where operating practices are of any consequence. For a proposed leach operation, the same type of exploration and development program is required as for any other mining project. The difference is that metallurgical testing is directed toward leaching instead of ore comminution and beneficiation.

This chapter describes the establishment of leach operating practices for treating whole ore, as opposed to some type of concentrate. Coverage begins with a section on ore–lixiviant systems for the different commodities, as well as bioleaching and metallurgical testing. This is followed by a section on materials handling that includes mining, leach systems, ore preparation, and emplacement. The next section covers solution management, including environmental considerations. The chapter concludes with shorter sections on downstream operations and infrastructure requirements.

Throughout this chapter, the following terms are used:

- *Heap leaching* refers to a mine-to-leach operation involving crushing, possible pretreatment, and careful stacking to optimize metal recovery.
- *Dump leaching* refers to an operation in which low-grade ROM material is placed in mine dumps and leached to obtain additional metal values.

ORE–LIXIVIANT SYSTEMS

One of the first decision points in a proposed leach operation is to select the optimum lixiviant with which to treat the ore. Clearly, if the mineralization is too refractory, leaching is not viable and other process options need to be considered.

The two key requirements for any lixiviant are high selectivity and rapid leach kinetics. The kinetics should always be

W. Joseph Schlitt, President, Hydrometal, Inc., Knightsen, California, USA

such that dissolution at the surface of the ore is the most rapid step, so that the overall leach rate is controlled by transport of reagents or products to or from the mineral surface. Other desirable characteristics for the lixiviant include low price, low toxicity, ease of handling, and capacity for regenerating or recycling. The lixiviant should also allow for easy concentration and recovery of the metal values.

In spite of many years of research on possible lixiviants, only a few are used widely in commercial operations. The principle reagents used to extract each major commodity are discussed in the following subsections.

Gold and Silver

Alkaline sodium cyanide solution is used almost exclusively to extract gold and silver during heap and dump leaching. Studies on the mechanism of dissolution indicate that two reactions are involved in gold dissolution (Dorey et al. 1988). Most of the gold dissolves according to the following reaction:

$$2Au + 4CN^- + O_2 + 2H_2O \rightarrow 2Au(CN)_2^- + H_2O_2 + 2OH^- \quad (11.4\text{-}1)$$

However, a small but still significant portion of the gold dissolves according to the Elsner reaction:

$$4Au + 8CN^- + O_2 + 2H_2O \rightarrow 4Au(CN)_2^- + 4OH^- \quad (11.4\text{-}2)$$

In both cases, the balancing cation is sodium (not shown, for simplicity), and oxygen is required. For any given ore, the gold dissolution rate depends on cyanide concentration, oxygen content, and solution alkalinity. The optimum pH is about 10.3 (Dorey et al. 1988), but many operators tend to run at somewhat higher values as a margin of safety. Because most ores are not so basic, alkaline reagent must also be added to the system to raise the pH. This is generally done by blending lime (CaO) with the ore, or adding milk of lime [$(Ca(OH)_2$] or caustic (NaOH) to the solution.

In theory, nothing should prevent dissolution of virtually all of the gold in a heap or dump. In actual operations, extraction seldom exceeds 85% and recoveries as low as 40% occur. The problem is caused by poor accessibility of the gold to the lixiviant. One cause for this is poor heap construction that leaves portions of the ore blinded off so that solutions do not wet the entire rock mass. Another cause is gold encapsulated in silica or other refractory minerals such as pyrite or arsenopyrite. The processing of these so-called refractory ores is an area of technology that is still developing but is often applied to concentrates rather than whole ore.

Silver, although commonly extracted along with gold, is generally not recovered as effectively. Its dissolution reactions with cyanide are analogous to those for gold, but a lesser chemical driving force is involved. In addition, silver is much less noble than gold and tends to associate with various refractory minerals in addition to pyrite and arsenopyrite.

In spite of its almost universal usage on low-grade material in heaps or dumps, cyanide has a number of inherent problems, including the following:

- High potential toxicity
- Environmental concerns such as aquifer contamination
- Relatively slow kinetics for dissolution of both gold and silver
- Generally poor extraction of silver
- Requirement for alkaline reagents when leaching acidic ores
- High reagent consumption due to poor selectivity when leaching complex ores containing various base metals

The presence of copper is particularly troublesome, as most oxide and secondary sulfide minerals leach well and form highly soluble cyanide complexes. In addition, copper usually reports with gold and silver as they are stripped from the leach solution. The presence of copper then complicates the final parting and refining of the precious metals.

In spite of the problems with cyanide leaching, operators have learned to deal with issues such as cyanide destruction in effluent streams and detoxification of heaps and dumps at closure. Nonetheless there remains a strong impetus to find an alternate lixiviant. Most attention has been focused on thiourea [$(CS(NH_2)_2$] (Hiskey 1981, 1984). Its potential benefits, compared to cyanide, include the following:

- Up to 12 times faster leach times, resulting in leach cycles of hours rather than days or months
- Functional in an acidic rather than an alkaline medium
- Better selectivity for gold and silver
- Lower toxicity

Unfortunately, however, after three decades of development, thiourea has not lived up to its potential, and its use generally remains confined to high-grade materials. The main problems are high unit costs and high reagent consumption.

Copper

Only three acidic lixiviants have been used in commercial copper leaching operations on ores and mine wastes: (1) acidic sulfate solution is the dominant choice and can be used on both oxide and sulfide mineralization, including ores that contain a mix of the two types; (2) acidic chloride solution has also been used; examples involve the use of sea water or saline groundwater for the leach solution and do not involve additions of hydrochloric acid; (3) sulfuric acid is used for leaching, even with a chloride solution, and actually produces a mixed sulfate–chloride lixiviant. Of these, sulfuric acid offers the following advantages:

- It is relatively benign with regard to materials of construction, with well-known handling characteristics.
- It is compatible with recovery of copper by conventional solvent extraction–electrowinning (SX-EW) technology.
- It is inexpensive and commonly available as a by-product from copper smelters that are often located nearby.

In addition to acidic systems, an alkaline ammonia-based lixiviant has also been used commercially in specialized cases, including the leaching of both ores and concentrator tailings containing malachite and azurite (copper carbonates). For many years, the Calumet and Hecla Mining Company ran ammonia leach plants to recover native (metallic) copper from mill tailings (Benedict and Kenny 1924). Today, no copper ores or tailings are treated in ammonia leach plants. The technology is therefore not covered further in this chapter; for more information, see Chase (1980).

The copper mineralization dictates how the ore should be leached. Oxidized ores, including most oxides, silicates, carbonates, hydroxides, and chlorides, can be dissolved effectively with a nonoxidizing acid—that is, sulfuric acid. The general reaction is a straightforward, irreversible dissolution

that consumes acid. The specific reaction for the common mineral chrysocolla is

$$CuSiO_3 \cdot nH_2O + H_2SO_4 \rightarrow CuSO_4 + SiO_2(H_2O)_{n+1} \quad (11.4\text{-}3)$$

However, unoxidized ores, mainly the various sulfide minerals and native copper, do require an oxidant. As described below, the chemistry is more complex and relies on natural oxidation processes to accomplish leaching. The oxidant may be either dissolved oxygen or an ionic species such as ferric iron in a sulfate-based system or ferric or cupric ions in a chloride system. Regardless of the lixiviant, the leach solution must be either acidic enough or basic enough to carry copper in solution, as copper salts tend to precipitate from near-neutral solutions.

In the absence of chloride input, the natural lixiviant for copper sulfide minerals is acidic ferric sulfate. An example for the leaching of chalcopyrite is

$$4Fe^{+3} + CuFeS_2 \rightarrow Cu^{+2} + 5Fe^{+2} + 2S^\circ \quad (11.4\text{-}4)$$

Here the balancing anion is sulfate (not shown). Although small amounts of elemental sulfur are detected on partially leached mineral surfaces, no accumulation of elemental sulfur is observed in actual operations. Thus, any elemental sulfur is transitory and progressively oxidizes all the way to sulfate in the presence of bacterial catalysts and oxygen in the air within rock-pile voids.

The ferric iron in Equation 11.4-4 can come from several sources, including acid-soluble iron in various gangue minerals. Without going into detail, much of the iron comes from the oxidation of pyrite (Hiskey and Schlitt 1982), which plays an important role in sulfide leaching. Pyrite is typically 3 to 10 times more abundant than the copper species, so it is important simply on a mass basis. Pyrite oxidation is analogous to the chalcopyrite reaction shown in Equation 11.4-4. In addition to supplying iron, pyrite oxidation is an in-situ source of acid generation that helps maintain the acid balance and low pH needed to keep copper in solution (Templeton and Schlitt 1997).

These sulfide oxidation reactions are also exothermic. Heat released during reaction boosts the temperature in the heap or dump and accelerates the leach kinetics. It also produces a buoyancy effect and promotes convective airflow through the rock pile, which provides the oxygen that is needed for reoxidation of ferrous iron back to the ferric state. This reaction is typically bacterially catalyzed, as described later in the "Bioleaching" section.

Uranium

Commercial heap leaching of low-grade uranium ores was first practiced in the United States during the uranium boom in the 1950s. More recent examples include the Los Gigantes acid heap leach in Argentina and the bacterial heap leach on pyritic ore at Urgeiriça in Portugal (now shut down). Commercial operations currently exist in Brazil, China, Niger, and Spain, and both acid and alkaline leach projects are being planned in Australia, Botswana, and Namibia. The list seems likely to grow, given the renewed interest in nuclear power and the economics of heap leaching.

As is also the case for copper, both mine-to-leach and secondary operations can use sub-mill-grade feed. Most of these projects currently produce no more than a few thousand tons of yellow cake per year, and total output is small compared to in-situ operations. In addition to primary production, uranium has also been produced as a by-product of copper leaching operations in a few cases (George et al. 1968).

Regardless of the leaching method, the same lixiviant chemistry is applicable to uraninite (UO_2) and coffinite [$U(SiO_4)_{1-X}(OH)_{4X}$] ores that are commonly treated. Both acidic and alkaline lixiviant choices exist (Grunig 1981). To minimize reagent losses in solution mining, the lixiviants have been tailored to avoid excessive gangue reactions. Thus a sulfuric acid–ferric sulfate leach was developed for sandstone ore, and a sodium bicarbonate or ammonium carbonate leach was developed for uraninite in calcareous ore. The oxidant in the latter system is either hydrogen peroxide or oxygen dissolved in the leach solution.

For both acid and alkaline circuits, dissolution requires oxidation of tetravalent uranium to the hexavalent state. In dilute sulfuric acid (pH 1.6 to 2.0), uranium is oxidized by ferric ion and goes into solution as the very stable uranyl sulfate complex. Similarly, sodium or ammonium bicarbonate lixiviants form uranyl carbonate.

The overall reactions in an acid circuit are (Merritt 1971)

$$UO_2 + Fe_2(SO_4)_3 \rightarrow UO_2SO_4 + 2FeSO_4 \quad (11.4\text{-}5)$$

$$UO_2SO_4 + 2H_2SO_4 \rightarrow [UO_2(SO_4)_3]^{-4} + 4H^+ \quad (11.4\text{-}6)$$

The overall reactions in an alkaline circuit are (Merritt 1971)

$$2UO_2 + 2H_2O_2 \rightarrow 2UO_3 + 2H_2O \quad (11.4\text{-}7)$$

$$UO_3 + Na_2CO_3 + 2NaHCO_3 \rightarrow Na_4\,UO_2(CO_3)_3 + H_2O \quad (11.4\text{-}8)$$

Both types of circuits are well established and have seen extensive commercial application in both solution mining and conventional mills using agitation leaching.

Nickel

Nickel and by-product cobalt are the most recent commodities to be recovered by heap leaching. The target ore types are laterites, which contain more than 70% of the world's nickel but account for only ~40% of the world's production (McDonald and Whittington 2008a, 2008b). Unlike gold, silver, copper, and uranium, virtually no discrete nickel or cobalt oxide minerals are found in laterite ores. The occurrence of both nickel and cobalt is quite variable, as they substitute for iron in goethite (limonitic ore) and smectite group clays or for magnesium in saprolite (serpentine) ore. A typical example is the hydrous magnesium silicate falcondite [$(Ni,Mg)_4Si_6O_{15}(OH)_2 \cdot 6H_2O$)].

As of this writing, the technology for heap leaching of laterites is still developing and competes with the more established high-pressure acid leaching. Key issues for heap leaching have recently been reviewed (Steemson and Smith 2009). For both types of leaching, sulfuric acid is the overwhelming choice of lixiviant. For heap leaching, the acid concentration is typically 50–75 g/L. Because nickel and cobalt substitute in the structure of various complex minerals, the entire mineral must be solubilized to release the metal values. As a result, sulfuric acid has poor selectivity, and mass loss can be as high as 30%. Acid consumption is also high and varies from 10 to 75 kg/kg (lb/lb) of nickel or 100 to >500 kg/t (200 to 1,000 lb/st) of ore.

Because of high acid consumption, heap permeability can be a problem. As a result, laterite heap leaching is typically done in shallow, single-lift heaps run in on/off mode, as described later in the "Leach Systems" section.

Other Metals

Other than the commodities covered previously, zinc is the only metal that is currently produced commercially by heap leaching. Teck Cominco (now Teck Resources) reportedly pilot-tested the heap leaching of low-grade sphalerite (ZnS) ore, but results have not been reported, nor has a commercial project been announced. However, a zinc silicate heap leach is reportedly operating in Namibia with sulfuric acid as the lixiviant.

Low-grade manganese ores should also be amenable to solution mining, although this has never been done commercially. The lixiviant would be aqueous sulfur dioxide (SO_2), which reacts with manganese dioxide (MnO_2) as follows:

$$MnO_2 + SO_2\,(aq) \rightarrow MnSO_4\,(aq) \qquad (11.4\text{-}9)$$

Less-oxidized forms of manganese require an oxidant such as dissolved oxygen, hydrogen peroxide, or perhaps ferric sulfate. Tests reported by Potter et al. (1982) suggest pregnant-leach-solution (PLS) grades ranging upward of 10% to 12% $MnSO_4$, implying that manganese can be recovered as the sulfate by evaporation or as the carbonate or hydroxide by neutralization and precipitation.

Polymetallic Systems

Other than gold/silver production, leach operations recovering more than one metal have been rare. In addition to the by-product uranium mentioned previously, efforts have also been made to extract cobalt from copper leach liquors in the United States. Cobalt recovery from some African copper leach operations seems certain, as does recovery of cobalt from nickel laterite heap leaching. Another possibility is dual-circuit recovery of copper and zinc. Recovery of cobalt, copper, manganese, and zinc was planned for the mine-to-leach operation at the Sanyati mine in Zimbabwe; however, the current status of this project is uncertain. The technology for cobalt recovery already exists for both copper and nickel circuits. However, when multiple recovery circuits operate in series, problems always exist with coextraction of metal values and carryover of reagents from one circuit to the next.

Bioleaching

Only the leaching of sulfidic ore and mine waste has a bacterial component; the leaching of nonsulfide materials is based on straightforward chemical control. Years of development work have been spent on bacterial or bioleaching, but commercialization has generally been limited to high-grade ores and concentrates.

The exception is Newmont Mining Company's two-stage heap-leach process for treating refractory (pyritic) gold ore. In the first step, bacterial leaching with forced aeration partially oxidizes the pyrite, liberating or at least exposing the gold inclusions. When at least 40% of the pyrite is oxidized, the heap is thoroughly rinsed to remove acid that was formed. In the original plan, the material was to be off-loaded, blended with lime, restacked on a second pad, and leached with cyanide to recover the gold. In actual operation, the first heap is off-loaded and hauled to the carbon-in-leach mill, where bio-oxidized material is neutralized in a semiautogenous grinding mill. This process has not found widespread use, but details are available in Logan et al. (2007).

Other commercial leach operations having a bacterial component all rely on indigenous microbial species for the necessary activity. The natural bacterial oxidation provided by the chemoautotrophic bacterial strains *Thiobacillus ferrooxidans* and *Thiobacillus thiooxidans* has been well known for years. *Thiobacillus* are generally active at temperatures below 40°C (104°F). Large sulfidic leach dumps typically operate at higher temperatures, with indigenous moderate or extreme thermophiles playing the same roles.

The exact mechanisms of bacterial action are still in dispute, but the accepted theory is that the bacteria obtain energy for growth from enzymatic oxidation of ferrous to ferric iron and elemental sulfur to sulfate.

T. ferrooxidans bacteria catalyze the oxidation of ferrous to ferric iron (Brierly 1978; LeRoux et al. 1973):

$$2Fe^{+2} + \tfrac{1}{2}O_2 + 2H^+ \rightarrow 2Fe^{+3} + H_2O \qquad (11.4\text{-}10)$$

Similarly, *T. thiooxidans* bacteria catalyze the oxidation of sulfur to sulfate:

$$S^\circ + 3/2O_2 + H_2O \rightarrow 2H^+ + (SO_4)^{-2} \qquad (11.4\text{-}11)$$

The rates of these reactions can increase by several orders of magnitude when catalyzed bacterially. With the addition of carbon, nitrogen, oxygen, phosphorous, potassium, and other elements as nutrients, the bacterial metabolism can be maintained to sustain a stable population.

The key factor to keep in mind in such an operation is that microbial populations are living organisms. Actions that cause sudden changes to their preferred environment should be avoided—otherwise the change can render the population inactive or even kill it outright, negatively impacting production. An example is sudden introduction of chloride ion via use of magnesium or calcium chloride as a dust suppressant or deicer on haul roads.

Metallurgical Testing

Regardless of the values to be recovered, a proper metallurgical test program is required for any new leach project. Test results establish expected operating parameters and set the design criteria needed to engineer and construct leaching and recovery facilities.

The most important single factor in any test program is the selection of samples to be tested. Great care must be taken to ensure that samples are representative of the material to be leached. If a deposit contains more than one type of ore, in terms of either mineralogy or lithology, then each type must be tested thoroughly. When a mine plan is available, samples representing various mining periods should also be tested to avoid surprises in recovery or reagent consumption. A common approach is to test quarterly composites for the first 3 years of operation and annually thereafter.

Test Levels

At least two and sometimes three levels of testing must be undertaken (McClelland 1988):

1. Preliminary tests: small-column percolation or bottle roll tests
2. Detailed tests: larger column tests to optimize feed size and other parameters
3. Large- (pilot-) scale tests: large-column or field tests

Preliminary tests accomplish the following: (1) provide insight into the amenability of the material for leaching; (2) allow selection of the preferred lixiviant, should the choice not be obvious; (3) provide information on the chemical aspects of the proposed ore–lixiviant system; (4) indicate whether or not agglomeration is needed to avoid permeability problems with clays or fines. With respect to the chemical aspects of the proposed system, chemical parameters include a first estimate of reagent consumption and the rate and ultimate level of extraction of the one or more metals. Differences in the behavior of the various ore types become evident.

Care must be taken in extrapolating preliminary test results to predict design parameters in the eventual operating system. Preliminary results are almost always misleading in the following ways:

- Leach rates are higher than in commercial operation. Material is crushed much more finely in small-scale tests than in a full-sized system. Finer crushing maximizes liberation of the metals and minimizes diffusion distances to any mineralization that is not exposed. Thus metals are solubilized rapidly and completely, assuming that results are not impacted by complete reagent consumption in typical batch-type tests.
- Reagent consumption is higher than in commercial operation. This reflects not only the high extraction of metals but also the high host-rock surface area. In particular, fine rock size tends to maximize reagent consumption when the lixiviant is not highly selective for the metals and attacks host-rock (gangue) minerals as well. Such behavior is particularly common for acidic lixiviants, which tend to be less selective than alkaline reagents. For example, in acid leaching of copper, on a mass basis there is generally much more reaction with gangue constituents than with copper minerals.

Detailed tests are run in larger columns. These tests are generally intended to determine whether or not the ore should be leached in ROM conditions, crushed to some smaller size, or crushed and then agglomerated. Extraction-rate curves and reagent-consumption figures are determined as a function of particle size and degree of agglomeration.

Detailed tests can be run in either of two ways: single- or multiple-feed sizing. In the former, medium-sized material is column-leached until the extraction rate levels off to near zero. The contents of the column are screened and assayed to determine recovery as a function of particle size. Generally a second confirmatory test is run on material crushed to the selected size. This approach is less costly but more time-consuming than running parallel tests on multiple samples crushed to a range of sizes. With either approach, the last step is to balance projected recoveries and revenues against the cost of progressively finer crushing and/or agglomeration. The most economical operating scenario can then be selected.

Similar detailed tests can be done to optimize other operating parameters as well. These parameters include agglomerating conditions, heap height, leach-solution irrigation rate, reagent concentration, pH, and, in some cases, oxidation potential. Along with crush size, these parameters define the operating conditions.

Large-scale tests are done less frequently now than in the mid- to late 1900s. They typically involve large columns or square cribs that represent a slice of the expected commercial heap. Cribs are frequently loaded in the same way that the commercial heap will be stacked, replicating ore emplacement with its natural angle of repose and size segregation with fines at the top. Typical large-scale column tests are run with 18–36 t (20–40 st) of gold/silver ore (McClelland 1988) and as much as 180 t (200 st) of copper ore (Murr 1980). In many cases, large-scale column tests are more meaningful than tests performed on small field heaps because of edge effects caused by the large percentage of material contained under the sloping heap faces.

Large-scale tests are often omitted, and test programs stopped at the detailed-test stage, for the following reasons:

- Considerable expense and an extended schedule are required to complete the tests and evaluate the results.
- Obtaining a representative sample can be difficult. Even driving an adit into the middle of the ore body may be insufficient if the deeper ore has different characteristics.
- For deposits that have only been drilled, there may simply not be enough core samples available for large-scale tests.
- Permitting and environmental requirements are likely to be as onerous as for full-scale operation.
- Extensive databases for actual projects, together with advanced computer-modeling techniques, now make projection of expected operating performance much more accurate than it has been in the past. However, this effort still requires a comprehensive test program that accurately replicates the proposed operating parameters.

Logistical considerations and the availability of representative leach material often limit really large-scale field tests to existing mine operations. Use of a large-scale heap or dump is required only when assessing the impact of a parameter that cannot be replicated in smaller-scale testing. A good example is the million-ton ROM test heap that Kennecott Utah Copper Corporation built at the Bingham Canyon mine (Utah, United States) (Schlitt 2006). The primary objective was to assess the impact of severe winter weather on performance of the heap and the 6 t/d (6.6 st/d) SX-EW plant used to recover the leached copper. A secondary objective was to provide a facility for operator training. By the end of the program, the project had produced 771 t (850 st) of cathode copper that was sold as a credit against the cost of the project.

Test Results

Regardless of the test scale, at the completion of metallurgical testing, results are typically presented as plots of cumulative metal extraction or reagent consumption versus a test variable.

One obviously useful plot is cumulative extraction versus time under leach (Figure 11.4-1). The leach curve has a pseudo-parabolic shape, indicating that the reaction rate is fast initially but slows progressively with time. The slope of the tangent to the curve at any given time gives the instantaneous leach rate at that time. For the curve shown in the figure, the rate is in units of percent extraction per day. A linear initial leach rate implies that the initial rate is controlled by either

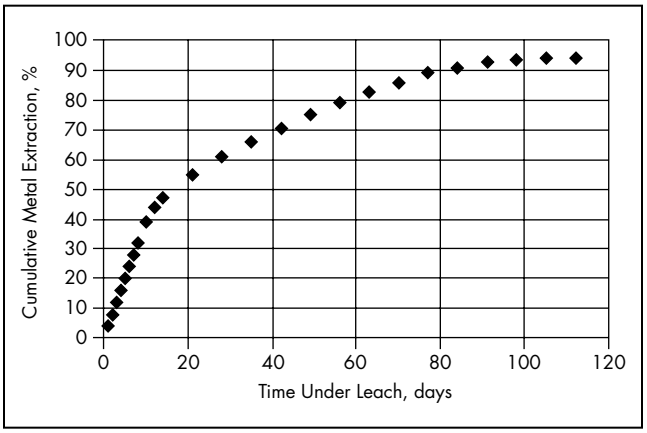

Figure 11.4-1 Typical leach curve for a heap leach

reagent availability or reaction rate at the mineral surface. As leaching continues, metal-bearing minerals exposed on the rock surfaces are consumed and the rate decreases as diffusion to or from less-accessible mineralization becomes rate-controlling. The rate continues to decrease until all accessible mineralization has reacted and the ore is leached to exhaustion.

Another useful plot is recovery versus cumulative solution flux (total quantity of leach solution applied per metric ton of ore under leach). Such a plot has a normalizing effect, enabling comparison of, for example, results for columns of different heights. Using solution flux also compensates for periods when flow to the heap is interrupted. Other plots may be appropriate for special situations. For example, for sulfuric acid lixiviant, a plot of recovery versus acid flux may be informative.

In addition to the general test criteria outlined previously, there are many commodity-specific aspects to metallurgical testing. These cannot be addressed in detail here but do require that a well-planned research program be conducted by knowledgeable metallurgists and engineers to get meaningful results. To cite just one commodity-specific example, bottle roll tests on cyanide extraction of gold should be done in open bottles. If the bottles are sealed, poor results may be due to oxygen deficiency rather than the presence of refractory mineralization.

MATERIALS HANDLING

This section covers everything from mining of the leach material to its emplacement on the heap prior to leaching. This includes a description of the leach systems, with alternatives to conventional heap and dump leaching. The section concludes with a description of ore preparation, which covers crushing, agglomeration, and the various methods of emplacement.

Mining

Surface heap and dump leaching operations are almost invariably associated with open-pit mining operations. These require essentially the same planning functions and use the same unit operations as those described in Chapter 10.2. However, two areas may be impacted by leaching operations: mine planning, and drilling and blasting.

If heap or dump leaching supplements conventional milling, mine planning can become quite complex. One complexity lies in the need for more segregation of mined materials. Material must be divided into not just two categories, mill ore and waste, but three: mill ore, leach material, and waste. Both leach heaps and waste dumps need to be designed, and movement of all three types of material must be scheduled. In addition, water distribution and collection systems must be designed and installed for the leach system.

Supplemental production of leach copper also affects calculation of the ore cutoff grade and ultimate pit limits. Since leaching permits partial recovery of copper from material that would otherwise be wasted, the effect of a leaching operation is always to raise the cutoff grade on ore going to the mill. This, in turn, lowers unit costs for the mill output. Also, since leaching boosts total recovery of values from the mineral resource, it also increases the tonnage of material that can be profitably mined. Stated another way, a supplemental leach operation expands the ultimate pit limits. The exact impact of leaching is site specific and depends on the relative costs and output of leach production and mill production.

Drilling and blasting is another area that may be impacted by leaching, particularly when a mine-to-leach operation uses ROM ore. The drill-and-blast pattern must be designed to give a well-fragmented product with minimal quantities of oversized rock, about plus 200–250 mm (8–10 in.) top size. The powder factor also requires control to avoid generation of excessive amounts of fines that could cause permeability problems in the pile. The well-fragmented product should stack and percolate well while providing good mineral exposure needed for effective leaching. Because rock characteristics are very site specific, costs for an optimized drill-and-blast program that gives the desired as-mined leach product may need to be compared with costs for a low-cost drill-and-blast program that includes primary crushing to produce material for leaching.

Leach Systems

Heaps and dumps are by far the most common types of surface leaching operation. There are two types of heap leach systems to consider: a permanent multilift system and an on/off single-lift system. Each has advantages and disadvantages.

Permanent Multilift Leach System

An advantage of the permanent multilift system is that it minimizes material-handling costs. After a lift is leached, fresh ore is stacked over the spent ore. If the original lift is leached to exhaustion, an interlift liner can be used to separate the old and new ore. This prevents high-grade leach liquor from percolating down into the old material where it will be diluted by the residual moisture in the heap. However, in most cases, the original lift still contains residual metal values that can be extracted. In this case, no interlift liner is used and the solution percolating down through the new ore continues through the original lift, recovering additional metal. Stability issues and installation costs require additional consideration when employing interlift liners.

A disadvantage of the permanent multilift system is that the base of the heap must be impervious to solution flow to avoid contamination of the environment and avoid loss of metal-bearing solution. As a result, the lined-pad area must be expanded as the heap footprint grows. At the end of operation, the lined area must be sufficient to contain the entire leach ore output. A related problem is that loading will develop at the base of the heap as additional lifts of ore are added. This may compact the lowest ore and cause permeability problems at the bottom of the heap. The result can be development of a perched water table within the heap, causing solution to break out at intermediate heights or even heap instability. Even in

the absence of permeability problems, the amount of residual moisture in the heap system increases as ore tonnage in the heap increases. This residual moisture typically varies from 6% to 12% of the ore's dry weight, increasing as ore size becomes finer. This moisture contains soluble metal values that were extracted from the ore but are not available for recovery. Thus, they represent in-process inventory and must be taken into account when forecasting production. These in-heap metal values will not be recovered until the operation is closed and the heap system is given its final rinsing as part of the closure exercise.

On/Off Single-Lift Leach System

The on/off single-use leach pad is typically used for ores that leach quickly or have serious permeability problems. The size of the lined pad area is fixed and is much smaller than that for a permanent multilift system. Ore is stacked on the pad, leached to exhaustion, rinsed, and removed to a permanent impoundment. Thus the pad must be large enough to hold material being stacked, leached, and off-loaded, and some additional area must be available for loading or to provide some flexibility in the leach cycle. If the residual ore is not acid-generating, the impoundment area may not require a liner. Because of the rinsing and small active ore volume, in-heap inventory is not a serious issue.

An on/off pad has two major disadvantages. One is the cost of double-handling the ore, once to stack it and once to remove it to the residual impoundment area. The other is the lack of opportunity to recover any values remaining when the leach cycle is complete and the spent ore is removed.

Alternate and Variant Leach Systems

Some alternatives or variations on these systems are appropriate for special circumstances.

Dump leaching is equivalent to a permanent multilift system but involves low-grade material handled in ROM condition. It is subject to the same issues as is the permanent multilift system.

Sand–slime separation is an alternate means for handling ore with a high fines content. Separation typically is done at 2 mm (10 mesh). The coarse fraction can be heap- or vat-leached and the fines can be agitation-leached in some type of countercurrent system. This circuit is currently in use at the Tintaya mine in Peru, where the coarse fraction is heap-leached and the fines are agitation-leached. It was previously used at the Ray mine (Arizona, United States), where the coarse fraction was vat-leached and the fines were leached in air-agitated Pachuca tanks.

In-place systems represent a special case of materials handling, intermediate between surface heap and dump leaching and in-situ mining. Broken or rubblized material is leached more or less in place. In-place leaching clearly involves no loading or hauling of broken ore to heaps or dumps. However, unlike in-situ mining, in-place leaching still relies on downward percolation of solution through unsaturated leach material. (In contrast, in-situ mining is characterized by pressure-driven solution flow in a saturated medium).

In-place systems are so site specific that discussion is limited to brief descriptions of a few commercial operations. Although broken uranium ore has been leached in underground settings, copper appears to be the main target to date. Probably the largest-scale operation was undertaken by Ranchers Exploration and Development Corporation when they drilled and blasted the entire upper portion of the Old Reliable mine (Arizona) ore body and then acid-leached the rubblized zone in place (Longwell 1974). Technically they were able to fracture and rubblize the ore, but leaching yielded less copper and produced a solution that was lower in copper concentration or tenor than expected. Thus the project was not the commercial success that was hoped for (Catanach et al. 1977).

Pit-wall leaching has yielded greater success. It involves progressive rubblization and leaching of abandoned pit walls. Since most porphyry ore bodies contain a halo of low-grade mineralization around the economically mineable zone, pit-wall leaching often recovers a portion of the copper that is otherwise left behind. Examples of pit-wall leaching include the Mineral Park and Silver Bell mines in Arizona. Examples of underground leaching of broken, remnant ore left behind in block-caving operations include the El Teniente mine in Chile and the San Manuel mine in Arizona.

Ore Preparation

Material scheduled to go to heaps or dumps can be handled in ROM condition or prepared for leaching by crushing, with or without agglomeration. Size reduction should be undertaken when the increase in production achieved with finer product generates sufficient incremental revenue to cover the capital and operating costs for crushing. In general, low-grade mine waste that must be removed to expose mill-grade ore does not merit much extra material handling or preparation. Such material is often dumped in ROM condition at locations that minimize haulage costs rather than maximize leach output. However, there has been a move to optimize at least the dump profiles to enhance recovery. Then the dump is leached to recover some of the values that would otherwise be lost.

Agglomeration

Agglomeration is widely applied in precious metals operations. It can provide at least two benefits:

1. Agglomeration provides strong, porous, and coarsely sized material that otherwise would be unleachable because of poor percolation characteristics when placed in heaps. This is particularly true when at least 10% of the material is finer than 420–500 μm (35–40 mesh). Such conditions usually lead to low metal extraction because of slow and uneven percolation (channeling) of solution and development of impermeable (dead) zones within the heap or dump. Clays are probably the leading source of fines, although fines produced by poor crushing practices are undesirable as well. Even tailings can be agglomerated and subsequently heap-leached, as was done for uranium–vanadium recovery from salt-roasted tailings at Naturita (Colorado, United States) (Scheffel 1981).
2. Agglomeration uniformly blends the lixiviant into the crushed ore. Leach reactions have a chance to start before the ore is even placed on the heap, which provides for quick release of metal values and high PLS grades. However, experience indicates that agglomeration is likely to have little or no effect on the final extraction level.

Agglomeration follows one of two pathways: it causes either adherence of fines onto coarser particles or conversion of fines into stable pellets.

For gold and silver, important process parameters include quantity of binder (typically 5 kg/t or 10 lb/st), moisture content (10% to 20% of total), and agglomerate

curing period (≥8 hours). Since the subsequent cyanide leach requires alkaline conditions, binders are typically lime or portland cement. These binders generally have two important properties: (1) clay permeability is improved by the exchange of sodium ions in the clay with calcium ions in the binder, and (2) the binders have a cementing or pozzolanic effect that strengthens the agglomerates. Leach extraction rates can also be accelerated by using a barren cyanide solution as the source of moisture.

For copper ores and other materials that use an acidic lixiviant, the purpose of agglomeration is often primarily to make the ore acidic. The acid-cure dosage is normally less than half the amount of acid consumption expected for the particular ore. A higher dosage does little to improve extraction but raises the amount of acid consumed by gangue mineralization. In addition to accelerating the initial release of copper, acid agglomeration prevents a high pH in the initial drainage from the heap—that is, the PLS. If the pH is higher than 3.5 to 4.0, copper can precipitate from solution and be difficult to resolubilize.

Other process parameters include feed characteristics (particle size and presence of fractures), process control, and equipment selection (Milligan 1984; McClelland and van Zyl 1988). For gold and silver, the most popular types of agglomeration equipment are belts, drums, and pans. For copper, the most popular type is the drum, which thoroughly blends the acid and water throughout the ore charge. To save on capital costs, however, acidulation is sometimes achieved by spraying acid on the ore while it is transported by conveyor belt, although significant blending occurs only at the conveyor drop points and transfer stations.

Alternate Methods

As an alternative to agglomeration, some operations perform sand–slime separation as described in the previous section. For dump leaching, size reduction is generally not accomplished unless primary (in-pit) crushing is performed so that the material can be transported and stacked by conveyors. For heap leaching, primary, secondary, and tertiary crushing are often used to produce a final product that is nominally 25 to 12.5 mm (1 to 0.5 in.). Screening requirements depend on the nature of the ore, extraction sensitivity to crush size, and equipment manufacturer recommendations. Modeling the crushing circuits based on the various rock properties can enable selection of the optimum equipment configuration.

Ore Emplacement

How material is stacked for leaching—how it is emplaced—is a major factor in the success of a surface leaching operation. The approach to emplacement represents a principal difference between dump leaching and heap leaching.

For dump leaching, dumping practices reflect topographic constraints and efforts to minimize haulage costs. Consideration of leach recovery is usually limited to practices such as waste segregation, modification of the heap profile, and dump-surface preparation. Segregation usually involves efforts to avoid mixing barren or mineralogically unleachable materials into the leach dumps. Surface preparation before addition of the next lift is typically limited to leveling and deep ripping to break up the compacted zone associated with the truck traffic pattern. However, dump profiles can be adjusted to enhance leach conditions. For example, sulfide leaching normally requires some type of aeration, and dump dimensions can often be adjusted to enhance natural convective airflow through the rock mass. Optimization of the profile for different conditions has been modeled extensively and provides a guide to dump design for a particular ore.

Waste dumps are often high to minimize haulage costs; elevation differences of 90 to 230 m (300 to 750 ft) between toe and crest are common. This profile exacerbates two types of segregation:

1. Size segregation, which occurs when ROM material is dumped over the crest. This allows the coarsest material to slide or roll to the bottom while the fines tend to remain at or near the crest. As a result, the least permeable and most easily compacted zone of material is found at the top. Leach solution then percolates slowly and unevenly at the top of the dump and tends to channel and short-circuit through this layer. These poor percolation patterns normally persist at depth so that a significant volume of material in the dump is leached poorly if at all. The presence of leaching material below the sloping face may also be a problem.
2. Layer segregation, which creates alternate layers of coarse and fine material that lie parallel to the angle of repose. The coarse zones act as conduits and carry the bulk of the lixiviant flow. Hence they are usually well leached in spite of their large particle size. In contrast, the fine material has a low permeability and so undergoes little solution penetration or leaching unless proper solution management practices are followed.

These factors in waste emplacement are responsible for the generally poor extractions observed in waste dumps. For ROM material, recovery of metal values seldom exceeds 50% after many years of leaching. Only 10% to 15% extraction during the first 1 or 2 years is not uncommon, at least for copper sulfide dumps.

For heap leaching, careful emplacement of rock is important to maximize extraction of values. This generally involves construction of much shallower lifts, typically 3 to 10 m (10 to 35 ft) high to minimize size segregation. A further way to minimize size segregation is to use crushed or agglomerated ore. In turn, solution percolation is more uniform and solution-rock contact is improved, resulting in faster and more complete metal recovery.

Several additional approaches to heap construction, described by Muhtadi (1988), warrant consideration due to their widespread use. Foundation requirements are covered later in the "Environmental Aspects" section.

Truck dumping and dozing. Emplacement by means of truck dumping and dozing is essentially as described previously for waste dumps. However, more care must be given to emplacement of material. Typically, a ramp of waste is constructed to the height of the first lift. Ore is dumped from the end of the ramp down onto the pad or foundation of the heap. As ore builds up, the heap extends away from the ramp. To minimize compaction, an elevated roadway can be extended as the heap expands, with haulage trucks restricted to this path. When the heap is completed, the roadway is dozed off and the surface of the heap is graded and ripped to ensure good permeability and uniform percolation of solution.

In general, this method of heap construction is restricted to ores that do not undergo compaction or generate fines. This requires a strong, competent material handled either in ROM or crushed condition. Agglomerated materials cannot generally be handled by truck dumping, as they are too soft and friable. In addition, truck dumping still causes coarse/fine segregation.

Plug dumping. Emplacement by plug dumping also involves trucks but is not characterized by the rough handling noted previously. Hence it is suitable for softer ores and agglomerates. The first step is to bed the liner or foundation with crushed rock as a protective measure to ensure liner integrity. Then each haul truck dumps its load as closely as possible to the previously dumped pile until the entire pad is covered with overlapping mounds. The maximum heap height is about 2 to 3 m (7 to 10 ft), slightly less if a dozer is used to level the tops of the mounds.

A variation of this method is to replace the trucks with large rubber-tired front-end loaders. These are very efficient and can stack material to heights of ≥5 m (16 ft) without the need to first bed the liner.

Conveyor system. Emplacement by conveyor stacking has gained widespread acceptance in heap leaching. The concept is not new, however. It started early in the 20th century when high-grade copper ores were bedded and removed from leach vats by means of a conveyor-tipper and a clamshell bucket on a traveling gantry crane, respectively. Indeed, one of the first stacking systems in gold heap leaching (Gold Fields Mining Corporation, Ortiz, New Mexico, United States) used a traveling bridge that spanned a reusable pad and used a moving tripper to continuously add ore to the face of the heap. Spent ore was removed from the asphalt pad by front-end loaders.

Now conveyor hauling and stacking of ore on heaps has evolved into a highly mobile operation. The front end of the system usually consists of a short fixed conveyor that receives prepared ore from a crusher, agglomerator, or a stockpile via a feed hopper. The conveyor transfers material to a mobile, radial-arm conveyor/stacker by means of a system of movable intermediate conveyor sections. The stacker has great flexibility and can bed the heap uniformly and without compaction to almost any height desired. Thus conveyor systems can handle anything from primary crushed ore to agglomerated tailings. For on/off systems, front-end loaders or bucket-wheel excavators are used to remove the leach residue.

SOLUTION MANAGEMENT

Materials handling and solution management are interactive, with rock preparation and stacking having a substantial effect on solution flow. For example, maximum recovery of metal values can be achieved only if the heap/dump design permits good distribution and collection of leach solution. The design must also provide for movement of air into the piled rock, as oxygen is needed as a reactant in solubilizing many values. Likewise, the rock must be broken and stacked so that the entire rock mass is accessible to solution percolating down from the surface of the heap or dump.

Nevertheless, after the rock has been prepared and put in place, there is little that an operator can do except optimize the way the leach solution is managed. Doing so accomplishes two things: (1) it transports the lixiviant to the mineralized values throughout the piled rock, and (2) it washes the solubilized values from the heap or dump to the recovery plant.

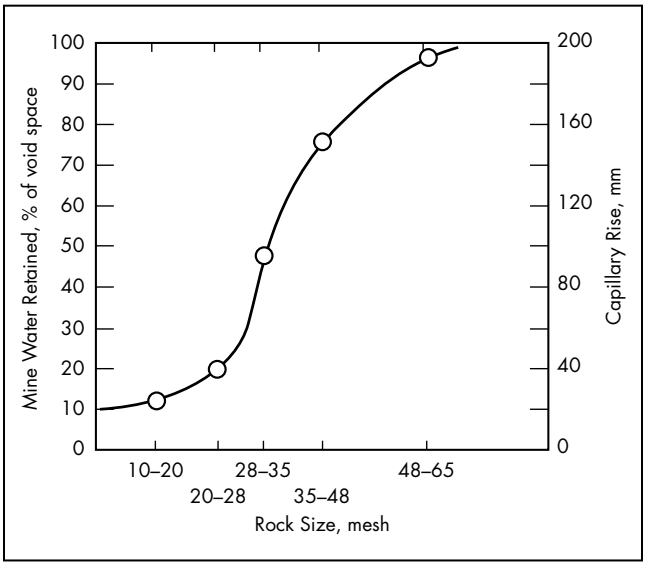
Fluid Flow Phenomena

Fluid flow phenomena include both static and dynamic aspects. The latter covers the optimum application rate and the potential benefits of leach/rest cycles and pulsed leaching.

Static Considerations

The first step in understanding solution flow through rock mass is to categorize the space within the dump or heap. There are at least three distinct regions:

1. Solid rock (including isolated pores). By far the largest, this completely stagnant space typically involves about 60% of the total volume.
2. Space associated with openings created by rock blasting and handling. This space exposes pores and creates fractures or cracks on the faces of the rock fragments. Generally only 2% to 4% of the total volume, nevertheless, this space greatly increases the exposed surface area and makes the contained mineral values more accessible to the lixiviant.
3. Void space that occupies the remaining volume within the rock pile. This space results from the swelling that is a consequence of rock fracturing and stacking during mining and handling. For newly prepared heaps, void space normally constitutes about 40% of the volume of the rock pile. This value decreases as weathering and leaching consolidate the material and typically drops to <30% if a mine dump is leached over a period of years.



Obviously, void space can be filled with either leach solution or air. However, because the water–rock interface has a lower surface energy than does the air–rock interface, all the pores within the rock fragments fill with solution. The rocks themselves are covered with water under conditions of percolation. The water-filled void space represents the area for active water flow. In contrast, mass transport within the water-filled fractures or pores occurs only by diffusion. A consequence of the difference in interfacial energies is the location of the air-filled void space. Under conditions of percolation, only the larger voids and channels contain air, and the smaller openings are flooded.

Except under conditions of flooding, competition between air and water for available void space is almost independent of the rate at which leach solution is applied. Instead, the controlling factor is the effective particle size of the rocks in the pile. This is a consequence of the limitations imposed by capillary forces. As shown in Figure 11.4-2, capillary rise or drain-down height is related to effective rock size. The figure shows the correlation between rock size and percentage of the total void space that remains filled with water after leaching ceases and drain-down is complete. At this point, capillary rise is balanced by the force of gravity, and only evaporation can further reduce the water-filled void volume.

The experimental results shown in Figure 11.4-2 are significant when ingress of air is needed to help solubilize the metal values. For material that is finer than ~320 μm (48 mesh), the pile does not drain down at all, and little or no air can penetrate the pile. For material that is coarser than ~2.0 mm (10 mesh), the pile drains down almost completely, allowing air to permeate throughout the heap or dump.

Dynamic Considerations

When leaching begins at a low application rate on a thoroughly drained dump, some additional air-filled void space

Source: Schlitt 1984.

Figure 11.4-2 Solution retention and corresponding capillary rise as a function of rock size

becomes water-filled at the solution–air interfaces. Flow then begins. As the application rate increases, the only change is to thicken the film of flowing water in the larger voids and channels where there is a solution–air interface. No substantial change in the volumes occupied by air and liquid occurs until the application rate increases to the point where the air-filled voids begin pinching off. When such bottlenecks occur, the open voids flood upward from the pinch points and the air-filled void spaces begin to disappear.

Experimental column data demonstrating this phenomenon are shown in Table 11.4-1. At typical application rates (4–40 mm/h or 0.1–1.0 gal/ft^2/h), there is considerable air-filled void space. Thus, adequate aeration should not be a problem unless the material being leached is very fine (e.g., flotation mill tailings).

Regardless of the application rate, the velocity of solution flowing through a water-filled void is controlled by the pressure gradient associated with the hydrostatic head and the permeability at that location. This relationship is expressed by Darcy's law:

$$V°_L = k/\mu\ (dp/dx) \qquad (11.4\text{-}12)$$

where

$V°_L$ = superficial velocity of the leach solution
k = permeability
μ = fluid viscosity
dp/dx = pressure gradient or hydrostatic head of the leach solution

Optimum Application Rate

From the standpoint of the leach operator, the maximum effective application rate (q_{max}) is limited by the zone of minimum permeability in the system under leach. This may be the bulk permeability of the rock pile. However, care should be taken to ensure that the solution application rate does not exceed the surface acceptance rate of the heap or dump. This is an important consideration because several factors can combine

Table 11.4-1 Effect of solution application rate on water-filled void space

Application Rate		Water-Filled Void	
mm/h	gal/ft^2/h	Space, %*	Comment
0	0	8.0	Drained
1.2	0.03	9.6	Capillaries filled
6.0	0.15	9.7	Typical range of rates
24.0	0.60	10.1	
120.0	3.0	10.3	
3,050.0	75.0	10.5	
4,070.0	110.0	27.6	Flooded

Source: Schlitt 1984.
*Expressed as a percentage of the total space within the rock pile.

to make surface permeability lower than the bulk value. These factors include the following:

- Accelerated decrepitation or weathering of the surface layer
- Breakup and compaction of the surface rock due to equipment movement, particularly haulage truck traffic
- Segregation of fine material at or near the top of the heap where dumping occurs
- Formation or accumulation of chemical precipitates such as gypsum or hydrated iron oxides due to evaporation and crystallization of the leach solution

Where surface permeability is lower than the bulk value, the application rate should be reduced to avoid ponding (surface flooding), which prevents air circulation into or through the rock. Ponding also provides ideal conditions for continued chemical precipitation that further seals the rock-pile surface.

To select the maximum effective application rate, the leach operator needs some knowledge of the permeability range in the system. This information is probably best obtained by performing one of the standard water permeability tests. Unfortunately, there is little published information on heap and dump permeability to serve as a guide. Limited field measurements on copper leach dumps suggest a value of q_{max} in the range 20–40 mm/h (0.5–1.0 gal/ft^2/h). Higher flows cause increasing amounts of water simply to short-circuit through the rock without recovering additional values.

The importance of controlling application rates is further demonstrated in Kennecott data for copper dump leaching (Jackson and Ream 1980). In a comparison of sprinkler leaching at 20 mm/h (0.5 gal/ft^2/h) and trickle leaching at 80 mm/h (2 gal/ft^2/h), sprinkler leaching produced 11% more copper and a 15% higher copper content in the PLS. Overall, 13% less water was pumped per pound of copper produced at the lower application rate, significantly reducing power costs per unit of copper produced.

Leach/Rest Cycles

Leach/rest cycles are a factor in solution management when the active lixiviant (such as ferric iron) is generated in situ. However, such cycles have little value when the lixiviant is delivered externally (such as by acid in the irrigating solution). For lixiviants generated in situ, when a volume of rock has been thoroughly wetted with solution, the lixiviant distributes throughout the rock mass. Then, during the rest cycle, dissolution of the values continues without further solution application. For lixiviants delivered externally, as soon as the externally

supplied reagent is consumed, leach reactions stop. Flow must resume supplying reagent before reactions can continue.

For appropriate ores, rest cycles can extend the economic life of older heaps and dumps, as they permit maximum recovery of metal values from material that was mined. Rest cycles also permit an operator to reduce costs by maintaining a limited flow of high-grade PLS to the plant. In both cases, the key factor is switching application of water from one leach area to another. While standing fallow, chemical and diffusional processes dissolve metal values and cause their concentrations to build up in the water-filled void space. Then a relatively short period of active solution application washes the solubilized values from the heap or dump. As an example, a 1-week leach cycle might be followed by a 4-week rest cycle. On older material, a longer rest cycle may be required to build up an economic concentration before washing.

Similarly, recycling barren solution to the oldest material first, then advancing the outflow to fresher material, reduces the volume and increases the grade of the pregnant solution being treated in the plant. This is sometimes referred to as *solution stacking*.

A third option is to reduce the irrigation rate progressively, which minimizes the solution flow when extraction is slow and helps to maintain a high-PLS metal concentration.

Thus, leach/rest cycles should not be overlooked as a way of optimizing a leach operation and minimizing pumping and facility costs.

Pulsed Leaching

Recent developments in vadose (unsaturated) zone flow (Breckenridge and Henderson 2005) may have application in situations where a heap or dump has a wide particle size distribution that includes a high fines content. Typically a leach dump would likely form a low-permeability zone that restricts leaching at higher flows. Under this condition, the capillaries are all filled and the strongest force is gravity, which leads to the familiar downward percolation of solution through the larger partially water-filled voids. However, as flow rate decreases, the point is reached where matric forces become dominant and most of the flow is via capillaries in the finer material.

Thus, for material with both coarse and fine sizes, leaching by cycling the irrigation rate between high and low values may improve recovery of metal values from the full spectrum of particle sizes, leading to higher overall production. For perspective, Breckenridge and Henderson (2005) give an example for a gold ore heap for which the high and low flows are 1.45 and 0.48 mm/h (0.036 and 0.012 gal/ft^2/h).

Production Aspects

The production aspects of solution management include the pumping systems and the pipeline requirements. Also covered are the types of equipment used to irrigate the heaps and dumps: either spray systems or drip emitters.

Pumping Systems and Pipeline Requirements

Selection of a pumping system depends on several factors: hydrostatic head on the system, line pressure needed to drive the solution distribution equipment on the leach surface, flow volume, and corrosion potential of the lixiviant. Because there are so many site-specific factors involved, only general guidelines are provided here.

In many operations, the recovery plant is located at a lower elevation than are the heaps or dumps. Thus, PLS generally flows to the plant by gravity in lined ditches or low-pressure pipelines. Any pumping from a heap or dump outflow or from a plant feed pond generally requires only a low-pressure horizontal pump, which can be mounted beside the pond with the pump intake suspended from a float in the pond to readily accommodate rising or falling water levels.

For the situation noted previously, recycling of barren (tail) solution back to the heaps or dumps requires a high-head pumping system, typically involving multistage vertical pumps. Pumps can be mounted on a fixed structure such as in a pump house where pumping is from a sump. Alternatively, they can be mounted on a barge and allowed to float in the barren solution pond.

If system pressure is not too great, flexible pipe or couplings can be used to tie the pumps into the shore-based pipeline system, allowing them to rise and fall with the pond level. The type of pipe is dictated by the elevation difference between the plant and the leach surface, plus the line pressure needed to drive the solution-distribution equipment on the heap or dump. The elevation difference can be as little as 30 m (100 ft) or as much as 600 m (2,000 ft). The latter requires sophisticated designs starting with heavy-walled metal pipe, shifting gradually to lighter schedules. The entire pipe system must be well anchored, yet allow for expansion and contraction due to temperature changes. In addition, the entire header system must almost certainly be higher than the 70–345 kPa (10–50 psi) pressure needed on leach areas, requiring installation of outlet stations on the main header line to serve as pressure-reduction points as well. When the pipeline profile and other flow parameters are defined, sophisticated computer programs can be used to aid in pipeline design.

Pipe materials must be selected with the chemical nature of the lixiviant in mind. For higher line pressures that dictate metal pipe, 316 L stainless is a frequent choice for acidic copper leach liquors that contain ferric and cupric ions. Polyvinyl chloride (PVC) or other liners have been tried on black iron or steel pipe, but the linings tend to deteriorate with time, particularly at joints, leading to corrosion and eventual failure at the joint. For alkaline solutions or concentrated sulfuric acid, black iron may be satisfactory. For lower line pressures, high-density polyethylene (HDPE) pipe has become the standard of choice. This is rugged, easy to cut and fuse in the field, resistant to scaling, and essentially corrosion-proof. PVC and other rigid plastic pipes may be less expensive but are not as rugged and tend to shatter. One of the few problems with HPDE pipe is its lack of rigidity: it twists and turns, and may require stakes or anchor blocks to keep it in place. However, this flexibility can also be an asset when routing the pipe during initial installation.

Solution Application Systems

As pointed out previously, careful distribution of solution on the heap or dump surface is required to optimize the leach operation. Development of such a solution management system requires a clear understanding of three concepts:

1. *Application rate,* calculated by dividing the leach solution volumetric flow rate by the surface area to which the solution is actually being applied
2. *Surface acceptance rate,* the maximum application rate that can be employed without encountering noticeable ponding on top of the heap or dump
3. *Irrigation rate,* a measure of the intensity of leaching, calculated by dividing the total volumetric flow rate by

the total area planned for leaching, including areas under active leach and areas that are being allowed to rest

For sulfidic copper minerals, typical irrigation rates are only 20%–25% of the application rate, and may be only 10% on old areas needing a long rest cycle. For gold, silver, and oxide copper, the percentages are much higher because the extraction rates are higher.

Only two classes of irrigation system are in widespread use today: spray or leach sprinklers and drip emitters. Pond leaching and high-intensity trickle systems have generally been abandoned, because their application rates normally exceed the optimum levels, leading to short-circuiting of solutions and dilution of values in the PLS. The desired application rate should be based on *q*.

Spray or sprinkler leaching devices include the following:

- **Sprinklers.** These are of two types: (1) rotating impulse sprinklers, which are much like typical "rain bird" agricultural sprinklers except that they are constructed of acid-resistant plastic or stainless steel for all wetted parts; and (2) Senninger wobblers, which are off-center rotary-action sprinklers that provide a coarse spray pattern to minimize evaporation. However, the off-center design creates a thrust problem, and wobblers must be staked down.

  Both designs provide a pattern of reasonably uniform solution coverage at an application rate of 20 mm/h (0.5 gal/ft^2/h), which is safely below *q*. With their own pressure regulators, wobblers are sophisticated enough to provide even lower rates (such as 12 mm/h or 0.3 gal/ft^2/h), the level typically cited as optimum for gold. Ranges of operating parameters for several types of sprinklers are shown graphically by Schlitt (1984) and are available in vendor literature.
- **Pressure emitters.** These are equivalent to drip-irrigation devices used in agricultural applications. They operate at low gauge pressure (100–140 kPa [15–20 psi]) and produce a steady seepage of leach solution that gives about the same application rate as sprinklers.

In spite of their similar delivery rates, each system has a number of relative advantages or disadvantages with respect to the following considerations:

- **Droplet impact.** Pressure emitters minimize droplet impact, reducing particle decrepitation and fines migration. This is particularly valuable when leaching soft, friable ore or agglomerates.
- **Winter weather.** Pressure emitters are effective even when buried. Thus they can be used in areas that experience severe winter weather and can cause sprays to ice up.
- **Wind.** Pressure emitters are immune to wind drift. Under extreme conditions, sprays may have to be shut down to avoid spreading acid or other chemicals beyond the boundaries of the leach system.
- **Evaporation rate.** Pressure emitters have low evaporation rates, only 1% to 2% of total flow, whereas spray losses have rates in the range of 5% to 10%. Which type has the advantage depends in part on a site's water balance. In dry areas where makeup water must be purchased, emitters are favored. In net precipitation areas, even on a seasonal basis, sprays are favored, since a high evaporation rate can benefit the water balance. In fact, special sprays called "foggers" are designed to maximize water removal by evaporation.
- **Blockage.** The major drawback to pressure emitters is the likelihood of blocking, or plugging, the small flow channels with precipitated salts. To avoid plugging, conditioning of the recycle solutions to prevent scale formation or remove suspended solids must receive careful attention. Conditioning can be done by means of settling ponds, filtration systems, or chemical additives.
- **Coverage.** Sprinklers give complete coverage of the top surface. In contrast, pressure emitters, which are actually arrays of point sources of water, create a conical volume of wetted ore below each emitter and leave some near-surface material unleached. For a permanent multilift system, this is not a serious issue, because any unleached ore will be wetted when the next lift is added and placed under leach. However, for a shallow on/off heap, as much as 10% of the ore can remain unleached.

Environmental Aspects

At least in the United States, obtaining the necessary environmental permits is probably the single most time-consuming activity in the development of a heap or dump leaching project.

Permitting requirements vary from state to state and may differ depending on whether the project is to be sited on private, state, or federal land. Because of these differences and constantly changing regulatory requirements, a detailed guide to the appropriate permitting process cannot be presented here. The best approach is usually to hire knowledgeable environmental consultants who practice in the area where the project will be located. These consultants should be quite familiar with applicable regulations and procedures and perhaps even know the local and state regulatory personnel.

Although specifics may differ from one site to another, regulatory agencies generally have two major concerns regarding surface leaching projects: (1) ensuring the safe handling of toxic chemicals and reagents, and (2) preventing contaminated runoff or seepage to groundwater. Detoxification of the heaps or dumps may also be a concern for all future operations and is already having an impact on the gold heap-leaching segment of the industry. However, groundwater restoration, a major factor for in-situ operations, has little impact on surface operations unless leaks have contaminated the subsurface aquifer.

Other environmental concerns are common to most mining operations. These include control of particulate emissions (dust) from the mining and any crushing or processing operations as well as topographic restoration to preexisting profiles and revegetation of mine and leach areas. Restoration activities usually have some sort of bonding requirements. In terms of costs, solution containment and heap or dump stability are the major considerations. Each is discussed in the following subsections.

Geotechnical Design

The design of piled rock structures that are stable under conditions of water flow, especially in seismically active areas, is a complex undertaking. Entire books have been written that address the necessary design features for both heaps (van Zyl 1987) and dumps (McCarter 1985). Because of this complexity, a detailed analysis of the problem cannot be presented here.

The first consideration is the method of heap or dump construction. Alternative methods involve use of reusable

pads, expanding pads, and valley dumping. Major requirements and considerations in each case are discussed by Dorey et al. (1988).

Reusable pads are best in terms of both containment and stability. This method involves a sloping base that is highly impermeable and can easily support the weight of a single shallow lift of ore. In the past, the base has been asphalt or even concrete. However, today a multilayer base with plastic liners over a clay foundation is more common. From an environmental point of view, the biggest concern is the integrity of the final impoundment area for the leached ore. This requires a properly designed retaining structure and one or more liners to prevent seepage losses of residual reagents. A monitoring system is also required to detect any leakage. Backfilling an abandoned pit area should not be overlooked for creating a possible containment site.

Expanding pads and valley dumping do not entail the material rehandling required with reusable pads. Rather, use of expanding pads involves periodic extension of the prepared heap foundation and liner system, which is then loaded with an initial lift of ore. This method is characterized by a gently sloping impervious liner that is overlain with a network of drainage pipes and a coarse drainage layer. The intent is to drain off the PLS as soon as it percolates down through the ore. Rapid removal minimizes the hydrostatic head on the liner to help minimize leakage. As more ore lifts are added, loading on the liner system can become an issue.

Valley dumping uses a natural or constructed retaining structure such as a ridge or dam located at the bottom of a canyon or valley. Ore is stacked upstream behind the structure in progressive lifts. Total land area required is usually less than that required for expanding pads, but lining the underlying surface can be difficult because of slope and terrain features. Solution containment for this type of system is addressed in the following subsection, while stability is covered here. In a true valley-fill system, such as that of Carlota Copper Company in Arizona, the PLS is retained within the heap system as a saturated zone. Submersible pumps then advance the collected PLS to the recovery plant.

Stability depends on a number of factors, including strength and slope of the retaining structure, load imposed by the stacked ore, and buildup of a saturated PLS zone at the foundation or elsewhere in the rock mass. The latter is critical, as more heap and dump failures have been caused by buildup of excessive pore pressure than by any other cause (Caldwell and Moss 1985). Without going into mathematical details, the reason for this is that pore pressure within a saturated zone reduces the shear strength and frictional resistance to movement of the stacked material. As pore pressure builds, especially near a free face, it can cause shear strength to drop below that needed to withstand the loading imposed by the rock mass. At this point, the structure fails, often catastrophically.

Solution Containment

An effective liner is the principal barrier to seepage loss. This is true not only for heap or dump foundations but also for catchment basins, flow channels (including ditches and trenches), and holding ponds. In addition, no containment system is perfect. Some seepage always occurs and can be measured by Darcy's law (Equation 11.4-12). The factors that control seepage are liner permeability and hydrostatic head. The engineer must design the system so that the expected seepage level is within environmentally acceptable limits.

Strachan and van Zyl (1988) cover liners in detail, including liner selection, system design, and installation. Selection is based on the type of application, nature of the solution to be contained, physical loading, and exposure to the elements. Liner materials include clays, clay or chemically amended soils, and geomembranes (PVC, Hypalon, HDPE, asphalt, etc.), used alone as single liners or in combination. When used in combination, the upper liner is usually a geomembrane and the lower one is a soil material. On double or triple liners, a leak-detection system is often installed in a porous zone between the layers. The topmost liner is overlain with drainage-collection piping and a coarse rock drainage layer. If a forced aeration system is to be used to boost the sulfide leach rate, then under-heap aeration piping should also be installed during construction of the leach-pad overliner system.

The use of systems that minimize seepage loss not only meet regulatory requirements, but also make good sense from an operational perspective. Even a small leak, if undetected, can cause a major loss in metal values and reagents over time. Such losses are equivalent to lowering the ore grade or getting poorer metallurgical recovery. In many cases, the dollar value of lost production can equal or exceed the cost of a good solution containment system.

COMMODITY RECOVERY SYSTEMS

Systems used to recover metals from heap and dump leaching operations are the province of hydrometallurgists. Although the recovery systems themselves depend on the lixiviant used in leaching, they are essentially independent of ore-emplacement or solution management practices. Thus the unit operations are commodity specific and covered in standard metallurgical texts and reference volumes. Current recovery systems are briefly described in the following subsections.

Copper

Historically, copper has been recovered as an impure metallic mud or "cement" by cementation (precipitation) on scrap iron. However, today, virtually all copper is recovered by means of SX-EW, a process that produces directly salable cathode copper at the mine site.

SX involves two stages. In the extraction stage, copper in the leach solution is transferred to the lean organic liquid at a low acid concentration ($\leq$10 or 15 g/L) and the two immiscible liquids are allowed to settle. The less-dense organic phase rises to the top and is drawn off. In the strip stage, the acid level in the lean electrolyte is much higher ($\geq$150 g/L) and copper transfers from the organic phase to the electrolyte. The rich electrolyte is then subjected to electrowinning to produce copper cathodes.

Gold/Silver

Pregnant solutions from gold/silver heaps and dumps are currently treated by either of two methods.

One method involves absorption on activated carbon granules packed in columns. The gold and silver cyanide complexes load on carbon, which is periodically stripped into a concentrated cyanide solution. The gold and silver are then recovered by electrolytic deposition from the strip liquor.

The other method involves stripping the gold and silver from solution as a sludge by means of zinc precipitation (the

Merrill–Crowe process). The precipitate is dried and smelted to produce doré metal for refining. Because carbon is less effective for silver than for gold recovery, high silver solutions are usually treated by the Merrill–Crowe process.

Uranium

The relatively low-grade leach liquors from uranium heaps and dumps are usually concentrated by ion exchange, then purified and concentrated further by solvent extraction. Yellow cake (U_3O_8 [triuranium octoxide]) is precipitated from the solvent-extraction strip liquor.

Nickel

As for copper, nickel and any by-product cobalt are normally recovered by SX-EW.

Solution Conditioning

The only potentially unusual feature of the various recovery systems is conditioning of the barren solution before recycling it to the heaps or dumps. Because most of these facilities must operate under conditions of zero discharge, use of a bleed stream to control buildup of undesirable impurities may not be possible. Thus, conditioning may be needed to control scale-forming constituents, remove potentially harmful impurities, replenish reagents that have been consumed, adjust solution Eh or pH, or simply make up the water lost to evaporation.

Conditioning is highly site specific and depends on the ore–lixiviant system, gangue reactivity, and even chemical makeup of the available process water.

Overall conditioning requirements for heap and dump leaching are less than for in-situ mining. This is due to the sensitivity of the in-situ formation to loss of permeability caused by suspended or precipitated solids building up and blocking the flow paths between the injection and recovery wells.

ANCILLARY AND INFRASTRUCTURE REQUIREMENTS

Ancillary and infrastructure requirements for surface leaching are much the same as for any open-pit mining operation. This is because leaching is merely the ore-processing operation associated with mining. The main requirements are for electric power, water, a transportation system, and access to a sufficient labor force. Fuel (e.g., natural gas) is not a concern, as there are generally no large furnacing or other heating operations. Building heat, small precious-metal furnaces, and driers can easily be fired electrically or with bottled gas if a natural-gas line is not available.

In general, ancillary and infrastructure requirements are lower for primary heap and dump leaching operations than for mine-and-mill operations. Leaching plants are thus well suited to operations that are small or remotely located.

Site Requirements

A mine-and-mill operation requires a rail line, heavy-duty haul road, or both to move ore from the mine to the mill and concentrate from the mill to a smelter. In contrast, a leach operation requires merely an all-weather access road, since shipping is limited to receipt of reagents and other supplies and shipment of small tonnages of crude or refined product. Acid trucks or similar vehicles are likely to be the largest units entering or leaving the plant on a regular basis.

Labor Requirements

Labor requirements are lower for leaching operations than for conventional mills, as most workers perform actual mining activities. Exclusive of mining, labor requirements for a leaching operation should represent no more than 15% of the direct operating costs. Thus, much of the work force can be recruited locally, even in rural areas. However, a camp arrangement may still be required at very remote sites. Specialized services such as instrument and computer-system maintenance or even assaying may have to be done on a contract basis.

Power Requirements

Power requirements vary widely, depending on the type of operation.

Gold plants generally have low requirements, mainly for pumping relatively small solution flows and running small heaters and furnaces. Many remote gold plants use diesel generator sets or other types of on-site generation, as power so generated is cheaper and more dependable.

However, large copper leach operations are power-intensive. With flows as high as 3.2 m^3/s (50,000 gpm), water-distribution systems may include multistage pumps with 37.5–110 kW (500–1,500 hp) motors. Copper electrowinning is also power intensive, requiring at least 2.2 kWh/kg Cu (1 kWh/lb Cu). Power is therefore usually purchased from a utility company. This purchased power is a big factor in the operating costs and the operation may incur a high capital cost if an extensive pole line with transformers, rectifiers, and substations is required.

Water Requirements

Water requirements vary according to operational stage. Start-up requirements are relatively high, principally because the various catchment basins and recovery-plant feed and tail-water reservoirs must be filled. The heaps and dumps must also be saturated with water before flow occurs. This represents a significant solution inventory, since the rock mass retains 8% to 12% moisture by weight, which is about 13 L/m^3 (0.1 gal/ft^3) of the heap or dump material.

Steady-state requirements are relatively low, because they cover only evaporation and other miscellaneous losses. Since most plants must operate under zero-discharge permits, no net makeup is required to compensate for bleed-off. The exact makeup requirement generally varies seasonally with the local evaporation rate. For copper in the southwestern United States, a typical annual average figure is 35 to 50 L/min/t (10 to 15 gpm/st) of daily production.

CHAPTER 11.5

In-Situ Techniques of Solution Mining

John I. Kyle, Douglas K. Maxwell, and Breanna L. Alexander

INTRODUCTION

In-situ solution mining is the selective dissolution and recovery of target mineral(s) without the use of conventional excavating techniques. Instead, the minerals are dissolved where they reside within the ore body. The dissolved mineral solution is then pumped to a processing plant located on the surface, where the desired metals are produced for market. This method can be considerably more economical than conventional mining methods, because massive tonnages of gangue materials are simply left where they exist, resulting in elimination of waste handling efforts, tailing piles, and waste brines.

More importantly, low-grade deposits can potentially be economic, because solution mining typically is cheaper than conventional mining methods. Additionally, through careful engineering, drilling, and monitoring, in-situ mining can have a greatly reduced environmental impact compared to mining by conventional methods. Mineral commodities exploited by in-situ techniques include salts such as sodium chloride, potash, magnesia, soda ash, borates, sodium sulfate, and lithium, as well as metals such as uranium and copper.

Deposit Characteristics

The primary requirement for in-situ solution mining is that the ore body has amenable characteristics to allow the lixiviant (the dissolving fluid employed to extract the valuable mineral) to come into contact with the target mineral throughout the ore body in sufficient quantity that an economical recovery rate of the mineral can be achieved. Beyond this requirement, metallurgical and ore host issues must be acceptable so the mineral can be leached from the ore. The deposit may have characteristics that prevent efficient leaching in a sufficient time frame. The general category of minerals where in-situ solution mining has proven to be economically successful includes both salts and metals.

The two main types of deposits associated with soluble salts are evaporites and brines. Evaporites may be classified as either marine or alkali; both types accumulate as a result of concentration through the evaporation of inland brines. Natural brines may occur as surface or subsurface deposits and are often associated with playas.

Marine Evaporite Deposits

Marine evaporite deposits are typically impermeable and located in large plastic salt domes. Often, they are found in a series of horizontal beds and in anticline deposits. Some deposits are hard to mine from a conventional perspective because of the deposit depths and the plastic behavior of the salt under stress. These deposits, however, can be quite attractive for a solution mining application. Marine deposits mirror seawater composition to a degree, which has about 31% sodium, 4% magnesium, 1% calcium and potassium as cations, and 55% chlorides, 8% sulfates, and less than 1% bicarbonate as anions. Therefore, halite, sylvite, and sodium sulfate are commonly found in marine deposits.

Alkali Evaporite Deposits

Alkali evaporite deposits are typically found in inland seas such as the Great Salt Lake in Utah and Searles Lake in California (both in the United States), and the Dead Sea in Israel/Jordan. Evaporation of an inland sea leads to formation of a playa or salt bed. If the salt bed formation is followed by geological burial, then a subsurface alkali basin is formed. Typical deposits that are mined include halite, potash, trona, borates, sodium sulfate, lithium (as lithium chloride), and soda ash.

Natural Brine Deposits

Brine occurs naturally as surface brine, such as in the Great Salt Lake or the Dead Sea, and as subsurface brine, such as at the Hector deposit in California. The Searles Lake deposit has both surface and subsurface brines at various times of the year. Where groundwater or surface water runoff congregates in a depression, subsurface brines typically exist in the permeable matrix below the depression. The water percolates through the depression or playa, dissolving water-soluble salts along the way. The salt-laden water then flows to a location where it is stable, creating a surface or subsurface brine deposit.

Metal Deposits

For metal deposits, in-situ leaching has been successfully employed in sandstone-hosted uranium deposits. The characteristics of these ore deposit types are discussed in depth later in the chapter, but in-situ recovery production for uranium requires ore within the water table so that a regime can be employed to move fluids through the sandstone in order to extract the uranium from the host rock.

Solution Mining Methods

Mining Impermeable Salt Deposits

Impermeable deposits are typically mined by introducing hot water or other solutions into the deposit to create a cavity. The formation of the cavity through dissolution of the target mineral produces a salt brine containing the mineral. The brine is pumped from the cavity to the ground surface where it is processed further in a plant to achieve the desired marketable product. Prior to the creation of the underground cavity, the potential for the collapse of overlying rock into the cavern must be considered. Salt-solution mining operations must be designed and carried out with the structural integrity of the resultant caverns in mind. A layer of rock or salt (beam) must be designed and left intact above the cavern to support the cavern. The minimum thickness and dimensions of this beam are designed based on the characteristics, strength, and cavern dimensions within the salt structure and the overlying geologic structure above the cavern. The cavern dimensions can be monitored with sonar, and its volume can be estimated from continuously recorded mass balance readings during production of the salt.

In order to develop a salt cavern, a vertical hole is drilled from the drill collar to a point near the base of the salt formation. Coaxial tubing is then inserted into the drill hole to provide for flow of lixiviant brine, product brine, and blanket fluid. Lixiviant brine chemically bonds with the target salt to make the product brine, which is extracted to harvest the target salt. The fluid blanket is used as an immiscible surface that rides on top of the salt brines to control vertical cavern creation. Alternately, tubing is inserted side by side rather than in a coaxial fashion. In either case, the depth of injection for each fluid is set at an appropriate vertical point for the leaching method and cavern design being implemented.

Using the direct circulation leaching method shown in Figure 11.5-1, an initial cavity (sump or sedimentation cavern) is formed at the bottom of the drill hole, which may extend below the base of the target salt bed. This sump creates an area designed to collect insoluble material as it drops out of the salt matrix in the cavern above, as the salt goes into solution. Lixiviant, as fresh water or brine, is pumped into the cavern at a designed elevation at a calculated flow rate. A blanket fluid, selected to float on top of the other liquids, or compressed air is injected at the top of the forming cavern to maintain the roof elevation of the developing cavern and drive the dissolution process horizontally rather than upward. As salt dissolves, a density gradient forms within the brine. During start-up, the lower density solution flows to the top of the cavern, becomes more saturated along the way, and is pumped out at the top of the cavern. As the overall brine saturation increases, the brine production flow rate is also increased. This method allows for the formation of a relatively wide lower cavity.

After the sump cavity is formed, the fluid injection levels are adjusted so the lixiviant is introduced near the top of the cavern. In some cases, heat may be added to the system to assist in facilitating dissolution. The new lighter-density lixiviant spreads horizontally under the blanket and removes the target salt in the ceiling of the cavern. The saturated brine, or pregnant solution, is pumped from the lower cavity region to the surface for processing. There is no need for a blanket to protect the cavern floor, because the brine at this level is already saturated. Periodically, the tubing is raised upward in successive steps, thereby controlling cavern diameter and mining of individual horizontal cuts upward through the height of the cavern. This reverse circulation leaching method is also illustrated in Figure 11.5-1.

The lixiviant can be tailored to selectively dissolve the target salt while leaving behind undesirable salts. However, the remaining salt matrix can drastically decrease dissolution rates and in some cases can *blind off*, stopping fluid flow altogether. Selective lixiviant can be prepared by recycling spent product brine from an established processing plant. The blanket can be any material that is immiscible with the lixiviant and brine, and has a specific gravity less than the lixiviant and brine—for example, compressed air or oil. Typical cavities can be 80 to 150 m (87 to 164 yd) in diameter.

Depending on the ambient surface temperature, *salting out* may occur when a change in brine concentration, due to temperature change or brine influx, causes premature crystallization. This is detrimental in a situation where, as the production brine nears the surface, the temperature drops enough to significantly decrease the solubility of a salt, causing crystallization of a potentially desirable product before it reaches the surface. The salt then comes out of solution prior to plan, which causes production problems—whether in the product brine line within the well, the pipeline on the surface, or in any facility accepting the brine prior to processing. Conducting dissolution and bench-scale studies prior to implementation

of a plan in the field will be helpful in determining the overall design of the system to avoid (or deal with) salting out issues.

Mining Permeable Salt Deposits

Permeable salt deposits, such as occur below playas or partially dissolved salt deposits containing natural brine, are deceivingly simple to mine in situ. This method does not require a long period to establish saturated brine, because the natural brine is already at equilibrium. To extract the salt, a series of wells are placed within the salt deposit to inject brine being used as a lixiviant. This lixiviant flows through the salt deposit to a pump that is placed within a centrally located production well, so the product brine can be collected, extracted to the surface, and processed.

The flow rate of fluids extracted/injected must be carefully designed to achieve maximum production while avoiding short circuiting. This occurs when the recycle/injection brine is not allowed enough time to resaturate, thus not reaching the desired target salt content. This then results in a lower density than desired, and flow of the injection brine within the formation (or cavern in an impermeable deposit) is compromised.

It is important to understand the initial permeability of the salt deposit and the salt characteristics to ensure that the well field, well, and flow rates are properly designed for production operations. These types of production schemes can be employed to feasible depths based on economic conditions that are dictated by commodity price, mineral grades, capital costs, and production costs.

Mining Permeable Metal Deposits

Permeable deposits are those that have sufficient space between the particles or grains (pore space) to allow a lixiviant to be passed through the deposit so contact with the desired mineral can be accomplished. For example, where uranium is found in permeable sandstone, a lixiviant can be injected into the sandstone to allow the lixiviant access to the uranium particles so the uranium can be chemically attracted by the lixiviant for pumping to the surface and on to the processing plant. Often, sandstone of appropriate character will have a pore volume of 20% to 30%. To accomplish this, a well field is drilled with a number of injection wells and a much fewer number of production wells. Wells are drilled to surround a single production well that has been established within the ore body and are specifically designed and cased so that a lixiviant can be pumped into the injection wells. The lixiviant then flows through the ore body to the central production well, in which a pump is installed to control the movement of lixiviant from the injection wells to the production well.

In some cases, the deposit needs to be submerged within an aquifer so that solution flow can be controlled. Often, the aquifer will already be tainted because of the ore body's chemistry, but, nonetheless, there are groundwater issues to consider and manage. In more developed countries, regulations concerning in-situ mining are quite evolved, providing good guidance on acceptable operating practice. It is also of great value to have aquitards or aquicludes (an impermeable layer that prevents fluid flow) above and below the target ore body, which helps manage production solutions. Generally, the solutions are overproduced from the production well, so that an excess of solution is pumped from the production area of the ore deposit. This bleed is performed as a protective measure to capture all the production solution placed in the aquifer.

New innovations include modifications to standard vertical drilling methods. By employing practices perfected in the oil sector, inclined and horizontal drilling methods are now being considered. Production monitoring has also become much more sophisticated. This is achieved by using monitor wells to check for and identify possible loss in the production solutions within the aquifer. New process-control instrumentation and logic controllers can now be employed in the complete production system. These methods are of solid value in ensuring that the water supply and quality are properly managed at the site.

Mining Abandoned or Flooded Conventional Mines

When conventional underground mining methods have reached their feasible or economic limits, solution mining can provide for the additional recovery of minerals. These conventional mines are commonly established in bedded deposits that typically used a room-and-pillar (R&P) mining method. With this method, pillars of valuable ore are left to support the roof as the mining operation is conducted. Valuable ore left in the walls of the mining openings can be extracted by flooding the mine, thereby introducing a lixiviant to extract the ore. As solution mining is employed, it is essential to consider existing groundwater regimes, undesirable ore types, lixiviant flow paths throughout the mine openings, recovery of saturated brine, and any issues relative to induced subsidence of the natural ground layers if the pillars have already collapsed (or will collapse) as solution mining is implemented.

Whether the mine is flooded deliberately or by natural means, extraction wells are drilled into the lowest elevations of the mine, and injection wells are placed at higher elevations. Gravity does its work, with the more dense saturated brine collecting at the bottom of the mine from where the pregnant solution is pumped to the surface for harvesting.

Hydraulic Fracturing

Hydraulic fracturing is the process of expanding or creating artificial fractures around a well to enhance its permeability or the communication between adjacent wells. It is typically used where a section of the well is segregated, and a liquid such as brine, water, or oil is used to pressurize the target zone and induce high pressures, which will either extend fractures or generate new fractures. In the oil industry, acid has been used for decades to etch the fracture sides, while sand/glass beads have been included in the fracture fluid to prevent fracture closure when the hydraulic pressure is bled off. The fracturing system is dependent on inherent weaknesses, such as bedding planes, within the host structure; regional stress fields; and other geologic phenomena. Two of the primary difficulties of the technology are projecting the fracture propagation direction, intensity, and growth; and estimating the pressure requirements for successful fracturing. However, the technique has been successfully employed for several decades in the oil industry, and hydraulic fracturing has been shown to be a valuable technique.

SALTS EXPLOITED

Salt

Salt is mined utilizing three methods:

1. Conventional underground mining, which produces rock salt
2. Solution mining, which produces evaporated or vacuum pan salt
3. Solar evaporation of ocean or lake brine, which produces solar or sea salt

Desirable Geologic Conditions and Chemistry

Salt occurring in underground salt domes is typically exploited using a solution mining method. Many salt deposits have been found in a thick bed located 6 to 8 km below the earth's surface. The high temperature and pressure encountered at these depths allow the salt to flow in a plastic mass. With the salt having a lower specific gravity (2.168 for pure sodium chloride [NaCl]) than the surrounding rock, the salt naturally pushes upward to reach equilibrium near the surface. These salt domes are generally pure halite (the mineral form of NaCl), typically have a circular footprint in the horizontal plane, are 1.5 to 3 km (0.9 to 1.9 mi) in diameter, and extend for a vertical distance of 6,000 m (6,562 yd) or more. The deposits become more commercial when the top of the dome is within a few tens to a few hundreds of meters below the ground surface.

Mining Method

Salt dome deposits (impermeable-type deposits) are typically solution mined by employing multiple wells. Sometimes, hydraulic fracturing or lateral drilling is used to link several wells together within a well field, or *gallery*. Employing hydraulic fracturing technology has been successful and has greatly improved the competitiveness of mining operations by

- Enhancing the stability of underground openings by changing the cavity configuration (to eliminate the unstable "morning glory" shape) to a design based on hemispheres and ellipsoids, which increases the stability of underground cavities. This is quite beneficial in reducing the potential for subsidence at the surface;
- Cutting the costs related to brine generation by approximately 50%;
- Greatly increasing product extraction by roughly 40%;
- Reducing well maintenance costs by about 95%; and
- Increasing the well productive capacity by a factor of 10 (Feldman 2006).

Processing Method

Salt brine must be evaporated to extract the entrained salt values. With the proper climate and available land, this may be achieved through solar pond evaporation followed by further upgrading using flotation and centrifuges, much like the processes employed for potash. Alternatively, high-grade salt is obtained through vacuum pan evaporation. This process uses a series of three to five steam-heated multiple-effect evaporators in which a vacuum is pulled to lower the boiling temperature of the brine. Each successive evaporator has a lower pressure than the previous, and the superheated vapor proceeds through the series, helping heat the subsequent evaporators. In either case, before processing, the brine is often chemically treated to remove impurities that may yield a lower-grade product or cause scaling.

Production

Much of the brine produced through solution mining in the United States is never crystallized but is used directly by chlor-alkali plants in the manufacturing of such products as chlorine, caustic, and soda ash. When the desired product is food-grade salt, vacuum pan evaporation can yield fine-grained salt that is 99.8% to 99.95% pure.

Worldwide, the chemical industry is the largest user of salt, consuming about 60% of the total salt produced. Salt for human consumption takes up 30%, and the remainder goes to road deicing, water treatment, and other minor applications.

Potash

There is a long history of producing potash from brines collected from mixed salt deposits on the earth's surface. Commercial production at Wendover, Utah, dates from 1937 (Garrett 1996). Production of potash-bearing brines from underground deposits that had no prior conventional mining production began in the early 1960s. Potash has also been recovered from flooded conventional mines since the early 1970s. In 2008, construction began on another operation to deliberately flood and recover potash by solution mining from mines in New Mexico (United States) that were closed due to prior reserve exhaustion using conventional mining methods.

Desirable Geologic Conditions and Chemistry

Typically, the types of deposits exploited are natural brines and underground evaporite deposits. In many parts of the world, natural brine sources contain sufficient amounts of potash to justify commercial production. Some operations produce potash from brine lake deposits such as the Dead Sea, Searles Lake, and the Great Salt Lake. Natural surface evaporite deposits dominated by halite at Bonneville Salt Flats in Utah contain a brine with 2.5% (potassium chloride or potash [KCl]). Potash has been produced by solution mining from the generally flat-lying, bedded sylvinite (mixed KCl-NaCl) underground evaporite deposits found in North America, particularly in Saskatchewan in Canada, and in Utah and New Mexico. Some properties have been developed solely as solution mines, while others started life as conventional underground mining operations and have been converted to solution mining after cessation of traditional mining operations.

The chemistry of the salt deposits is important in both naturally occurring brines and in minerals. Naturally occurring brines containing potash are found in many locations around the world. The most common anion in those brines is chloride, but sulfate and other anions are known. The potassium levels are typically low (often less than 1% KCl), with sodium and magnesium being the most prevalent of the other metals.

The most commonly exploited mineral containing potassium is sylvite (KCl), which is found in the mineral sylvinite, a mixture of sylvite and halite. However, some leaching operations exploit carnallite ($KCl{\cdot}MgCl{\cdot}6H_2O$) for its potash content.

Mining Method

Solution mining for potash employs three of the mining methods previously discussed: (1) mining of permeable salts; (2) mining of impermeable salts; and (3) mining abandoned or flooded conventional mines.

Mining of permeable salts. This includes naturally occurring brines containing potash that are recovered from brine lakes, salt beds, and wells. Brine lake operations, such as those at the Dead Sea and Great Salt Lake, pump brine from the lake into a solar evaporation pond system. The pond system is either created from a portion of the lake bed or uses nearby shore land that is separated from the main body of brine by human-made dikes. Initially, the brine can simply flood the solar ponds through holes in the dikes, but pumping arrangements are necessary for continued recharge of fresh brine into the system.

The Intrepid Potash operation at Wendover, Utah, gathers brine from the Bonneville Salt Flats via a system of collection canals. Intrepid has a network of canals that extends for miles into the salt flats. About 3 m (10 ft) deep and 5 m (16 ft) wide

at the bottom, these canals are dug with hydraulic excavators to allow brine to flow to pumping stations near the solar evaporation ponds. Cantilever pumps are used to transfer brine from the pumping stations to the solar ponds. This system of canals is effective, but it requires constant and extensive maintenance. Intrepid Potash has also installed brine wells drilled into the salt beds. About 10 m (33 ft) deep, these wells provide a more constant baseload flow to the solar ponds than do the collection ditches.

Mining of impermeable salts. Underground evaporite deposits can be classified as impermeable-type deposits. Two operations, one in Saskatchewan and one in the Netherlands, exploit potash-containing salt beds by means of single hole—a combined injection and extraction well—without any other preparation. Large-diameter drill holes are drilled, and downhole, multistage extraction pumps are lowered to the bottom of the target leaching area. The leaching fluid is often pumped down the annulus, and pregnant brine is pumped up a pipe hanging in the center of the well. Some wells are designed to use parallel injection and production lines contained within a large casing.

Beds have been exploited at depths ranging from 1,400 to 1,700 m (1,530 to 1,860 yd) (Garrett 1996). Leaching begins at or below the bottom of the potash bed. These operations use a blanket or pad of an immiscible fluid floating on the brine in the cavity. The immiscible liquid limits the dissolution of minerals in the roof of the cavity, which causes the cavity to expand laterally. The cavity diameters typically grow to more than 100 m (109 yd) and may even reach 150 m (164 yd). Initial leaching is conducted with water to create an open cavity. Selective leaching, using saturated NaCl brine, leaves a matrix of salts that slows diffusion of the lixiviant into the bed and the brine out of the bed. The salt matrix also can blind off completely, preventing further dissolution.

Recovery of potash minerals from an impermeable type of deposit varies. Depending on overburden characteristics and thus well-field design, the mineable area becomes limited; extraction of minerals can be as low as 30% to 40% (strictly before processing.)

As reported by Garrett (1996), Kalium (now a subsidiary of the Mosaic Company) produces potash from a sylvinite bed about 9 to 15 m (10 to 16 yd) thick, at depths of up to 1,650 m (1,804 yd) in Saskatchewan. Formation temperature is 57°C (135°F), which increases solubility. Water is injected to dissolve both the potash and salt until the cavity is more than 100 m (110 yd) in diameter. As the cavity size increases, the large surface area allows selective leaching despite the slower diffusion rates. Annual production is more than 1,800,000 t/a (2,000,000 stpy).

BHP Billiton in the Netherlands exploits a deposit dominated by carnallite, with other salts that are bounded at the top and bottom with halite. The bed averages 100 m (328 ft) thick with depths of 1,400–1,700 m (1,531–1,859 yd). Directional drilling is used to create a *seven-spot* pattern of wells in the salt bed from a single drilling site on the surface. Both the leach solution composition and the flow rate must be carefully adjusted and maintained to ensure dissolution of the potash. Production is approximately 820,000 t/a (900,000 stpy).

The Potasio Rio Colorado project in Argentina, now owned by Vale Inco, proposes to use solution mining to produce up to 5.1 Mt/a (5.6 million stpy) of potash.

Mining abandoned or flooded conventional mines. There are many examples of such mines being exploited for solution mining operations. Texas Gulf developed a conventional underground potash mine near Moab, Utah, in the 1960s, which is now owned by Intrepid Potash. Before the solution mining was initiated, mining conditions were difficult because of methane problems, a weak roof, and an undulating ore body. After several years of R&P mining, a decision was made to flood the mine and operate it as a solution mine. Extraction wells were drilled into lower elevations of the mine, injection wells were placed at several higher elevations, and the mine was flooded with lixiviant through the injection wells. Saturated brine is pumped from the production wells within the mine to solar evaporation ponds for potash recovery.

The Potash Company of America's (purchased by Potash Corporation of Saskatchewan in 1993) Patience Lake mine in Saskatchewan was a conventional R&P operation that experienced repeated problems with major water inflows that closed the mine for 6 years early in its life. Eventually, this caused the company to abandon conventional mining techniques and convert the operation to a solution mining methodology in the late 1980s. A recovery well was located at the deepest point in the mine, and 10 injection wells were drilled into the old workings at higher elevations to establish the flow through the old workings.

In 2008, Intrepid Potash began a project to convert an abandoned mine in the Carlsbad, New Mexico, district to solution mining. The former Eddy Potash Company mine had been closed for many years after exhausting the resources available for R&P mining that it controlled on its leases. As with the mines previously described, extraction wells will be drilled into lower elevations of the old workings and injection wells drilled into the higher elevations. In this operation, because of the large surface area available in the old workings, the leach solution is proposed to be NaCl-saturated brine, to selectively leach the KCl from the pillars, floor, and roof of the old mine. Pregnant brine will be treated in a solar pond system.

Processing Method

Two basic approaches are employed to treat potash containing brines: solar evaporation ponds and evaporator-crystallizers. The low concentration of potash typically found in most naturally occurring brines makes solar evaporation pond treatment a necessity because of its low cost. The use of evaporator-crystallizers greatly increases the capital costs as well as the operating costs because of higher energy requirements. Solar evaporation ponds are limited to operations having locations with sufficient land area and suitable climate for the solar pond application. In northern climates, producers typically recover potash by crystallization rather than solar evaporation, because of low ambient temperatures.

The brines produced from the underground deposits may contain high enough concentrations of potash to allow the use of vacuum evaporators and crystallizers without pretreatment. This system has the advantage of being able to produce finished potash without need for further upgrading, but there is an increased cost in the form of additional energy requirements. When a potash product of sufficient grade is produced, regardless of the method employed, common operations include debrining in centrifuges, drying, compacting, and screening to produce the various market products.

As described, naturally occurring brines are universally processed by solar evaporation as a concentration step. Some brines containing relatively high concentrations of sulfate will be treated with lime to remove most of that anion. The

low-sulfate brine is pumped into a series of shallow, flat-bottomed ponds, which are often unlined and are simply lakes that have been divided or contained by dikes. The brine is sequentially transferred from pond to pond as the water evaporates and the concentrations of the contained salts increase. With careful monitoring, different salts will saturate and precipitate in different ponds. This allows operations, such as Searles Lake and the two Dead Sea plants, to make several different products. Evaporation rates vary with the environmental conditions, so solar pond operations are generally found in areas that enjoy warm, sunny, and dry conditions for long periods during the year. Rainfall is a risk, because high rainfall can slow production, and unusual rain events have even shut down operations for a year or more.

Generally, relatively pure NaCl is precipitated in one or more stages. Depending on location, this may be a marketable product, rather than a waste. When the potash approaches saturation in the brine, it is typically sent to harvesting ponds where the potash precipitates along with sodium chloride if there is little magnesium present. At the Israeli Dead Sea operation, the potash precipitates as carnallite. Harvesting ponds are typically constructed to have a 300-to-600-mm (12-to-24-in.) thick layer of hard NaCl deposited first to build a solid floor for the harvesting process and to protect the liners, if present.

A variety of methods are used to recover the precipitated salts from the evaporation ponds. Floating dredges are used in a few operations (Dead Sea Works), but dry harvesting is more common. In some dry harvesting operations, the salt mixture is plowed into windrows with graders, loaded with elevating scrapers, and hauled to a dump pocket. In others, specialized salt-harvesting machines dig up the salt or collect it from windrows and load it into dump trucks. The harvested solar salt typically contains 24% KCl and 75% NaCl. This material is commonly upgraded with froth flotation to produce a high-grade KCl concentrate. The concentrate is leached with a saturated KCl brine to remove the remaining NaCl and is then de-brined in centrifuges and dried. Potash for fertilizer or feed supplements is usually 93% or more KCl, which is also called muriate of potash.

Brines from underground mines are exemplified by the Intrepid Potash mine at Moab, where they are treated in a system of ponds similar to those for naturally occurring brines. However, the total area of the ponds at Moab is considerably smaller than the area at a natural brine operation with a similar production rate. This is due to the higher potash concentration in the brine from the mine. These ponds are also lined with synthetic material to prevent leakage into the local groundwater. Additionally, dye is also added to the brine in some ponds at Moab to increase evaporation rates. The dyed brine absorbs more light and heat than a clear brine over a reflective white salt bed.

The Patience Lake operation uses a pond to recover potash from the mine-produced brine, but by cooling rather than evaporation (Garrett 1996). The brine pumped out of the mine is warm and, when pumped to a pond near the plant, it cools by natural convection, especially during nighttime. Potash crystallization rates in this pond are highest in the wintertime as temperatures drop. This is one operation that recovers potash by dredging. The precipitation is fairly selective, and the dredged potash can be upgraded to market standards by leaching.

Some brines with high potash content from underground mines and some solar evaporation operations are treated by a combination of evaporators and crystallizers. Triple-effect evaporators remove much of the water from the brine and in many cases precipitate NaCl. The resulting slurry is separated and the salt is washed with potash brine to recover dissolved potash. The strong potash brine is fed to vacuum crystallizers where the potash is precipitated. Although these plants are compact, compared to the solar pond operations, the energy consumed in the evaporators and vacuum crystallizers results in higher operating costs. The potash from the crystallizers generally does not need further upgrading before it is dewatered, dried, compacted, and screened into final products. The brine from the crystallizers is recycled in the plant, but a bleed stream is generally required to eliminate deleterious elements.

The most prevalent waste product from potash solution mining is sodium chloride. In many natural brine operations, the sodium chloride is a co-product with the potash. In others, the sodium chloride can be returned to the brine source. Some of the salts associated with potash production, notably magnesium chloride, have virtually unlimited solubility in water. These will produce *bitterns,* which are brines of high concentration. Some bitterns can be treated and used as a source of magnesium chloride or even magnesium metal. In many cases, disposal of the bitterns is managed by returning them to brine lakes, deep-well injection, or storage in ponds.

Production

Worldwide consumption of potash was 52 Mt (57.3 million st) in 2005. Two-thirds of its production comes from Canada, Russia, and Belarus, with only nine other countries contributing to production. Primary consumers of potash include the United States, China, Brazil, and India. The most prevalent use of potash is as a fertilizer, primarily in the form of muriate of potash, KCl. Muriate of potash is also sold as an animal feed supplement.

Magnesium

Magnesium is found in about 60 minerals, of which only a few are of commercial value. The third most common element in seawater, it is found in deposits of magnesite and dolomite, and, in soluble form, in lake brines, mineral waters, and springs. Magnesium is produced from minerals, seawater, wells, and lake brines.

Desirable Geologic Conditions and Chemistry

Much like many other soluble salts of value, magnesium is produced from evaporites and brines. The brines are typically sourced from concentrated seawater, wells drilled into salt deposits, and concentrated inland salt lakes. In addition, brines are produced from saline aquifers, oil-field production brines, and mineral springs. In salt beds, magnesium is found in minerals such as carnallite found in New Mexico, kainite found in the Stassfurt mines in Saxony, Germany, or bischofite. The primary water-soluble magnesium minerals are shown in Table 11.5-1.

Mining Method

Solution mining of magnesium, practiced for decades, has been proven to have substantial advantages over conventional mining methods, given the right deposits. Heated water is used as the lixiviant and injected into impermeable deposits, as described previously in this chapter. Naturally occurring brine simply needs to be collected from the source. US Magnesium LLC uses

Table 11.5-1 Principal magnesium minerals

Mineral	Composition
Carnallite	$KMgCl_3 \cdot 6H_2O$
Kainite	$MgSO_4 \cdot KCl \cdot 3H_2O$
Bischofite	$MgCl_2 \cdot 6H_2O$

Table 11.5-2 Principal soda ash minerals

Mineral	Composition
Trona	$Na_2CO_3 \cdot NaHCO_3 \cdot H_2O$
Nahcolite	$NaHCO_3$
Dawsonite	$NaAlCO_3(OH)_2$
Thermonatrite	$Na_2CO_3 \cdot H_2O$
Natron	$Na_2CO_3 \cdot 10H_2O$

solar evaporation to concentrate natural brine from the Great Salt Lake prior to processing and production of magnesium metal.

Recovery is based on the ore deposit characteristics, the mining method employed, and the volume of nonproduct minerals such as alumina, silica, lime, and iron oxide.

Processing Method

The processing method varies by desired product. Magnesium hydroxide ($Mg(OH)_2$) is used to produce magnesia (MgO). Magnesium chloride ($MgCl_2$) can be used as is or further processed to produce magnesium metal. Magnesium can also be a by-product of other soluble salts such as salt, potash, and borates. Because of its very high solubility in water and other brines, magnesium is typically the last salt to precipitate in solar evaporation processes.

Magnesium hydroxide. Magnesium hydroxide is recovered from brines by precipitating the dissolved magnesium as magnesium hydroxide with the addition of dolime (calcined dolomite CaO·MgO). After precipitation of calcium carbonate, the product-bearing solution is treated with sulfuric acid to remove any remaining calcium bicarbonate and then pumped to thickeners where concentrated magnesium hydroxide slurry is generated. This slurry is then filtered to produce a filter cake containing about 50% solids. The filter cake is either directly calcined to produce refractory or caustic-calcined magnesia, or it is calcined and pelletized before dead-burning to produce the desired size and density characteristics.

Magnesium chloride. To recover magnesium chloride from brines, the brine is pumped to a series of solar evaporation ponds where water evaporates, thus concentrating the brine. Generally, the first salt to precipitate as the water evaporates is sodium chloride. Double salts containing potassium and magnesium precipitate next and, dependent on other factors, kainite ($MgSO_4 \cdot KCl \cdot 3H_2O$), schoenite ($MgSO_4 \cdot K_2SO_4 \cdot 6H_2O$), and carnallite ($KMgCl_3 \cdot 6H_2O$) can be precipitated. Sodium sulfate is then precipitated, while the final product to be precipitated from the brine is magnesium chloride.

Although magnesium chloride is a directly marketable product, it can be used to produce magnesium metal by feeding high-quality, anhydrous magnesium chloride to a direct-current electrolytic cell with a very high amperage to reduce the magnesium chloride feed to magnesium metal and chlorine gas.

Soda Ash

Egyptian writings mention crude soda ash (Na_2CO_3) as early as 5,000 years ago. Natrun, crude trona, has been used as a valuable resource well before 3500 BC from the Wadi Natrun lakes in Egypt. Although natural deposits are rare, soda ash has been historically obtained by leaching wood or plant ashes. The uses of soda ash as a cleansing compound and as a flux in the making of glass were eventually discovered, and these are now its primary uses.

In 1792, the Leblanc synthetic soda ash process replaced the leaching of wood ashes. In 1865, the Solvay process made the Leblanc process obsolete because Solvay was simpler and more efficient and its by-products were less difficult to manage. In the late 1930s, the discovery of the large Green River deposit in Wyoming made natural soda ash less expensive in the United States than the synthetic soda ash obtained via the Solvay process.

Desirable Geologic Conditions and Chemistry

Using natural soda ash deposits rather than synthetic generation of soda ash from salt and limestone is preferable because the synthetic process is usually more expensive and produces more waste. About 60 natural sodium carbonate deposits are identified globally, only some of which have been assessed. Natural soda ash deposits can be defined in two manners: solid evaporites and brines.

Solid deposits of trona mineral are found in the extensive Green River Formation in Wyoming and at Lake Magadi in Kenya. Sodium-carbonate-rich deposits, in the form of nahcolite and dawsonite minerals, are located in the Piceance Creek basin in Colorado (United States). Other deposits occur as trona in dry lakes such as Searles Lake in California. The Rift Valley of northeast Africa has a series of lakes and dry lake beds that contain both solid trona and brines of various minerals, such as Lake Natron in Tanzania and the Sua Pan deposit in Botswana. The principal soda ash minerals are shown in the Table 11.5-2.

The Green River Formation is host to the world's largest deposit of trona. It is believed that about 45 billion t (49.6 billion st) of soda ash resources can be recovered through mining processes. Bed thicknesses are typically greater than 1.8 m (6 ft) thick and occur as beds that are primarily trona or with trona and halite intermixed. The Green River basin contains geologic formations created by inland lake sediments with many saline minerals.

The brines of the Searles Lake and Owens Lake deposits in California contain a series of dissolved minerals of sodium, calcium, magnesium, and sulfur, and are said to contain about 740 Mt (815 million st) of soda ash. The nahcolite deposit located in the Piceance Creek basin of northwestern Colorado contains reserves estimated at 26 billion t (29 billion st). Solution mining was practiced by American Soda for 4 years but was halted in 2004 because of economic conditions. Other deposits, such as those in northeastern Africa, have been created by the carbonatite leaching of volcanic ash or lava.

Mining Method

The conventional in-situ solution mining method most commonly employed is to create a cavity within the target ore formation and use a blanket on top of the lixiviant to control the shape of the cavity. Different methods of hydraulic fracturing of the beds are also used to increase permeability within

Table 11.5-3 Principal boron minerals

Mineral	Composition	B_2O_3, wt%
Boracite	$MgB_7O13{\cdot}Cl$	62.2
Sassolite	$B(OH)_3$	56.4
Kernite	$Na_3B_4O_7{\cdot}4H_2O$	51.0
Colemanite	$Ca_2B_6O_{11}{\cdot}5H_2O$	50.8

Meyerhofferite	$Ca_2B_6O_{11}{\cdot}7H_2O$	46.7
Ulexite	$NaCaB_5O_9{\cdot}8H_2O$	43.0
Szailbelyite	$MgBO_2(OH)$	41.4
Inyoite	$Ca_2B_6O_{11}{\cdot}13H_2O$	37.6
Kurnakovite	$Mg_2B_6O_{11}{\cdot}15H_2O$	37.3
Borax (Tincal)	$Na_3B_4O_7{\cdot}10H_2O$	36.5

the formation. The average recovery, using solution mining techniques, is about 30%, whereas recovery with conventional mining techniques is about 45%. Techniques are now being investigated to improve this recovery percentage.

Mining operations began in the Green River basin in 1949 using conventional underground methods. As economic conditions changed, new methods were considered. For example, one operation, the Granger plant, was shut down as a conventional mining facility in 2001 because of poor markets but was reopened in 2005 employing a solution mining method.

Solution mining at the American Soda project at Yankee Gulch in the Piceance Creek basin injected adequately pressurized high-temperature (177°C to 216°C [351°F to 421°F]) water to thermomechanically fracture the nahcolitic oil shale and generate a bicarbonate liquor that was further processed on the surface. Ore-body depths were 670 to 800 m (733 to 875 yd), and the cavities were approximately 150 m (164 yd) tall with diameters up to 60 m (66 yd).

Trona and nahcolite ore are solution mined with aqueous sodium hydroxide and aqueous hydrogen chloride. After processing, the brine is regenerated in an electrodialysis cell before being returned to the solution mining cycle. After the trona is captured, it is clarified, filtered, recrystallized, and placed in a centrifuge to dewater the product. After this, it is dried and packaged or shipped in bulk to the market.

Processing Method

In cases where solution mining has been used, the pregnant liquor is a carbonate solution that has been carbonated to form sodium sesquicarbonate or sodium bicarbonate. In some instances, both carbonates are formed. These carbonates are then calcined to produce monohydrate or anhydrous sodium carbonate, depending on the required soda ash product. The extraction solution is then treated with slaked lime and water to produce a weak sodium hydroxide solution to recirculate back to the mine.

Borates

Although borates are commonly found, economic deposits only occur in the Alpine belt of south-central Asia, the Andean belt of South America, the eastern part of Russia, and the Mojave Desert in California. Most borate production is by conventional mining methods.

Several types of deposits are mined to produce specific products that typically have stringent standards. Approximately 70% of global borate supplies come from sodium borates produced in North and South America, while nonsodium borates are produced in Turkey. The primary borate minerals are shown in the Table 11.5-3. Borate deposits occur as natural brines and as crystallized underground deposits. Underground ore bodies may contain natural brine within void spaces.

Mining Method

Searles Lake employs permeable-type techniques to solution mine natural subsurface brines in addition to processing weak lake brines. The Fort Cady Minerals project in the Mojave Desert mines a deep permeable-type deposit consisting of colemanite ore beds permeated with naturally occurring brine. The deposit is situated more than 400 m (437 yd) below the surface, has an average thickness of 36 m (39 yd) that extends across 110 ha (272 acres) and appears to be completely encapsulated in clay. This encapsulation allows hydrochloric acid to be used as a lixiviant to further saturate the existing brine, allowing 50% boron content to be achieved. The operation is permitted for a production of 90,000 t/a (99,000 tpy) (Hartman 1996).

In-situ mining of an impermeable deposit was tested at the Kramer deposit in Death Valley, California, in 1948. This deposit was 72% borax with an 8.8-m (28.9-ft) thick layer at a depth of 107 m (351 ft). Water was injected at 102°C to 110°C (216°F to 230°F). The experiment ran for 38 days and leached 230 t (250 st) of borax (Garrett 1998).

Processing Method

Most commercial deposits have borax, colemanite, kernite, or ulexite as the primary boron mineral in the deposit. The chemical makeup of these minerals dictates the required different processing methodology. At Fort Cady, the leach liquor is sent to solar evaporation ponds where crude boric acid is crystallized or lime is added to precipitate synthetic colemanite, with the option to regenerate hydrochloric acid with sulfuric acid, for re-injection (Garrett 1998).

At the Searles Lake Trona plant, currently operated by Searles Valley Minerals, solvent extraction is used to recover boric acid from weak lake brines and produce anhydrous borax (Pyrobor) and borate decahydrate. The Searles Lake Westend plant manufactures anhydrous borax (Pyrobor), borax pentahydrate (V-Bor), and sodium sulfate. Borax production methods can be quite varied when the brines contain a complex of soluble salts. At Searles Lake, two processing methods are used: evaporation and carbonation.

In the evaporation process, the brine is evaporated to crystallize sodium chloride, licons, and burkeite, thereby saturating the potash. Rapid cooling then precipitates filterable potash. The property of slow borate crystallization assists in separation of the potash from the borates. The liquor from the potash recovery operations is pumped to crystallizers where the boron is recovered as boron pentahydrate. The sludge from the crystallizer is thickened, filtered, washed, repulped, and redissolved to prepare a liquor, which is sent to polishing filters and vacuum crystallizers to make a high-purity deca- or penta-hydrate, which is then carefully dried and prepared for market. Boric acid and anhydrous borax are also made.

In the carbonation process, the brine with high borax and sodium carbonate is loaded into the top of carbonating towers. It is then subjected to compressed flue gas, which is

Table 11.5-4 Principal sodium sulfate minerals

Mineral	Composition
Thenardite	Na_2SO_4
Mirabilite (Glauber salt)	$Na_2SO_4 \cdot 10H_2O$
Glauberite	$Na_2SO_4 \cdot CaSO_4$
Astrakanite (bloedite)	$Na_2SO_4 \cdot MgSO_4 \cdot 4H_2O$
Burkeite	$2Na_2SO_4 \cdot Na_2CO_3$

controlled with very fine bubbles and rotating screens from distributors in the base of the towers. Carbon dioxide causes sodium carbonate (Na_2CO_3) to convert to sodium bicarbonate ($NaHCO_2$), and since the latter has very low solubility in the brine, it crystallizes, further purifying the brine. The liquor from the carbonation towers is then sent to the boron vacuum crystallizers, where borax seed crystals serve as nucleation points for growth.

Sodium Sulfate

Sodium sulfate has been used for more than 5,000 years. Records show that thenardite was used in ancient Egypt to preserve mummies while later uses included soap production and a mixture for glass. Its many applications and convenient location in playas and lake beds has made it a common industrial mineral for centuries.

Geologic Deposits

Sodium sulfate deposits can range from very large to quite small. Deposits in the Gulf of Kara-Bogaz in Turkmenistan, Searles Lake, Laguna del Rey in Mexico, Great Salt Lake, Lake Kuchuk in Russia, and the Aral Sea in Central Asia fall into the large-deposit category. Some of the smaller deposits of glauberite or thenardite in nonmarine deposits are less pure than the larger deposits. About 95% of the global sodium sulfate production comes from the larger deposits, which employ more sophisticated processing plants.

Many of the sodium sulfate deposits are found in playas, saline lakes, or brine deposits that have been developed along with a complex of other salts. One would think that sodium sulfate deposits would be formed within a mixture of salts, but, because of the steep solubility curve of sodium sulfate, mirabilite selectively crystallizes during cool evenings to form a more pure deposit that can be quite massive. In many deposits, mirabilite is then further enhanced to produce thenardite, astrakanite, burkeite, or glauberite. The chemical formulas for these minerals are shown in Table 11.5-4.

Mining Method

Although conventional mining methods have been used, solution mining is also being employed on suitable projects. Typical lixiviant is injected at moderate temperature (around 40°C [104°F]) with the mining operations determined by mineral solubility rather than by a chemical methodology of extracting the desired mineral.

One of the world's largest glauberite–thenardite deposits is located in Spain where 2.5 billion t (2.7 billion st) of equivalent sodium sulfate has been estimated. These resources are located in the central Madrid and Tajo basins along with the northeast Ebro basin.

Quimica del Rey S.A., a subsidiary of Industria Peñoles, produces sodium sulfate from subsurface brines, which are pumped from the subsurface to the surface and processed to produce sodium sulfate. The spent brine is further treated to produce magnesium oxide.

Processing Method

Equipment used to process naturally occurring sodium sulfate varies widely and includes air-cooled ponds, spray pipes, spray towers, polished-tube coolants within agitated tanks, scraped surface coolers, multicompartment vacuum crystallizers, and growth-controlled vacuum or heat exchange crystallizers. Generally, all operations are quite different up to the point where the evaporative process begins.

The production of a pure product requires that a minimal amount of insoluble material remains in the brine and that other soluble salts be minimized as well. To accomplish this, the feed brine is filtered, and an intermediate crystal sludge is prepared and then washed. The evaporators must be thermally efficient, have high capacity, and be able to operate in an economic manner in order to hold down costs. Multi-effect evaporators should be used to ensure lower operating costs, and heat sources should be selected in order to provide for lower costs. The design should reflect the fact that uniform crystals produce a higher-quality product.

Lithium

Lithium carbonate production from alkali brines started in 1966 at Clayton Valley, Nevada (United States), by Foote Mineral Company, which has been producing lithium carbonate from brines ever since. This is the only primary lithium carbonate-producing plant in North America.

Three types of brines are usually associated with lithium deposits: continental, geothermal, and oil-field. Continental brines occur where the lithium content is mainly derived from the leaching of volcanic rocks. These brines vary greatly in regard to lithium content, largely as a result of the extent to which they have been subjected to solar evaporation in concentrated solutions in lakes. They range from 30 to 60 ppm in the Great Salt Lake, where the evaporation rates are modest and dilution is constant because of the high volume of fresh water inflow. Examples of subsurface brines are Searles Lake (a former location of lithium production), Silver Peak, Nevada (a current source), and the high-altitude salars in Bolivia, Argentina, Chile, Tibet, and China, where lithium concentrations can be very high.

Geothermal brines occur as small quantities contained in brines at Wairakei, New Zealand (13 ppm Li), at the Reykanes Field (8 ppm) and other areas in Iceland, and at El Tatio in Chile (47 ppm). The most attractive known occurrences are in the Brawley area south of the Salton Sea in Southern California. Large tonnages of lithium are contained in U.S. oil-field, brines in North Dakota, Wyoming, Oklahoma, east Texas, and Arkansas where brines grading up to 700 ppm are known to exist. Other lithium brines exist in Paradox Basin, Utah.

Lithium salts are produced from brine processed in both North and South America. Lithium salts crystallize out of solution after the precipitation of sodium, potassium, and magnesium compounds. In marine evaporites, the Li:Na ratio is generally equal to or less than a 0.0001:1 ratio due to natural concentrations of natural seawater. In contrast, the average lithium concentration in seawater is about 0.174 mg/L, or 0.174 ppm. In nonmarine evaporites, the Li:Na ratio is substantially enhanced.

Lithium deposits with higher lithium and lower magnesium concentrations are more economic than other alkali

evaporites (Bartlett 1998). The ratio of magnesium to lithium is a critical factor in recovery of lithium from brines. If the level of magnesium in the brine is too high, the evaporation rate is slowed and the lithium yield is reduced. The average magnesium concentration in seawater is about 1,200 ppm, or a Mg:Li ratio of 7,000:1, making recovery of lithium from seawater uneconomical.

Mining Method

Subsurface brines are produced from wells, whereas lake brines are simply pumped to solar evaporation ponds. The brines have high concentrations of chloride ions, which are corrosive to most common metals, so materials of construction for pipe and pumps are generally plastic, polyethylene, and stainless steel. In the past, these solar evaporation ponds were not lined. The evaporation of the brine produced a layer of salt that sealed the ponds. However, present operations have to consider liners to reduce leakage of bitterns and loss of solution. Characteristics of several lithium-contained lake brines are shown in Table 11.5-5.

The depth of the ore deposit, thickness of the zone with high lithium concentrations, and the permeability of the material are of primary importance to the successful extraction of brine from the deposit. Typically, in production environments, the subsurface solutions flow by gradient into the extraction wells. Experience has shown that if brines are pumped into these systems to accelerate the capture of the lithium, they typically short-circuit, which causes the production system to fail.

A driving factor for the production of lithium from brines is the evaporation rate in solar evaporation ponds. High rainfall, high humidity, and high altitude are all detrimental to rapid evaporation of the water and subsequent concentration of the salts in the starting brine. Based on the measured lithium content of the brines, recovery of lithium carbonate is typically only 50%.

During mining, there is limited potential for gas generation, with the exception of working with oil-field brines, which underlie deposits of oil and natural gas. Because of the association with petroleum products, these brines must be carefully handled. Caution must be exercised during lithium extraction so that combustible gases are properly vented.

Most, if not all, solution mining and solar-evaporation-based lithium carbonate operations have yet to start production, so little history is available on the final reclamation of lithium production operations. However, reclamation requirements will be similar to most salt production operations and most likely will require removal of any residual sodium chloride, potash, or other materials in the ponds, removal of the dikes and liners, and leveling the area for natural drainage. The groundwater status in the immediate area will also have to be addressed and the site recontoured and revegetated to regulatory standards.

Processing Method

The process used to obtain lithium carbonate (Li_2CO_3) is known as the lime soda evaporation process. Brine is pumped from the evaporite deposits as a naturally occurring solution with little or no recharge or makeup with fresh water from the operator. The brine then flows through a series of evaporation ponds. Sodium chloride is the first to precipitate and is often harvested from the first set of ponds in order to avoid either raising the height of the pond dikes or adding ponds as they fill with precipitate. The sodium chloride may also be a by-product that can be sold, if there is a nearby market. The next series of ponds produce a mixed sodium/potassium chloride precipitate that may also be recovered for reprocessing to separate the potassium chloride (potash or KCl) as a by-product. At this point, the lithium content is 40 to 60 times the original concentration of the evaporite brine. The bittern is further processed to remove the soluble magnesium and boron, if present. Though the boron is removed by solvent extraction, the magnesium is precipitated using lime. The magnesium hydroxide and magnesium sulfate are then settled and filtered. The final bittern may be further concentrated by evaporation or, if in sufficient concentration, is precipitated with soda ash. The lithium carbonate precipitate is then filtered, dried, and prepared for market.

The primary product from in-situ mining of lithium, which is followed by solar evaporation and precipitation, is lithium carbonate. Other products that can be produced are lithium hydroxide, lithium chloride, and mixed lithium-magnesium sulfates.

Table 11.5-6 summarizes the main lithium resources, recoverable reserves, and potential chemical grade lithium carbonate production to 2020.

METALS EXPLOITED

Uranium

Because uranium was recognized in the 1940s as having significant value in several applications, underground and surface mining were employed to recover this material in quantity. As the industry was founded in the western United States, ores were treated in a number of conventional surface milling facilities. In the late 1960s in Wyoming and Texas, the uranium industry pioneered the commercial use of in-situ acid leaching. In the mid- to late 1970s and 1980s, in-situ leaching (ISL)

techniques were largely perfected and proven to be economically feasible, and the technology became universally acceptable and employed in sandstone-hosted uranium deposits. At the same time, ISL techniques were also developed in the Soviet Union, utilizing similar approaches in slightly different geological environments. A few decades later, Australia also started to use the ISL technology for uranium recovery, and presently Kazakhstan is a major producer of uranium by ISL. The overall process of solution mining is now largely known as in-situ recovery (ISR).

Several types of uranium deposits are suitable for exploitation by ISL/ISR technologies. Of these, sandstone-hosted and paleochannel-type (as mined in Australia) deposits are amenable to ISR mining. These deposits typically occur as roll-front or tabular deposits and account for about 18% of known uranium resources. Ore bodies that can be economically recovered range in size from a few million pounds to hundreds of million pounds and are typically low- to mid-grade (0.04% to 0.15% U_3O_8), although higher grades are certainly possible. Typical uranium minerals in sandstone deposits include uraninite (UO_2), coffinite ($U(SiO_4)\cdot 0.5(H_2O)$) and carnotite ($K(UO_2)_2(VO_4)_2\cdot H_2O$). Often, vanadium that occurs with the uranium can also be processed and recovered. Conversion factors for uranium species are given in Table 11.5-7.

In the United States, the ISR of uranium from sandstone deposits started in the 1950s with research into the heap leaching of run-of-mine ores. Eventually, it progressed to working subsurface deposits of uranium when mining conditions were favorable. Generally, flat-lying deposits with groundwater within confined ore zones and with good permeability are necessary prerequisites. Economical ore zones can range from a meter to tens of meters thick. Good permeabilities are typically considered to be better than 0.5 darcys, but deposits with lower darcy ratings have been successfully operated. After the ore deposit is drilled to determine thickness and uranium content, maps are generated to depict the grade multiplied by the thickness in order to prepare a grade-thickness map

Table 11.5-7 Uranium species conversion factors*

Species	Multiply by
U to U_3O_8	1.1792
UO_2 to U_3O_8	1.0395
UO_3 to U_3O_8	0.9814
UO_4 to U_3O_8	0.9294
UO_2SO_4 to U_3O_8	0.7667
$UO_2(SO_4)_2^{\{2-\}}$ to U_3O_8	0.6074
$UO_2(SO_4)_3^{\{4-\}}$ to U_3O_8	0.5028
$UO_2(CO_3)_2^{\{2-\}}$ to U_3O_8	0.7196
$UO_2(CO_3)_3^{\{4-\}}$ to U_3O_8	0.6237
$UO_4\cdot 2H_2O$ to U_3O_8	0.8303
$UO_4\cdot 2H_2O$ to U	0.7041

*For example, 1 kg U is equivalent to 1.1792 kg U_3O_8.

(in Kazakhstan, a similar method is used to develop a *productivity* map, which shows metal per square meter) that is used to guide evaluation and planning exercises. The minimum acceptable economic grade thickness is determined by evaluating economics, including the depth of ore zones, price variations, and establishing what ore can be mined by in-situ techniques at that time after considering overall project economics. After this minimum is established, the ore resources exceeding this amount, if the ore bodies are of sufficient size, are included in the mining plan.

Because it is critical to understand the leachability of the target uranium ore zones, metallurgical tests are conducted. Simple bottle roll tests, or column leaches, can be used to obtain an idea of potential optimal leachability, but this needs to be followed by complementary groundwater studies to establish groundwater quality, permeability, and other in-place characteristics. The overall geologic framework must also be fully defined to understand the structural geology, fracturing, definition of confining layers for the target groundwater regime, and, of course, both valuable and gangue mineral

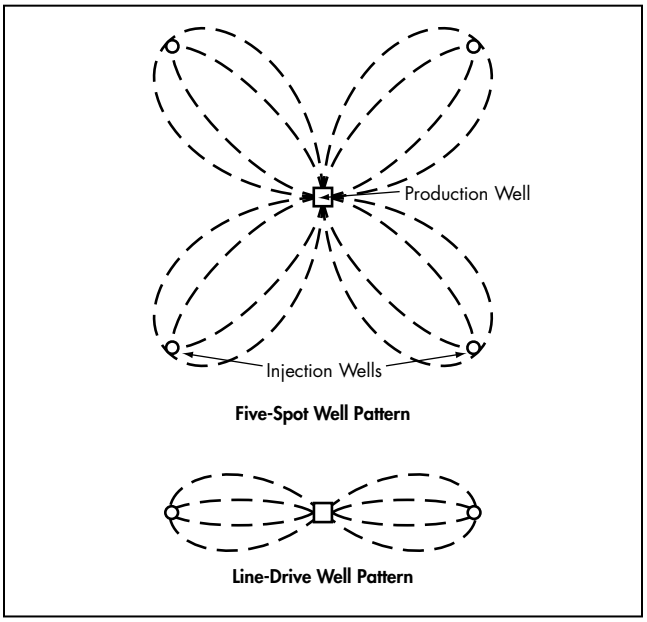

Figure 11.5-2 Well patterns

content. It may be necessary to conduct more in-depth mineralogical and metallurgical studies to define other constituents, types of clays, types of grain cement, and other items of interest. For example, titanium might be found, which is indicative of branerite; or clays or gypsum that create permeability problems; or highly reducing environments that must be overcome for effective in-situ leaching to be conducted.

Mining Method

The mining concept is to drill holes into the ore body and inject a lixiviant and then extract the pregnant lixiviant from a central production drill hole that is surrounded by the injection drill holes. Figure 11.5-2 provides a graphic of a five-spot and a line-drive production pattern, while Figure 11.5-3 shows the injection and production concept for a single target bed with a line-drive pattern. The type of pattern is dependent on the deposit shape, access, and the specifics regarding geohydrology. The specific design of the well-field pattern is dependent on the ore zone width, which can be tens of meters to hundreds of meters wide; the number of ore zones in the vertical ore zone to be mined; and the thickness of these ore zones. A third pattern, which is similar to the layout of the five-spot pattern, uses six injection wells so that a seven-spot pattern is created. This pattern is generally used in the United States when permeability of the ore zone, and therefore lixiviant flow, is low and more wells are needed for better lixiviant distribution throughout the ore zone. In Australia, seven-spot patterns are often used in very high permeability and/or high-grade zones. The additional wells help to ensure better contact and allow for the ability to reverse flow directions to stimulate production rates and obtain the highest uranium recovery possible. Figure 11.5-4 shows the transmission of pregnant and fresh/barren lixiviants to and from the ore body.

Economic ISR overall uranium recovery factors can range from 50% to 90%, depending on the deposit and time allowed for the mining process. Typically, recovery factors in the range of about 60% to 80% are common in the United States, while Kazakh well fields have often been operated with much higher recoveries, despite being uneconomic, and lower recoveries have historically been achieved in Australia. However, evaluation of recovery factors is not a simple task and requires in-depth knowledge of the ore calculation methodology to ensure that the ore in the margins of the roll front, the nose, and the tails, which may be included in the mine plan, can in fact be economically recovered. Some portions of a deposit might not be accessible to leaching because the uranium could be contained in lower-permeability units and/or clays. To further complicate this issue, detailed drilling is necessary to establish the most accurate location and characteristics of an ore body.

Both acidic and alkaline lixiviants are used to extract uranium from sandstone and paleochannel deposits. Alkaline lixiviants are prevalent in North America, while acidic lixiviants are common in Kazakhstan, other former Soviet Union countries, and Australia. Alkaline lixiviants place fewer metals into solution, and leave the well field easier to reclaim once the mining process has been completed. These lixiviants are generally composed of sodium carbonate and sodium bicarbonate, and many include oxygen or an oxygen-bearing compound that will oxidize the uranium to a soluble state.

Sulfuric acid is generally used as an acidic lixiviant, which is more powerful and places more metals into solution, generally leads to faster leaching rates, and can be necessary in specific types of deposits. The choice of lixiviant depends on the metallurgical characteristics of the deposit (specifically acid-consuming gangue), the economics associated with recovery rates, the groundwater regime, and the sociopolitical acceptability of using an acidic lixiviant. In addition, it is necessary to consider other groundwater uses and class of use within the region, as well as the potential for self-amelioration of the deposit once mining has ceased.

Processing Method

Uranium contained in the pregnant lixiviant extracted from the ore body is pumped to the processing plant where it first undergoes ion exchange to load the uranium onto the resin; the now barren lixiviant is recycled to the well field. The loaded resin is stripped of the captured uranium through an elution process. The eluate is subjected to precipitation and filtering processes, which generate yellow cake slurry that is dried in a low-temperature vacuum dryer, dehydrating the product while controlling emissions by capturing particulates. After drying is completed, the yellow cake is packaged and stored for shipment. In some cases, where salinity precludes the use of ion exchange, solvent extraction methods may be utilized.

The recovery of uranium within the processing plant is about 98%. The design of the plant is typically specific only to uranium, but other by-products can be produced. Uranium deposits typically contain other metals, such as molybdenum, vanadium, and copper, and it may be possible to economically extract these metals from lixiviant solutions. The overall processing plant can be designed to include modules to either remove or recover these metals as is economically feasible.

The uranium production process generates waste products. Under U.S. regulations, these solid waste products are classified as 11(e)(2) material and must be disposed of in a Nuclear Regulatory Commission–licensed disposal facility. The primary methods for liquid waste disposal are by deep disposal wells or by evaporating the liquids and disposing of the solids under the directives of regulatory requirements. In Australia, liquid wastes are disposed of in the mining zones

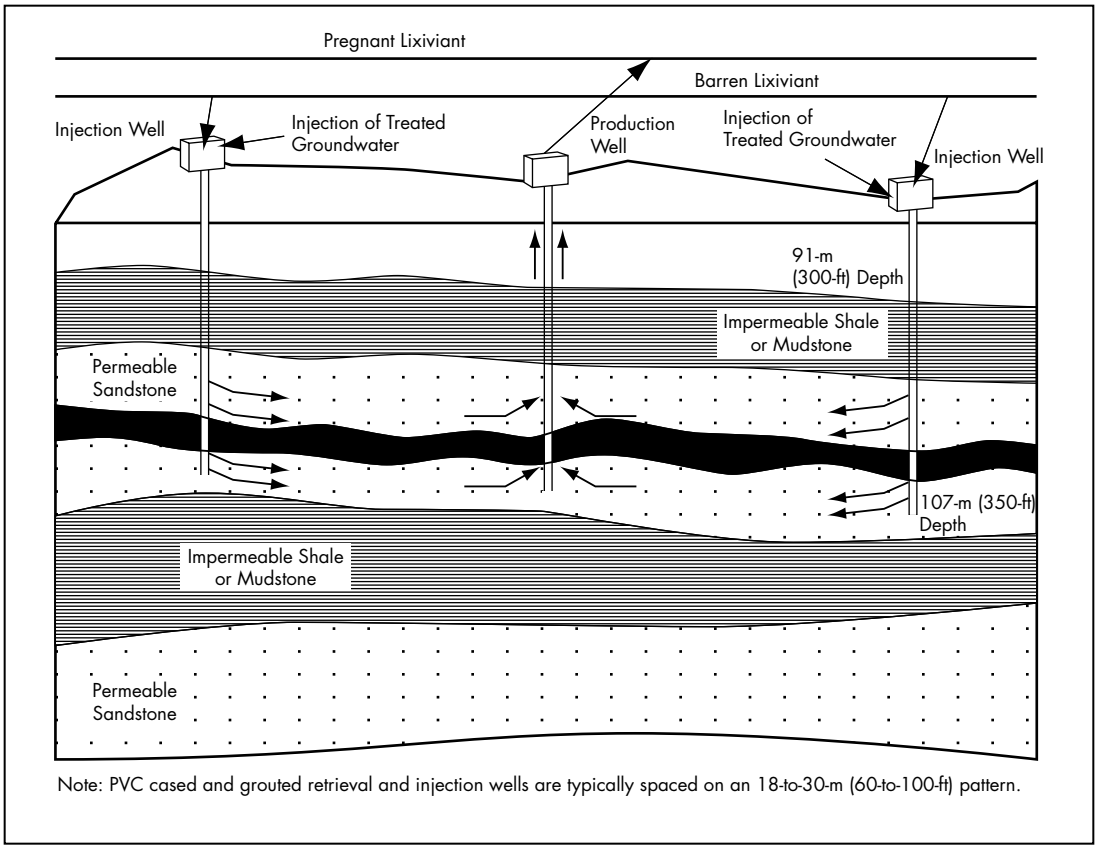

Figure 11.5-3 Cross section of uranium production wells

and solid wastes are disposed of in lined disposal facilities under the directives of the state or territory governments.

Groundwater Restoration

The ideal goal of groundwater restoration is to return the production zone (the area of an aquifer where uranium extraction occurs) to premining conditions. In the event this is not feasible, the Nuclear Regulatory Commission regulations allow for the achievement of restoration to the aquifer's quality of use class prior to mining operations. These standards have been deemed to be protective of public health and the environment.

The type of reagent used determines types of contaminants to the aquifer. ISR using acidic reagents causes a drastic decrease in pH and dissolution of other minerals in addition to the target uranium ores, concentrating most of the elements present in the surrounding rock to levels above the maximum admissible for drinking water supply. Microbes in the sulfide environment of the leach zone can produce a reducing environment, which may cause metals to precipitate in their sulfide forms. Meanwhile, bicarbonate reagents selectively dissolve the uranium ore, and contamination is noticeably lower. However, radium, selenium, and arsenic are still issues that must be addressed during remediation.

Two approaches can be used for groundwater restoration, direct cleaning and self-cleaning, as described in Table 11.5-8.

In Kazakhstan, the mining aquifers are allowed to attenuate naturally, whereas in Australia, some aquifers have been considered unusable for human or animal consumption and hence require no restoration. More recently, however, some of the proposed ISR projects are in areas that may have better quality and more valuable groundwater resources. In these areas, it will be necessary to perform some measures of restoration to at least initiate increases in pH and return to class of use.

Current Production

According to the World Nuclear Association, primary global uranium production for 2008 was approximately 52,000 t (114 million lb) of U_3O_8 (World Nuclear Association 2010). Primary producers include Canada at 10,600 t (23.4 million lb), Kazakhstan at 10,000 t (22.1 million lb), Australia at 9,900 t (21.9 million lb), Namibia at 5,200 t (11.4 million lb), Russia at 4,200 t (9.2 million lb), Niger at 3,600 t (7.9 million lb), and the United States at 630 t (1.4 million lb). Most of the production from the United States and Kazakhstan comes from ISR production, which is recognized as the most cost-effective and environmentally friendly method of uranium production.

Uranium is primarily used in nuclear reactors throughout the world. Total demand forecast, which for 2009 was 77,000 t (170 million lb) U_3O_8, is met by both primary production from mining operations and secondary supply, which includes drawdown from inventories and highly enriched uranium sources. Nonetheless, most researchers forecast that demand will continue to outstrip supply unless more uranium mines are placed into production or expanded.

FRASCH SULFUR MINING

The process by which elemental sulfur is produced from a geological formation is singularly credited to Herman Frasch.

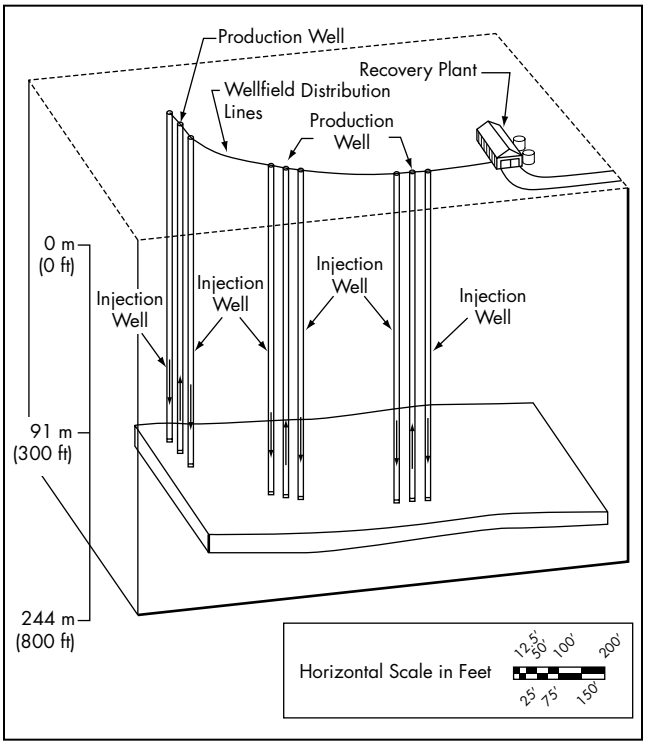

Figure 11.5-4 Schematic of ISR facility

Table 11.5-8 Groundwater restoration methods

Method	Description
	Direct Cleaning
Cleaning by reverse osmosis (RO)	• Varying number of pore volumes drawn to surface RO unit • Permeate recycled back underground • Brine sent to disposal • Most common method in United States
Washing with formation water	• 5–10 pore volumes drawn to surface • Depleted volume restored by adjacent natural groundwater
Cleaning by precipitation with reagents	• 5–10 pore volumes pumped to surface for uranium recovery and precipitation of undesirables with lime pulp • Saline residuals buried • Only recommended when other methods not suitable
	Self-Cleaning
Method of natural attenuation	• Given time—tens to hundreds of years—natural groundwater current restored to mined area • Rate dependent on natural flow rate, residual compositions, minerals present in rock, and acid versus alkaline reagent
Methods for accelerating natural attenuation	• Increase flow rates by pumping groundwater from beyond ore-body limits; introduce material to encourage natural bacteria growth; e.g., cheese whey, and molasses

Source: Data from IAEA 2001.

His concept of the mechanism of melting sulfur and then airlifting the molten liquid to the surface required a persistent effort in technical development and an expenditure of time and capital for a span of more than 10 years before realizing significant success.

The initial production of sulfur by the airlift (Frasch) process began in 1896 with the operation of three wells that produced 2,134 t (2,352 st) of sulfur (Haynes 1942). From a worldwide standpoint, however, the Frasch process is applicable to situations where fuel and water are available and the geological circumstances are favorable—for example, the Middle Eastern petroleum production areas, Poland, and Russia.

Basic Requirements for Frasch Sulfur Mine

Three basic resources are needed to develop a profitable Frasch sulfur mine:

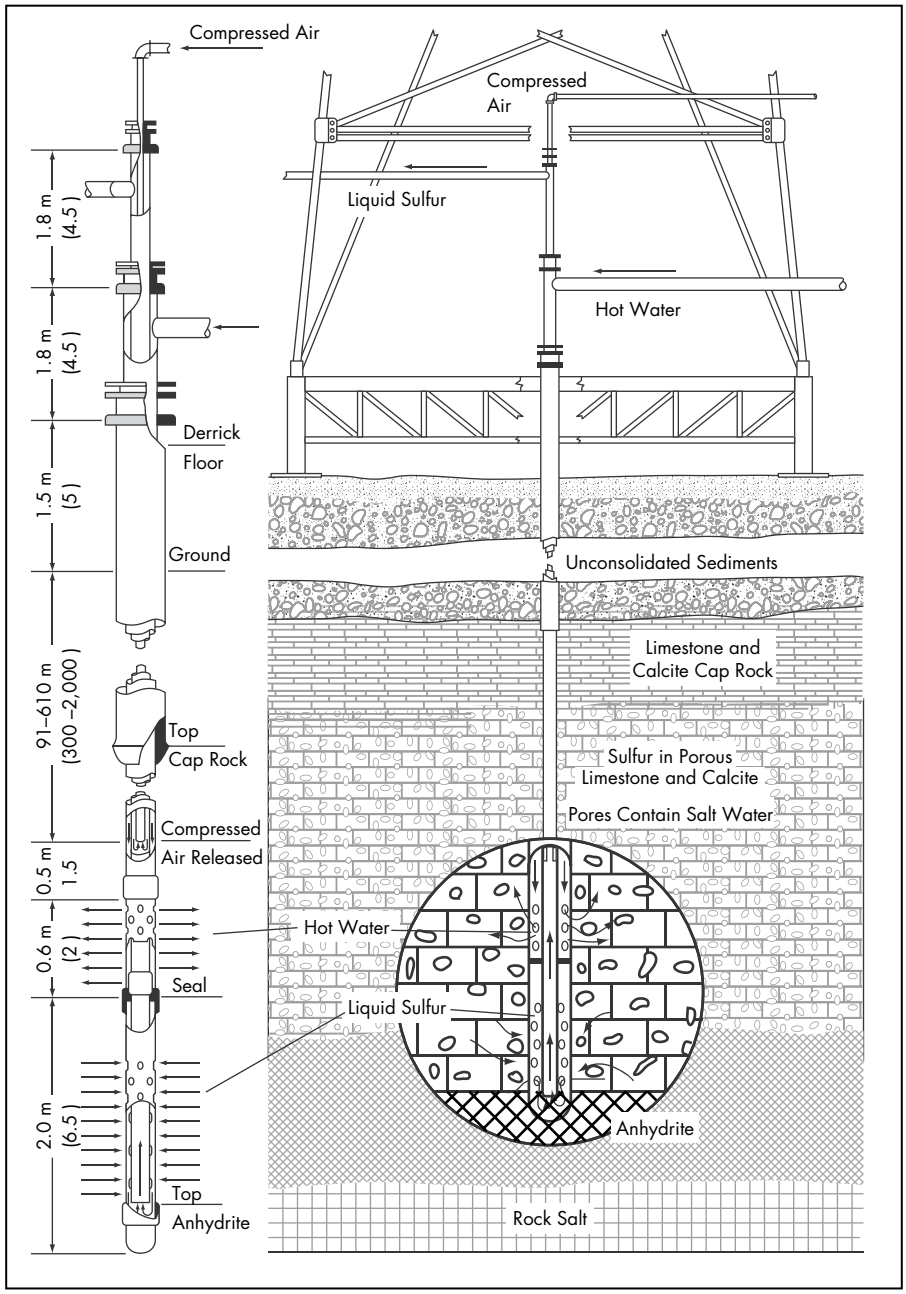
1. Large deposit of ore of good grade (5% sulfur is suggested as a lower limit)
2. Adequate, reliable, and inexpensive source of water, preferably containing little dissolved solids
3. Low-cost source of fuel

Other factors such as market price, royalty payments, tax liabilities, and transportation costs also influence the economic feasibility of the project. Utilities that mine sulfur have been quoted requirements for

- Average water: 19.2 m^3/t (5,000 gal/long ton) of sulfur mined;
- Fuel: 20,000 to 22,300 Mm^3 of gas/m^3 (2,700 to 3,000 million ft^3 of natural gas/million gal) of mine water; and
- Power: 118 to 138 W/m^3 (600 to 700 hp/million gpd) of mine water (*Oil and Gas Journal* 1967).

Reliable and economic transportation systems are also essential for distribution of the bulk sulfur. In this regard, transportation and storage of molten sulfur has been growing, particularly where low-cost water transport can supply shore-based distribution terminals. Sophisticated production personnel are needed to operate and maintain the production and delivery systems.

Ore Deposit



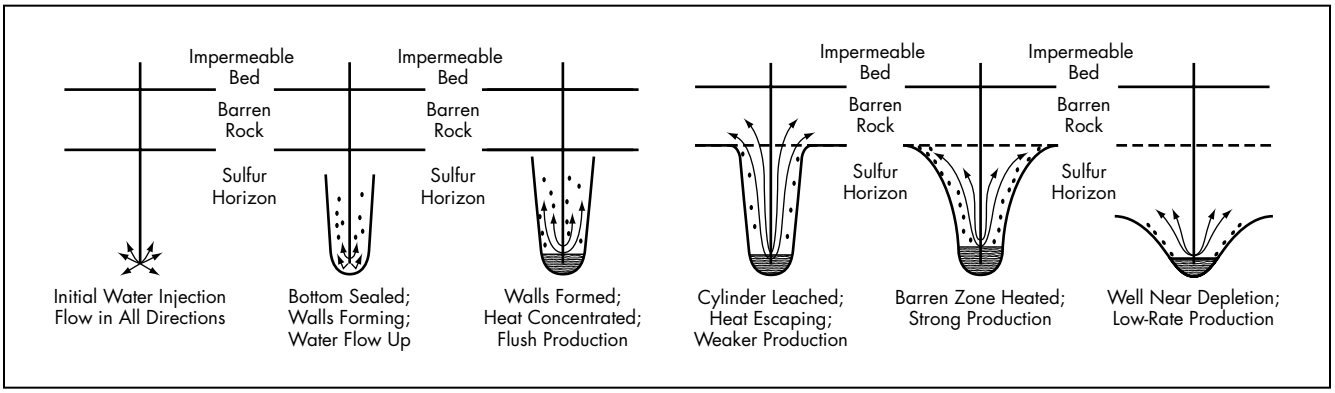
The Frasch process was originally applied to removing sulfur from deposits associated with salt domes formed by the intrusive flow of deep-bedded salt that penetrates the upper layers of sediments. Typically, the sedimentary layers are mud, shales, limestone, gypsum, and anhydrite. The salt plug normally is covered by an insoluble mineral cap, below which the sulfur is found in the vuggy porosity of the limestone. The sulfur location in the cap rock of the domes is highly variable, and not all salt domes contain sulfur-bearing rock.

Sulfate-reducing bacteria in conjunction with hydrocarbons and water are clearly capable of producing elemental sulfur. Thus sulfur can be formed from the gypsum and anhydrite and be precipitated in the porous limestone with the progression of water circulation.

The west Texas deposits of sulfur are associated with layers of gypsum, anhydrite, limestone, and dolomite. These deposits are not associated with salt plugs, and the porosity and permeability of sulfur-bearing beds follow the natural layered porosity of the strata and fracture system (Zimmerman and Thomas 1969; Hentz et al. 1987).

Field Development

Efficient extraction of sulfur from the deposit depends on several interrelated factors. The hot water has to be introduced in such a way and at such a rate as to melt the sulfur so it will



Source: Adapted from Ellison 1971.

Figure 11.5-5 Operation of a sulfur well

form a pool below the hot water, which is then airlifted to the surface. The piping system consists of concentric pipes which extend into the mineable formation (Figure 11.5-5). The operating strings are a series of these concentric pipes. The outer casing is set into the cap rock above the sulfur-bearing strata. The next string conducts the hot water and is set through the sulfur-bearing strata and is perforated at the bottom and also at some distance up the pipe. Another pipe is set concentrically within this pipe, and an internal seal is placed between the upper and lower perforations so that the flow of hot water is above the lower level. At a higher level, another pipe is run concentrically. The piping diagram in Figure 11.5-5 shows how hot water is introduced first, melting the sulfur, which is heavier, sinks to the bottom, runs into the lower pipe, and fills the second string. The molten sulfur is then airlifted with the compressed air and emerges as shown in the figure.

The molten sulfur is sent to storage, which can be handled in a number of ways. Since it may contain solid materials, or even small amounts of acid hydrocarbons, further processing may be required. Steam-heated leaf filters are commonly used for sulfur filtration. Precoating, usually with diatomaceous earth, is almost universal. The precoat should do the actual filtration to minimize blinding and will also neutralize some acid and reduce corrosion. However, small amounts of hydrated lime or ammonium bicarbonate may be added to the filter feed to neutralize acid. Such a system will produce

Source: Adapted from Donner and Wornat 1973.

Figure 11.5-6 Sequence during operation of sulfur well

sulfur that is free of ash and acid. If hydrocarbons must also be removed, activated clay may be added to bleach the dark sulfur. Other filter aids are also available to remove hydrocarbons. Filtration rates and precoat requirements will depend on the quality of the sulfur coming from the wells.

The sequence of the development of the well is shown in Figure 11.5-6. The initial injection melts a pool of sulfur and seals the bottom, as shown. Hot water is forced farther up the string, and a larger cylinder of rock is heated, melting more sulfur, which is airlifted to the surface. This yields a concentrated flush production. This scenario is simple in concept, but in practice, where variability of permeability, sulfur content, heat flow problems, and the influence of other wells exist, the actual operation is complex. It is necessary to reinject water produced in bleed wells to control flow, save heat, and dispose of wastewater. The mining process is highly variable because of the nature of the deposits, and the uncontrollable nature of the reservoir system makes the process something of an art that is gained by years of experience. Attempts have been made to apply reservoir engineering by substituting paradichlorbenzene as a meltable material for sulfur with some interesting insights (Rayne et al. 1956).

As mining proceeds, subsidence and collapse of overburden become a problem that can sometimes be helped by reducing the volume of hot water necessary, but may also shear tubing and cause many difficulties. Wells are often separated into groups to help control these problems and avoid total loss of field control. Corrosion due to molten sulfur contact is quite negligible. When the sulfur pool is drawn down to where the hot water and air come up together, the water flashes as steam, and a *blow* takes place. Hot water rising up the sulfur production string produces a corrosive environment, and, with a blow, it becomes appreciable. The salinity of the water influences the rate markedly. If seawater is used and a blow occurs, the corrosion rate is disastrous (Hackerman and Shock 1947; Shock and Hackerman 1949). One of the practical solutions to controlling corrosion has been to use specially produced cement-lined pipes as well as limiting the salinity of the water. Treatment of the water to minimize corrosion and scale problems is essential.

Bleed wells are required to balance the water pumped into the formation at the production wells. Location of the bleed wells will depend on such site-specific factors as the depth, permeability, and hydrology of the sulfur-bearing structure. Because of environmental concerns, bleed water should be recycled to the maximum extent possible. When required, disposal of bleed water needs to be carefully planned because of the high concentration of dissolved hydrogen sulfide and other sulfur-bearing compounds. Aeration in ponds, chemical treatment, and use of deep disposal wells are all methods of handling these waters.

Facilities Needed at Frasch Sulfur Mine

When a sulfur deposit has been located and defined by exploration drilling, a water supply located, and a fuel supply established, the design and construction of the needed facilities can proceed. Typical layouts showing both the well field and surface facilities are provided in the literature (*Oil and Gas Journal* 1970). Most mines will require some or all of the following:

- Pumps, pipelines, and reservoir for the water supply
- Power plant for heating and treating the water, compressing the air, and generating the electricity and steam
- Equipment for drilling and servicing wells
- Pipeline system for carrying the mine water and air to the wells and the sulfur to collecting stations
- Control stations for the producing wells
- Sulfur collecting, loading, and storage facilities
- Purification equipment needed to meet customer specifications
- Shipping facilities for solid and/or liquid sulfur
- Bleed-water disposal system
- Equipment needed for the maintenance of these facilities
- Employee transporting, dining, and housing facilities if the mine is remotely located
- Offices and buildings for material storage, laboratory, engineering, personnel, administration, and supervisory staff

ACKNOWLEDGMENTS

The authors recognize the work of D'Arcy A. Shock for his contribution of the section on Frasch sulfur mining, which has been reprinted (with minor reductions on history) from the previous edition of this handbook. Minor alterations have been made to convert to the International System of Units.

Additionally, coworker Edwin Bentzen, project manager at Lyntek, Inc., is thanked for his contribution of the section on lithium, as are the draftsmen turned illustrators who helped with the figures; Rachel Hawkins who offered moral support; and Nick Lynn, owner of Lyntek, who gave us the opportunity to complete the work.

CHAPTER 11.6

Coal-Bed Methane Production

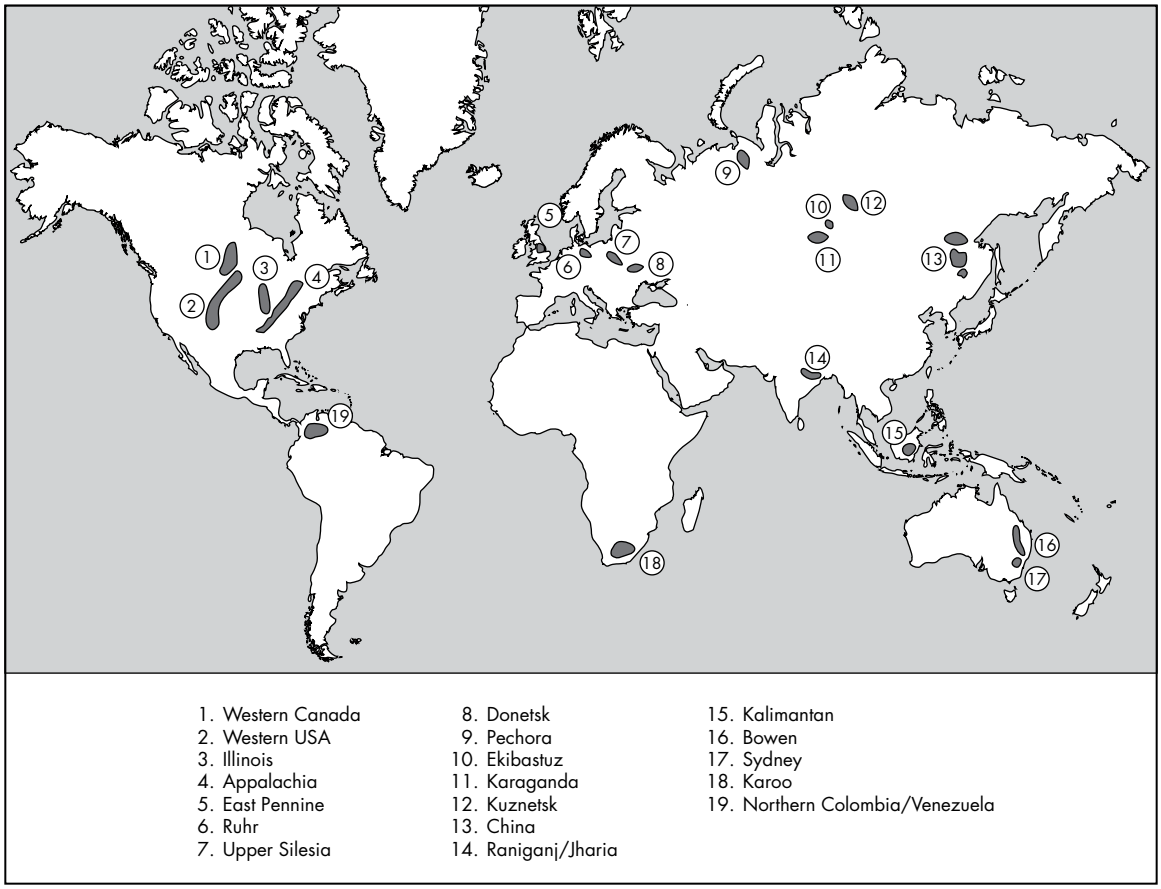
Pramod Thakur

INTRODUCTION

Coal seams were formed over millions of years by the biochemical decay and metamorphic transformation of the original plant material. This process, known as coalification, produces large quantities of by-product gases. The volume of by-product gases increases with the rank of coal and is the highest for anthracite at about 765 m^3/t (Hargraves 1973). Most of these gases escape to the atmosphere during the coalification process, but a small fraction is retained in the coal. The amount of gas retained in coal depends on a number of factors such as the rank of coal, the depth of burial, the immediate roof and floor to the coal, geologic anomalies, tectonic pressures, and temperatures prevailing at the end of the coalification process. In general, the higher the rank of coal and the greater the depth of the coal seam, the higher the gas content. Gas contents of coal seams generally range from 0.1 to 25 m^3/t.

Methane is the major component of gas in coal, accounting for 80%–95% of the total gas content. The balance is made up of ethane, propane, butane, carbon dioxide (CO_2), hydrogen, oxygen, and argon. Because the coal-bed gas is mainly methane, it is generally called coal-bed methane (CBM). Methane recovered from active and abandoned coal mines is called coal mine methane.

Coal-bed methane production (CMP) from longwall gobs started in Europe in the 1940s, but methane drainage from virgin coal prior to mining began in the United States in the 1970s. The primary need for CMP was to make the coal mines safe from explosion hazards. The methane gas control techniques are discussed in Chapter 15.4 in detail. As the CMP process developed and became widespread, other benefits became apparent. In moderately gassy and very gassy mines, immediate improvement in coal productivity was realized. In some very gassy mines in the United States, the productivity improved from a low 15 t/worker-shift to 40 t/worker-shift. It significantly reduced the cost of mining by minimizing the gas delays caused by excessive gas emissions. In the 1980s, the volume of CBM produced prior to mining and postmining continued to increase, eventually leading to gas processing and commercial marketing. Extensive drilling of nonmineable coal deposits, such as CMP activities in the San Juan Basin of the United States, also produced a large volume of CBM. At present, nearly 10% (51 Gm^3 [billion cubic meters]) of U.S. natural gas production is from CMP. This number is likely to increase to 20% in the near future because CMP is less cost-intensive and financially less risky than deep drilling for natural gas production. The CBM, after processing to remove impurities, is exactly like natural gas with a calorific value of 35.8 MJ/m^3 (million joules per cubic meter).



Another financial incentive is driving CMP forward. Methane gas is a powerful greenhouse gas (GHG) with a radiative forcing that is 21 times higher than carbon dioxide (*radiative forcing* is a phrase used to measure the capacity of a gas to trap infrared energy). In many industrialized countries (e.g., the United States and Australia), a financial incentive is provided to capture CBM from active mines. The current U.S. incentive is $6.50/t of carbon dioxide. Thus, 1 t of CBM can qualify for a carbon credit of $136.50 if it is captured and marketed.

CMP today is a standalone, profitable enterprise. Besides saving lives and reducing the cost of coal production, it provides a clean-burning fuel and reduces GHG emissions. With adequate financial incentives, it can become a major supplier of natural gas in many countries such as the United States, China, India, and Australia.

COAL-BED METHANE RESERVES

As illustrated in Figure 11.6-1, coal deposits occur in 19 major basins around the world, and global reserves of coal and CBM are large. Coal has been a global energy source for a long time, but for the past 200 years it has played a vital role in the growth and stability of world economy. At present, 70 countries around the world annually mine about 6,500 Mt of coal. China, the United States, and India, the three largest coal producers, derive most of their electricity from coal. The total proven world reserve of mineable coal is 1 Tt (trillion metric tons), but indicated reserve to a depth of 3,000 m ranges from 17 to 30 Tt (Landis and Weaver 1993). Estimated reserves of CBM range from 78–959 Tm^3 and are shown in Table 11.6-1.

Pramod Thakur, Manager, Coal Seam Degasification, CONSOL Energy, Inc., Morgantown, West Virginia, USA

United States	11	30–41
Other countries	5–10	—
Total	78–320	877–959

*Recoverable reserve: 30%–60% of the total gas in place.
†Data from Kuuskraa et al. 1992.
‡Data from Cairn Point Publishing Company 1997.

CMP techniques were originally developed in the United States but are now prevalent in the rest of the world. At present, most CMP is realized from relatively shallow (<1,000 m deep) mineable coal deposits. However, coal deposits reach a depth of 3,000 m in many basins. Deep coal deposits are rich sources of CBM, but production techniques are not very successful yet because of very low permeability. New techniques are currently being developed (Thakur 2002). The vast global deposit of deep coal can be used in three ways:

1. CMP from deeper horizons (1,000–3,000 m)
2. Sequestration of carbon dioxide, a GHG. Production of CBM from deeper formation is assisted by CO_2 flooding. Coal seams have a much higher affinity for CO_2; hence, they absorb CO_2 and at the same time release methane.
3. Underground coal gasification (UCG). Coal seams not used for CO_2 sequestration can be burned in situ with a limited supply of oxygen to produce low-calorific-value combustible gases. In-situ combustion of coal also greatly enhances methane production by heating the coal formation.

Thus, there is a synergy in methane production from deep coal seams, CO_2 sequestration, and UCG. The subject will be discussed in the order that a typical CMP project is undertaken:

- Reservoir properties
- Wire-line logging
- Production technology
  - Shallow coal
  - Medium-depth coal
  - Deep coal
- Well servicing and maintenance
- Produced water disposal

- Gas gathering and processing
- CO_2 sequestration
- UCG

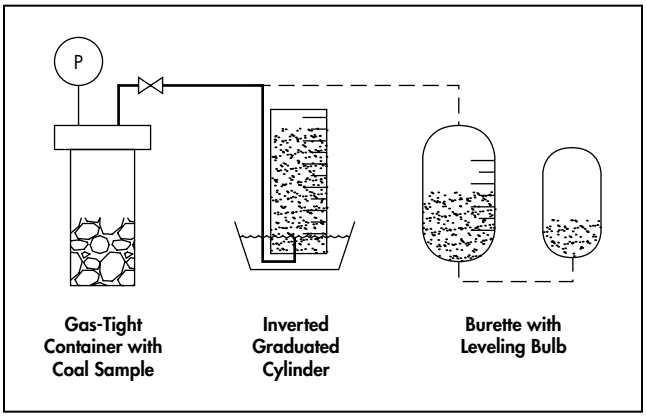
COAL-BED RESERVOIR PROPERTIES

The most important reservoir properties that not only influence the gas production rate but also determine the production techniques are

- Gas content of coal seams and their gas isotherms;
- Permeability;
- Reservoir pressure;
- Diffusivity of coal;
- Water content and quality of water; and
- Ground stresses and elastic properties of surrounding strata (e.g., compressive strength and Young's modulus of elasticity).

Coal porosity is generally low (1%–4%) and does not have a significant influence on gas production or production techniques.

Measurement of Gas Contents



The volume of gas contained in a ton of coal is termed *gas content* of the coal and is expressed in cubic meters per metric ton (m^3/t). It is generally accepted that the gas is stored in a monolayer on the micropore surfaces of coal. The volume of gas contained in coal is dependent on the rank, temperature, and pressure or depth of the coal seam. The micropore surface in coal is large; a ton of coal has a surface area of approximately 200 Mm^2. One cubic meter of coal can store two to three times the amount of gas contained in a typical sandstone reservoir for natural gas of the same volume.

For commercial gas production, it is best to core drill the entire field on a grid pattern and do a direct measurement of gas contents of all coal seams that comprise the gas reservoir. A typical spacing for core holes is one in every 200 ha.

Gas content measurement methods are classified as (a) conventional and (b) pressurized desorption techniques. In the conventional technique, coal cores or drill cuttings are retrieved from the core hole and immediately put in a sealed container to measure the desorbed gas. The method suffers from the uncertainty in the estimation of gas lost during sample retrieval and handling. To eliminate this problem, the pressured core desorption technique has been used. In this method, gas loss is minimized by sealing the coal sample down the core hole.

Both methods provide a positive proof of gas presence and data on the gas desorption rate that can be used to calculate diffusivity (to be discussed later). Desorbed gases are chemically analyzed to determine the composition and calorific value of the seam gas.

The industry standard for direct measurement of gas content is the U.S. Bureau of Mines method shown in Figure 11.6-2 (Kissell et al. 1973). Coal cores or drill cuttings are deposited in a sealed vessel and desorbed gases are measured periodically until the desorption rate is insignificant. Total volume of gas thus produced is known as the desorbed gas. The cumulative volume of desorbed gas plotted on the y-axis against the square root of time yields a straight line, and its intercept on the y-axis is a measure of the gas lost from the core before it was deposited in the sealed container. Subsequently, a portion

Source: Kissell et al. 1973.

Figure 11.6-2 Direct measurement of coal-bed gas content

of the core is ground in a hermetically sealed mill to release the residual gas. The sum of the three component volumes—desorbed gas, lost gas, and the residual gas—is the total gas contained in the sample. This total volume of gas is divided by the weight of the sample to obtain the gas content of the coal seam.

Total gas reserve (gas-in-place) for the coalfield must be established before any commercial undertaking is started.

$$\text{gas reserve, } G, = \wp AHV$$

where

$\wp$ = density of coal, t/m^3
A = area of deposit, m^2
H = height of coal seam, m
V = gas content, m^3/t

If there is more than one coal seam in the reserve, as is the normal case, the total gas reserve is the sum of individual coal seam reserves.

Permeability

The permeability of a coal seam is the most important reservoir property next to gas content. Permeability of a porous medium is defined as 1 darcy when a fluid with a viscosity of 1 cP (centipoise) flows with an apparent velocity of 1 cm/s under a pressure gradient of 1 atm/cm (atmosphere per centimeter). The permeability is usually expressed in millidarcies (1 mD = 1/1,000 of a darcy).

Coal seams can have a permeability range of 1 microdarcy to 100 mD depending on the depth of the seam. Shallow coal seams have higher permeability, but deep coal seams show very low permeability.

Reservoir Pressure

The reservoir pressure can be calculated from the depth of the coal seam, but it is best measured directly. A vertical well is drilled and cased just above the coal seam. The coal seam is cleaned up with high-pressure water jets. A commercially available recording pressure gauge is installed in the well and the borehole is shut off at the surface. The gas pressure begins to build up, and in 4 to 6 days the final pressure is reached. The pressure gauge is retrieved and the final pressure is read from

the chart. The coal seam reservoir pressure is typically less than the hydrostatic head (about 0.7 times).

Thus a 300-m-deep coal seam in the Northern Appalachian Basin of the United States has a reservoir pressure of approximately 2 MPa, whereas 600-m-deep coal seams in the Central Appalachian Basin have a reservoir pressure of 4–5 MPa. The reservoir pressure will rarely exceed the hydrostatic head, but if it does, it is a very fortunate situation for commercial gas production. The "fairway" area of the San Juan Basin in the United States is an example of an overpressurized basin. Many highly productive CBM wells have been drilled and produced in this area.

Diffusivity of Coal Seams

The diffusivity of a coal seam is a parameter that measures how fast the coal seam will desorb the gases when the confining pressure is reduced to the atmospheric pressure. It is commonly measured by a parameter called "sorption time." It is the time a coal seam needs to desorb 63% of the original gas content and is measured in days. Sorption time for some coal seams in the San Juan Basin is less than 1 day, whereas it can be as high as 900 days for coal seams in the Northern Appalachian Basin (Rogers et al. 2007).

Coal seams with high sorption time will take a long time to yield a high percentage of in-situ gas and should be drilled at a closer spacing and produced for a long time. On the other hand, coal seams with shorter sorption times should be drilled at a wider spacing (greater than one well per 20 ha) but produced for a shorter time (usually fewer than 10 years).

Water Content and Quality of Water

The coal seams are usually saturated with water. Actual fluid flow in coal seams is a two-phase flow. Invariably, the water phase is produced first. As the water content depletes, the gas production begins to increase, reaching a peak when water is almost drained out. A typical CBM well can produce from a few cubic meters per day to hundreds of cubic meters per day of water.

The amount of water produced and its quality have a serious impact on the economy of a CBM project and will be discussed later in the chapter.

Ground Stresses and Rock Properties

Every point in a coal seam lies in a stress field that comprises the vertical stress (σv), the major horizontal stress (σH), and the minor horizontal stress (σh). The comparative magnitudes of these stresses are the determining factors for a successful "hydrofracing" of a vertical well. For successful hydrofracing, the sequence $\sigma H > \sigma v > \sigma h$ must be true. This results in the most favorable vertical fracture because the fracture is always orthogonal to the least stress. It will also travel in the direction of σH; that is, the azimuth of the fracture is parallel to σH. Major directional permeability of a coal seam is also parallel to σH (refer to Chapter 15.4).

Rock mechanics properties such as compressive strength, elastic modulus, and Poisson ratios are also needed for a successful design of gas-production techniques.

WIRE-LINE LOGGING

The vertical boreholes drilled to establish the gas reserve and determine reservoir properties are also used for wire-line logging. The process involves lowering special sensors down the hole to measure various characteristics of the coal seam and sending the data to the surface using electrical wire line, hence the name. The most commonly used logging techniques to evaluate coal seams for CMP are

- Gamma ray logging (passive and active),
- Resistivity logging,
- Sonic logging,
- Neutron logging,
- Density logging, and
- Induced gamma ray spectrometry logging.

All these techniques had their origin in the oil and gas industry. They are only slightly modified, if needed, for coal-seam logging. Details of their application are described in literature (Scholes and Johnson 1993).

Figure 11.6-3 shows basic log responses for multiple coal seams in a vertical well. For coal seams, the gamma ray response is low, the resistivity response is high, the density response is high, and the neutron density response is also high. Most commonly, only gamma ray logging is used to precisely locate coal seams in a borehole. Some tools measure the natural gamma ray emissions from the formation, whereas others use an active gamma source and measure the scattered gamma rays.

The only other logging technique commonly used in CMP projects is sonic log, particularly the cement-bond log technique. Several acoustic sources mounted on a tool are lowered into the borehole. The sound wave is reflected by the steel casing and the cement in between the casing and the formation. The velocity of sound and/or the amplitude of sound waves indicate whether the cement is there or only a void is present.

These two logs are highly recommended to locate the coal seam and to make sure the steel casings are well set. All other logging techniques are optional. New logging tools that measure the gas contents, gas isotherms, and directional permeability in situ are being developed, but they are not yet commercially available as of 2010.

PRODUCTION TECHNOLOGY

The CBM resource as shown in Table 11.6-1 is huge. Production strategy varies from basin to basin, and even in the same basin based on local reservoir properties. Since all coal seam reservoir properties are depth dependent, the CBM resources can be classified into three broad categories to identify the best production technique for different depth ranges: shallow, medium-depth, and deep. The main characteristics of these reservoirs are summarized in Table 11.6-2.

Shallow Reservoirs

Shallow reservoirs are characterized by high-permeability, low gas content; low reservoir pressures; and low diffusivity. Vertical stresses (<3 MPa) are smaller than the horizontal stresses. Hydrofracing of a vertical well in these reservoirs results in horizontal fractures that are inefficient for gas production.

The following are preferred production techniques:

- Mine shafts with multiple laterals (horizontal boreholes) at the bottom of the shaft. A plan view of this drilling pattern is shown in Figure 11.6-4. A 3-m-diameter shaft is drilled in the target coal seam and the coal seam is reamed out to a larger size to accommodate drill rigs. In active coal mines, these shafts can be 6–8 m in diameter and are later used as ventilation shafts. The entire mine property may need six to eight shafts to recover coal. They can be sunk 10 to 20 years ahead of mining for CBM production. Depending on the price of gas, the marketed gas can

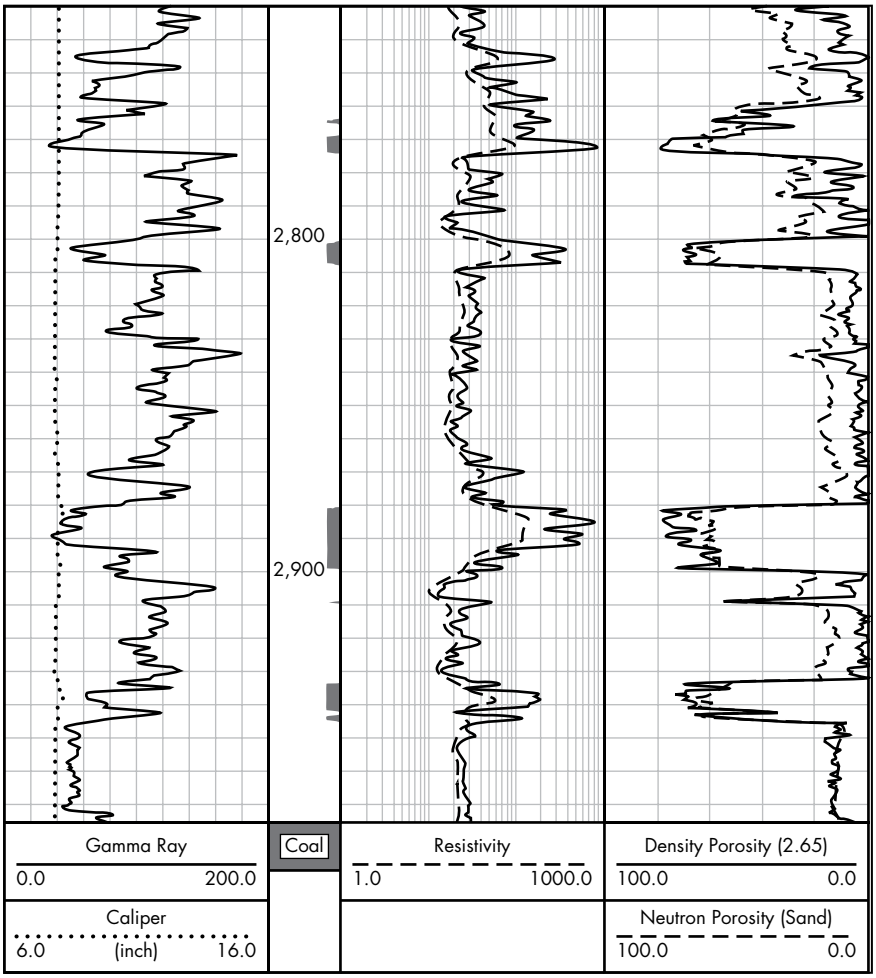


Figure 11.6-3 Basic responses to various logs in coal

defray all costs associated with shaft sinking. Specific gas production from these shallow coal seams ranges from 10–25 m^3/d/m of the borehole. The specific gas production for a coal seam is a characteristic of the coal seam and is a measure of the rate of gas production per unit length of a horizontal borehole drilled for gas production. Assuming six horizontal boreholes drilled to 1,000 m, an initial production of 60,000–150,000 m^3/d can be realized.

- Another production technique uses surface-based rigs to drill horizontal laterals (see Chapter 15.4 for details). The property is drilled with "production wells" on a grid pattern. Typically, four to six horizontal laterals are drilled from access wells 1 km away to intersect the production wells to realize commercial CMP (Figure 11.6-5).
- A special case of gas production from a shallow reservoir is the Powder River Basin of Wyoming (United States). Coal seams in this basin are very thick (30–60 m) and shallow; the maximum depth is <200 m. The gas is of biogenic origin (unlike deeper seams where gas is of thermogenic origin) and gas content is quite low (<3 m^3/t). Permeability and water content are quite high. The production technique used here is a vertical well with hydrojetting but no hydrofracing. A typical well completed with a cost of $50,000 can yield gas production rates of 7–10 km^3/d, making it a profitable venture. More than 10,000 wells have been drilled and completed this way in the Powder River Basin so far. The technique can work successfully in similar deposits in Montana (United States) or other places in the world.

Medium-Depth Reservoirs

Medium-depth reservoirs are characterized by low to medium permeability, high gas contents, relatively higher reservoir pressures, higher diffusivity, and the coal tends to be of higher rank. Vertical wells with well-designed hydrofracing are ideally suited to such reservoirs for gas production. Specific gas productions for vertical fractures created in these seams range from 4 to 8 m^3/d/m. The hydraulic fracturing process basically involves pumping a fluid (such as water, nitrogen foam, or a high-viscosity gel) with fine sand (0.1–2 mm diameter) at a pressure high enough to hydrofrac the coal seam. Under ideal circumstances ($\sigma h < \sigma v < \sigma H$), a vertical fracture is created in the coal from the floor to the roof (Figure 11.6-6). Depending on the volume of the frac fluid pumped, the total frac length can be 300–600 m. The fracture will typically have two wings of 150–300 m that travel in the opposite directions but on the same azimuth that is parallel to the direction of σH.

For commercial gas production, all coal seams with a thickness >1 m are hydrofraced in the vertical interval 500–1,000 m. Multiple coal-seam fracing techniques are well

Table 11.6-2 CBM reservoir characteristics

Reservoir Type	Approximate Depth, m	Permeability, mD	Remarks*
Shallow	≤500	10–100	$v < h < H$
Medium-depth	500–1,000	0.1–10	$h < v < H$
Deep	≥1,000	<0.1	$h < v < H$

*v is the vertical stress; h and H are the minor and major horizontal stresses.

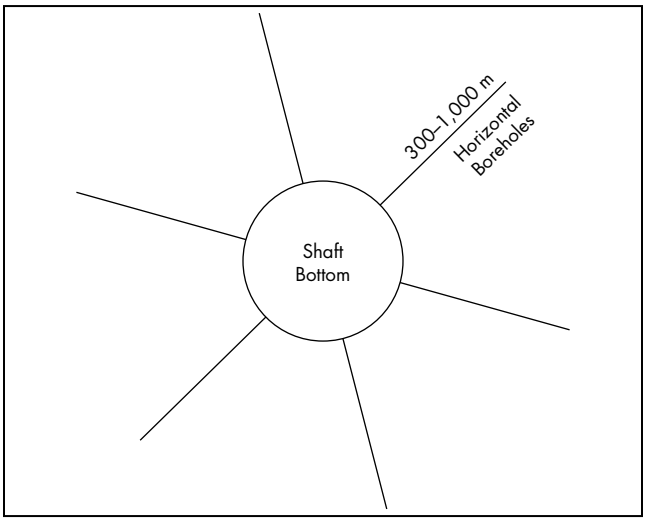

Figure 11.6-4 Mine shaft with horizontal boreholes

established but beyond the scope of this chapter. A typical gas production from each horizon of 1.5–2-m-thick coal seam is 3,000 m^3/d. If three or four horizons of this thickness are hydrofraced in a well, gas productions of 9,000–12,000 m^3/d can be realized.

Observations of nearly 200 hydrofraced wells and mapping of the subsequent mining of the fracture created can be summarized as follows:

1. The fracture volume (length × width × height, or LWH) is always proportional to the fluid volume, Q, pumped in:

   $LWH = CQ$

   where C is the leak-off coefficient; it is typically 1 or 2 orders of magnitude higher than that for sandstone or limestone reservoirs.
2. The fracture plane is always orthogonal to the least stress (σh or σv, whichever is smaller).
3. The fracture azimuth is always parallel to the major horizontal stress, σH.
4. The fracture always travels up into the roof but not in the floor, following the law of physics that the fluid will always flow down the pressure gradient.
5. When a coal seam bounded by shale or sandstone is fraced, the formation with the smallest modulus of elasticity, E, will hydrofrac first. In fact, strong shale and sandstone provide a confining barrier containing the fracture in coal.
6. The fracture width is proportional to (fluid viscosity/E) raised to the power of 0.25.

Figure 11.6-7 shows two methods of completion, namely (coal-bed A) open-hole and (coal-bed B) through perforations.

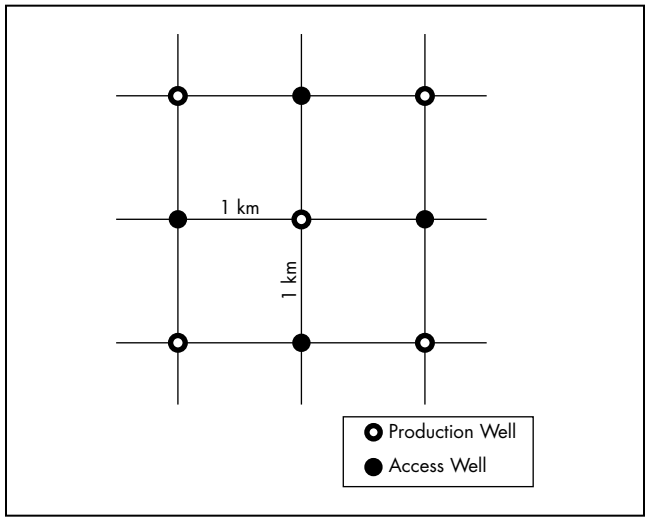

Figure 11.6-5 Horizontal laterals drilled from the surface

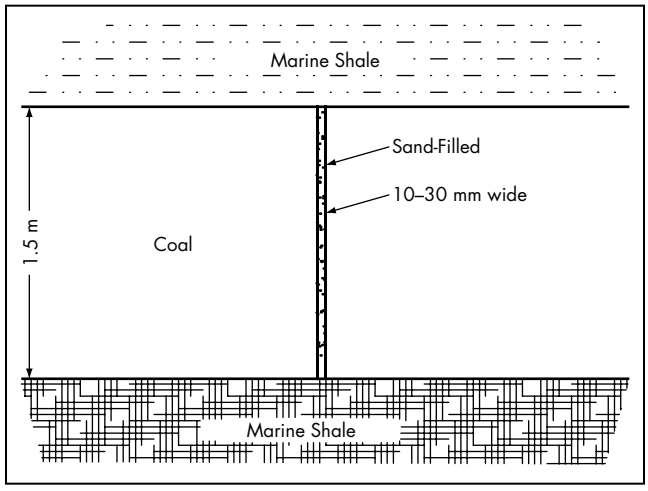

Figure 11.6-6 Sectional view of sand-propped hydraulic fracture

If the coal seam has a high compressive strength, the lowest coal seam can be fraced open-hole. The upper coal seams are fraced through perforations in the steel casing. If the coal seam has low compressive strength, it is preferable to hydrofrac it with perforated casings.

The choice of frac fluid varies from basin to basin. In the depth range of 500 to 750 m, gelled water or nitrogen foam, 70% quality, has given good results in the Central and Southern Appalachian Basin of the United States. On the deeper end (750–1,000-m depth) and for thick coal seams (>10 m), cross-link borate gels with very high viscosity have produced better results. An example is the San Juan Basin of New Mexico and Colorado. Sand concentrations in the frac fluid vary from 0.1 t/m^3 to 0.5 t/m^3 depending on the viscosity of the fluid. Fluids with higher viscosity can carry higher concentrations of sand.

A special case of CMP from deep and thick coal seams is the cavitation technique. Figure 11.6-8 shows a completion technique called cavitation through a perforated casing. If the coal seam has high compressive strength, cavitation can be

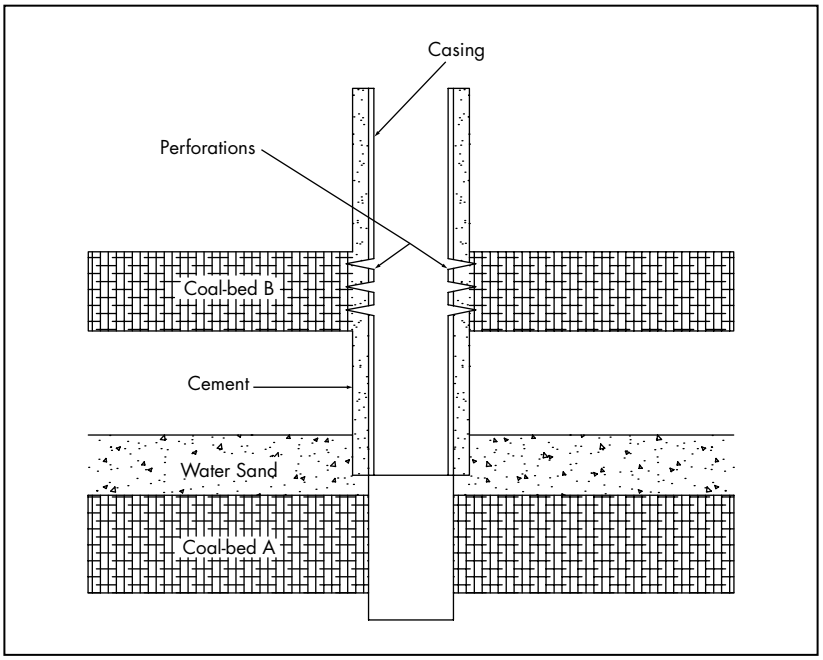

Figure 11.6-7 Two completion procedures for vertical wells in thin coal seams

done in an open hole. In the cavitation technique, the borehole is pressurized with water and the pressure is released. The process is repeated several times in a quick sequence with the hope that coal will cavitate in the depressurizing phase and enhance permeability leading to good gas production. Cavitation completions have worked well yielding 30,000–60,000 m^3/d of gas production in 10–20-m-thick coal seams.

Deep Coal Reservoirs

The bulk of the worldwide CBM reserves are in deep coal seams. These reservoirs are characterized by high gas content and high reservoir pressures but extremely low permeability (a few microdarcies). Coal is a viscoelastic material. An extreme reduction in permeability with increasing depth (and hence pressure) is a quite natural phenomenon. Because of depth, no horizontal drilling from a mine or from the surface has been done. As such, specific production of horizontal boreholes is not known but it is likely to be low, <1 m^3/d/m.

Mine shafts are obviously too expensive for these seams. Even vertical wells with hydrofracing are very inefficient. Actual hydrofracing efforts in Virginia (United States) at a depth of 1,400 m and in eastern France at a depth of 1,800 m ended in failure.

The only feasible technique at present is to drill long horizontal laterals from the surface. Figure 11.6-9 shows a plan view of 12 horizontal laterals drilled in four groups from the same surface location. The outlying horizontal laterals in each subgroup are hydraulically fractured at intervals of 300 m. Hydrofracing should be designed such that the fractures can extend at least 300 m on each side of the vertical well.

In the beginning, all hydrofraced horizontal laterals will have a high gas production rate, but after the gas production rate has significantly declined, the middle lateral in each subgroup should be injected with carbon dioxide. Coal seams have a much higher affinity for CO_2. It will be preferentially adsorbed by the coal matrix releasing methane at the same time (Thakur 2002).

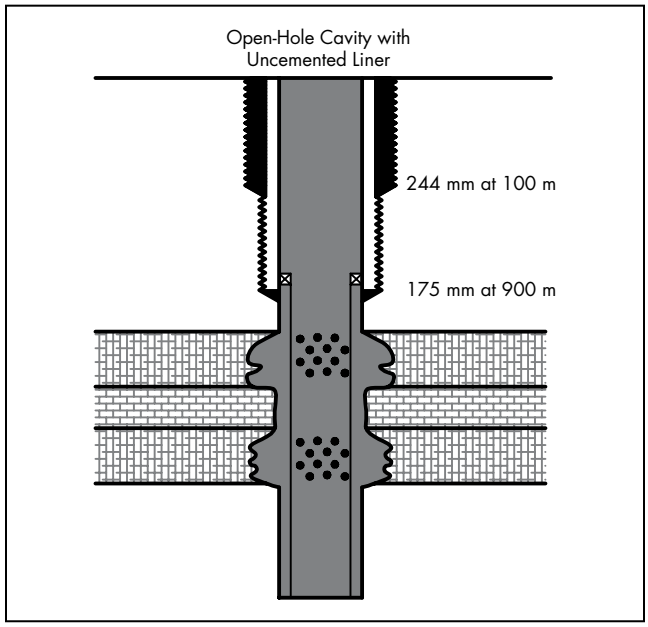

Figure 11.6-8 Cavitation completion procedure for thicker coal seams

WELL SERVICING AND MAINTENANCE

After drilling and completion, all CBM wells will produce water and gas, in that order. All wells need some servicing and maintenance. Figure 11.6-10 shows a typical gas and water production profile. Depending on the water content of the coal seam, a CMP well can produce moderate to large quantities (1–100 m^3/d) of water. As the reservoir pressure is reduced and more water is produced, the water production declines and gas production rises, reaching a peak. After that, the gas production rate also declines. Horizontal and vertical wells need different kinds of servicing and maintenance.

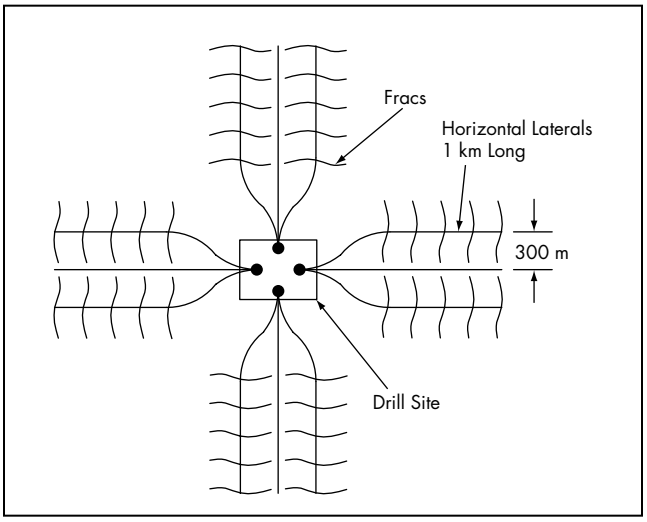

Figure 11.6-9 Gas production from deep coal seams

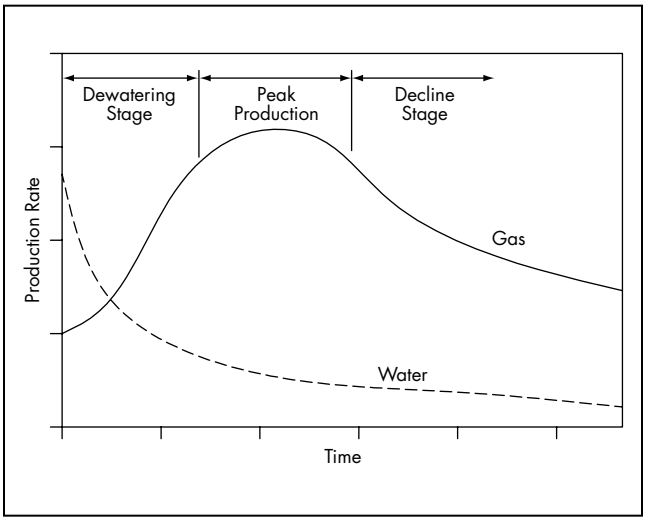

Figure 11.6-10 CBM well production profile

Horizontal Laterals Drilled from the Surface

These wells do not need much maintenance. The produced water collects at the bottom of the production well. If several horizontal laterals discharge water in one production well, the volume is large enough to warrant the use of a progressive cavity pump. As water production declines, the pump can be put on a timer. The gas pressure in the reservoir is enough to clean up the borehole.

This method of well completion still suffers from two drawbacks: an inability to stay in the coal seam and an inability to completely dewater the well. The first problem is due to drilling-instrument limitations. The borehole exits the coal seam and often enters the roof or floor, limiting gas production and the ability to completely dewater. Hence the specific production (cubic meters per day per meter) is generally only 50% or less compared to in-mine drilling, which is more precise (see Chapter 15.4). It is also difficult to reenter a horizontal lateral for maintenance, especially if multiple laterals are drilled from the same vertical well.

Vertical Hydrofraced Well

The servicing procedure and equipment for these wells is borrowed from the oil and gas industry.

After hydrofracing, a well is generally swabbed clean to remove any debris, and a dewatering pump is installed. Depending on the depth, gas and water production rates, and reservoir pressure, one of the following systems is used:

- Sucker rod pump
- Progressive cavity (Moyno) pump
- Submersible electric pump
- Gas lift

A sucker rod pump is most often used when water flow is less than 20 m^3/d. For heavier flows, a progressive cavity pump is used. In the dewatering phase of gas production, the pump is usually kept slightly above the coal seam and a 30–60-m water column is maintained above the coal seam to prevent a blowout (i.e., a sudden discharge of gas and proppant sand). Submersible electric pumps are used when the water production is excessive and progressive cavity pumps are unable to handle the flow. Gas lift is used when no electric power is available to operate a dewatering pump.

PRODUCED WATER DISPOSAL

All produced water must be metered to determine the flow rate. If the water is clean, a turbine meter is used to precisely measure the water flow. If the produced water contains some solids, a positive displacement water meter is used. The latter is more durable and commonly used. Where the water flow is intermittent and low, a 20-L bucket is used to collect the pump discharge, and the time of discharge is measured by a stopwatch from which the flow rate is calculated.

Gathering water and its proper disposal is often a significant part of the CMP. The following are the possible options for water disposal:

- Surface disposal
- Deep-well injection
- Evaporation in a pond or a boiler
- Land application
- Off-site disposal in abandoned mines
- Reuse for hydraulic stimulations

The choice of the technique depends on the volume of water produced per day and its quality. Permitting from national and state authorities is often needed and it is a prolonged process. Most commonly, only the first two choices are used, and they are the only ones discussed here. Figure 11.6-11 shows a layout of various options.

Surface Disposal

The simplest method of surface disposal comprises pH (a measure of water acidity) adjustment of water to meet the permit requirements, aeration of water with compressed air, and addition of some polymers to facilitate settling. The clean water is used for land applications or simply discharged into a local stream. The total dissolved solids (TDS) and chloride concentrations are monitored to match the quality of treated water with that of water in the stream.

If the produced water has a higher concentration of contaminants, it is pretreated, and the reverse osmosis process is

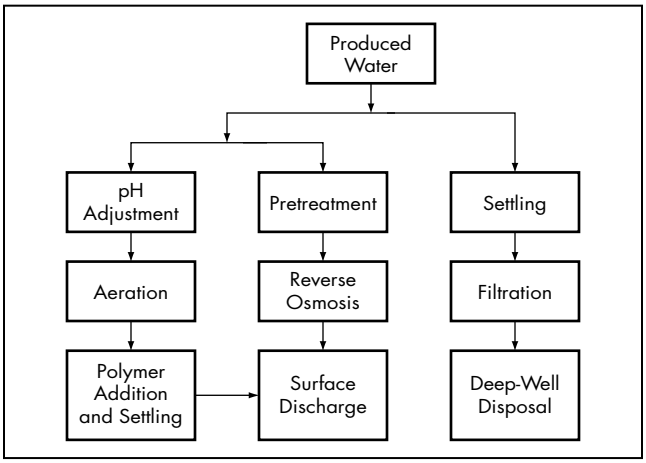

Figure 11.6-11 Options for treating produced water

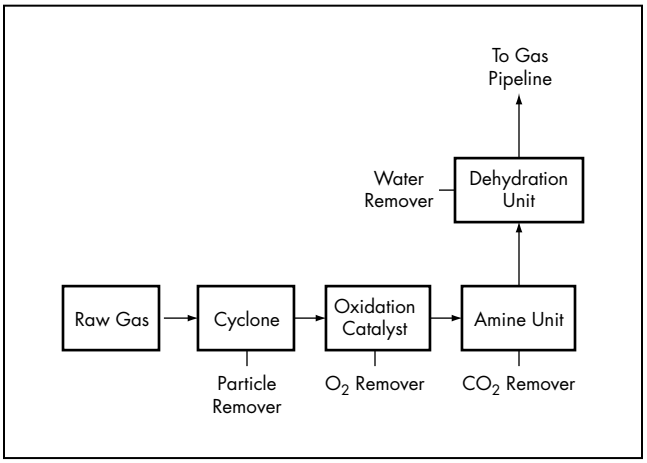

Figure 11.6-12 Gas processing flow

used to remove the TDS. Average efficiency of TDS removal is in excess of 95%. Only in the presence of bicarbonates does the efficiency go down to 50%–80%. The main limitation of this process is membrane fouling caused by suspended solids or oils in the produced water.

Deep-Well Injection

If there are no streams in the neighborhood of a CBM field or the necessary permits to discharge into the local streams cannot be obtained, the treated water can be injected into a deep well. Deep-well injection also requires a permit but it is easier to get. Typically these injection wells are old gas wells with a depth of 3,000 m or so. They are often hydrofraced to create good permeability.

Produced water must be properly treated before injection to keep the injection pressure below the permitted limits. Thick sandstone or limestone reservoirs with high porosity and permeability are ideal for this purpose. Preinjection filtration is almost always essential. Scale and corrosion inhibitors and bactericides are often added to the injected water to increase long-term use of the injection well. Finding or even drilling an injection well in the vicinity is crucial because the cost of gathering and hauling water can be quite substantial.

GAS GATHERING AND PROCESSING

CMP must be gathered to a central location for processing and commercial marketing.

Gas Gathering and Measurement

Gas flows from individual wells must be measured. The primary measurement instruments are either an orifice meter or a turbine meter. The orifice meter measures the differential pressure upstream and downstream of a measured orifice. The pressure drop is a function of the flow rate, gas pressure, and temperature. The pressure differential is continuously recorded on a chart that is calibrated to give the gas production. This is the most common method of measuring individual well production.

The turbine meter measures the flow rate and total volume of gas produced. Gas flows over rotary blades, and magnets in the meter housing pick up signals that are proportional to gas velocity. The area between the blades has fixed volumes so that the number of turns equates to the volume of gas produced. The turbine meter is more accurate than the orifice meter, but it is more expensive and needs frequent maintenance.

Gas from each producing well is gathered using polyethylene pipes and compressors. Usually a cluster of wells is connected to a small compressor. These small compressors deliver the compressed gas to a central compressor facility where it is processed for marketing. In the design of the gas-gathering system, the main object is to maintain a low wellhead pressure, usually <3–5 kPa. Pipe diameters and compressor sizes are designed to minimize line losses. In general, one may start with 50-mm-diameter pipe at a single wellhead, but progressively the pipe diameter may increase to 250–300 mm at the main gas-gathering and processing plant.

Gas Composition and Processing

For commercial marketing, the CBM composition must meet the pipeline specification. All major pipeline companies require a minimum calorific value and put a limit on oxygen, moisture, and noncombustible concentrations. CBM composition varies from basin to basin, but generally it contains 85%–95% methane. Impurities must be removed to raise the calorific value to about 37 MJ/m^3. Other requirements are that the noncombustible content of gas should be <4%, moisture should be <0.11g/m^3, and oxygen is restricted to 20 ppm. In many applications, CBM is mixed with coal mine methane that contains higher oxygen and nitrogen, in which case excess nitrogen is removed by a cryogenic process.

Figure 11.6-12 shows a typical gas processing flow diagram. First, the raw gas is passed through a cyclone to knock solid particles out. Next, the gas is passed over an oxidation catalyst where methane is oxidized that consumes all oxygen and produces water and carbon dioxide (CO_2). Next, the CO_2 is removed by passing the gas through an amine unit. Finally, the moisture in gas is removed by dehydration units containing glycol. If there is excess nitrogen in the gas stream, it is generally removed by a cryogenic process. The clean, pipeline-quality gas is compressed to pipeline pressure, typically 7–8 MPa for delivery into a commercial gas pipeline.

Small rotary compressors are used for primary gathering because they are more efficient in compressing somewhat dirty but large volumes of gas. The main station compressors are generally reciprocating piston-type compressors that are more efficient for duty. The prime mover for compressors can be electric, diesel, or even a CBM engine to keep the cost low.

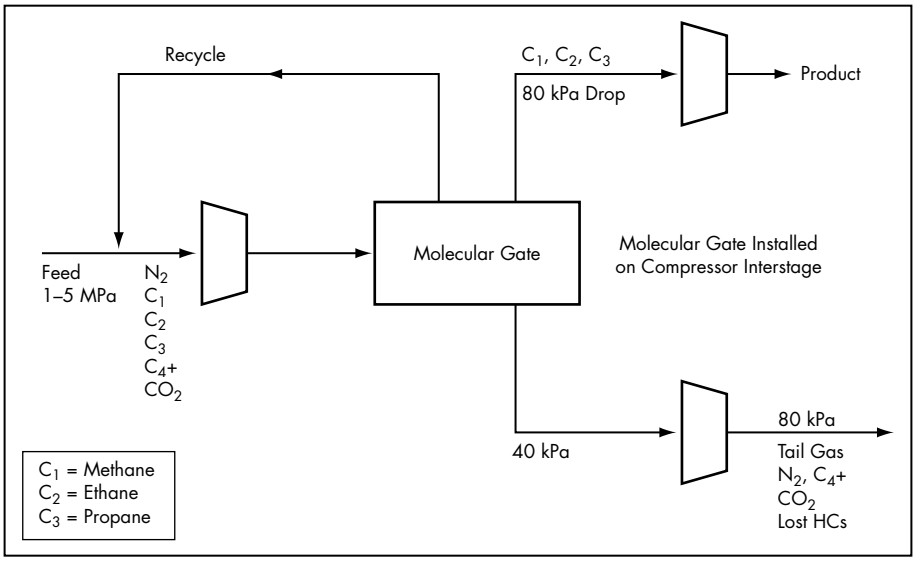

Figure 11.6-13 Molecular gate separation

Molecular Gate Separation System

The molecular gas separation system is a recent breakthrough for processing gases where gas molecules differ in size by only a fraction of an angstrom (Å). A new family of titanium silicate molecular sieves has a pore size that can be controlled down to 0.1 Å (0.01 nm).

In upgrading CBM and coal mine methane, the desired product, methane, has a molecular diameter of 3.8 Å whereas the impurities such as nitrogen (3.6 Å), carbon dioxide (3.3 Å), and oxygen (3.5 Å) are all smaller in size and easily fit within the pore of an adsorbent, where they can be adsorbed and removed in one step from the product stream (Mitariten 2001).

Figure 11.6-13 illustrates the basic flow sheet for a molecular gate separation process. The feed gas is compressed to 1–5 MPa and fed into the molecular gate system. Several repetitions/cycles are made to achieve high purity. The product gas comprising methane, ethane, and propane is recovered at practically the original pressure, which avoids recompression. The tail gas contains most impurities but often has enough methane that it can be used for steam production. The process has a methane recovery efficiency of 95% at 2.4 MPa, but it becomes more efficient at higher pressures. It can remove CO_2, N_2, and O_2 in one step. It is available in sizes of 30,000–900,000 m^3/d of methane. The cost of gas processing declines significantly with increase in the flow rate.

CARBON DIOXIDE SEQUESTRATION

It was mentioned earlier that coal has a great affinity for CO_2 and it can displace methane stored on the micropores of the coal matrix. This property of coal has been used to produce methane from deep coal seams and sequester CO_2 in it simultaneously. Laboratory experiments to displace methane from coal using nitrogen, helium, and carbon dioxide show that the latter is the most effective flooding agent. The storage capacity of coal for CO_2 is at least twice the capacity it has for methane (Collins et al. 2002).

Figure 11.6-9 shows an ideal layout for CO_2 sequestration. When gas production begins to decline, CO_2 injection can start. The optimum parameters of CO_2 sequestration have not yet been established, but many research projects are in progress to determine the following:

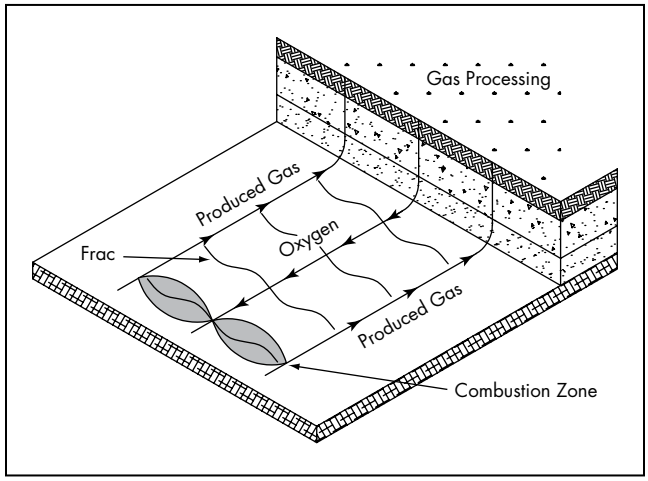

Figure 11.6-14 Underground coal gasification

- Optimum storage capacity for CO_2 in various coal seams
- Rate of injection and travel velocity of CO_2 in coal
- Optimum pressure of injection; generally the reservoir fracturing pressure should not be exceeded
- Ideal mix of gases; CO_2 by itself is slow moving and nitrogen is often added to accelerate the process
- Economics of CO_2 sequestration

CO_2 sequestration research is encouraged by many countries because it is considered a GHG. In many countries, there are financial incentives for sequestering CO_2. The current carbon finance instrument in the United States is fixed at $6.50/t of CO_2. Two sources of CO_2 can be related to coal: (a) power plants that burn coal, and (b) CBM itself that may contain 10%–50% CO_2 in some coal seams. CO_2 can be stripped using gas-processing techniques discussed earlier and its sequestration may become a profitable venture.

UNDERGROUND COAL GASIFICATION

CMP from deep coal seams can also be enhanced by heating the coal matrix. The drilling layout shown in Figure 11.6-14 is a schematic for UCG. Heating of the central horizontal boreholes can be done with steam or radio frequency devices, but the most synergistic approach is to ignite the coal with a limited supply of air/oxygen-combustible gaseous blends. The UCG process is, in fact, already well established, but it has not been done in conjunction with methane recovery. In this process, the outer horizontal laterals are used for gas production. When most methane is driven out, the coal matrix is combusted in situ to produce a lower calorific value gas. The process is also called in-situ gasification of coal.

The product gas composition depends on coal composition and process parameters such as operating pressure, outlet temperature, and gas flow. These parameters are not only monitored but constantly adjusted to optimize the process.

The UCG process is quite flexible. It can be used in coal seams with a thickness of 1–60 m, and calorific values of 10–30 MJ/kg including lignites and other low-quality coal. The coal deposits shown in Figure 11.6-1 have a reserve of 17–30 Tt. Only 1 Tt is amenable to actual mining. Thus, the remaining reserve can be economically exploited by the UCG process.

UCG experiments carried out in the 1970s by the U.S. Department of Energy in West Virginia and Wyoming (United States) produced only low calorific value gases (10–20 MJ/m^3), but new processes are being developed to improve the calorific value. Products of different UCG projects can be mixed with gases with higher calorific values to meet a consumer's specific need.

CMP and UCG processes supplement conventional mining by recovering energy from coal seams that are abandoned or cannot be economically mined. The gaseous product of the UCG process can be used in a variety of ways, such as

- Boiler fuel to produce steam for electric power generation,
- Feed to chemical plants to produce Fischer–Tropsch liquids or fertilizers, and
- A clean gaseous fuel after the raw gas is processed using techniques discussed earlier in the chapter.

The U.S. Environmental Protection Agency is making a great effort to export CMP technology to all major coal-producing countries. This is mainly being done to make mining safer and more productive. But it also creates a clean source of energy that supplements the natural gas supply. Additional incentives such as the carbon credit can provide a great impetus to develop this valuable resource even further. The combination of CMP with CO_2 sequestration can be used to enhance CMP from deeper coal seams and eventually, using the UCG process to convert coal into natural gas, can greatly increase the world supply of natural gas. Further research is needed to make the UCG process more efficient. In the future, the in-situ coal may also be converted into liquid fuel to increase the petroleum supply.

PART 12

Underground Development

CHAPTER 12.1

Introduction to Underground Mine Planning

Richard L. Bullock

GENERAL BASIS OF MINE PLANNING

Many details go into the planning of a mine. The information gathered must come from several sources. First is the geological, structural, and mineralogical information, combined with the resource/reserve data. This information leads to the preliminary selection of potential mining method and sizing of the mine production. From this the development planning is done, the equipment selection is made, and the mine work force projections are completed, all leading to the economic analysis associated with mine planning.

Planning as just described, however, will not necessarily guarantee the best possible mine operation, unless the best possible mine planning has been done correctly. Any sacrifice in mine planning introduces the risk that the end results may not yield the optimum mine operation. Planning is an iterative process that requires looking at many options and determining which, in the long run, provide the optimum results.

This chapter addresses many of the factors to be considered in the initial phase of all mine planning. These factors have the determining influence on the mining method, the size of the operation, the size of the mine openings, the mine productivity, the mine cost, and, eventually, the economic parameters used to determine whether the mineral reserve should even be developed.

PHYSICAL AND GEOTECHNICAL INFORMATION NEEDED FOR PRELIMINARY MINE PLANNING

Many pieces of engineering and geologic data must be gathered before mine planning can take place. These are covered in the sections that follow. This section draws heavily from Chapter 2 of *Underground Mining Methods* (Bullock 2001).

Technical Information

Assuming that the resource to be mined has been delineated with prospect drilling, study will be based primarily on information supplied through exploration. The results of the exploration are recorded in a formal report for use in project evaluation. The exploration report should contain the following information with appropriate maps and cross sections:

- Property location and access
- Description of surface features
- Description of regional, local, and mineral-deposit geology
- Review of exploration activities
- Tabulation of geologic resource material
- Explanation of resource calculation method, including information on geostatistics applied
- Description of company's land and water position
- Ownership and royalty conditions
- Mining history of property
- Rock quality designation (RQD) values and any rock mass classification work that has been done
- Results of any special studies or examinations the exploration group has performed (metallurgical tests, geotechnical work, etc.)
- Report on any special problems or confrontations with local populace of the area
- Any other pertinent data such as attitude of local populace toward mining, special environmental problems, availability of water and hydrologic conditions in general, and infrastructure requirements

This critical information should be established to assist the mine planning. If the exploration project is one that has been drilled out by the company exploration team, this information should have been gathered during the exploration phase and passed to the mine evaluation team or the mine development group. More information on each of these subjects may need to be obtained, but if the inquiry can be started during the exploration phase of the project, time will be saved during the feasibility/evaluation and development phases of the project. If this is an ongoing mine operation, then most of the technical information will be available from other mine planning projects.

Geologic and Mineralogic Information

Knowledge of similar rock types or structures in established mining districts is always helpful. In developing the first mine in a new district, there is far more risk of making costly errors than in the other mines that may follow. The geologic and mineralogic information needed includes

- The size (length, width, and thickness) of the areas to be mined within the overall operations area to be considered, including multiple areas, zones, or seams;

Richard L. Bullock, Professor Emeritus, Mining & Nuclear Engineering, Missouri University of Science & Technology, Rolla, Missouri, USA

- The dip or plunge of each mineralized zone, area, or seam, noting the maximum depth to which the mineralization is known;
- The continuity or discontinuity noted within each of the mineralized zones;
- Any swelling or narrowing of each mineralized zone;
- The sharpness between the grades of mineralized zones within the material considered economically mineable;
- The sharpness between the ore and waste cutoff, including
  - Whether this cutoff can be determined by observation or must be determined by assay or other means,
  - Whether this cutoff also serves as a natural (physical) parting resulting in little or no dilution, or whether the break between ore and waste must be induced entirely by the mining method, and
  - Whether the mineralized zone beyond (above or below) the existing cutoff represents submarginal economic value that may become economical at a later date;
- The distribution of various valuable minerals making up each of the potentially mineable areas;
- The distribution of the various deleterious minerals that may be harmful in processing the valuable mineral;
- Whether the identified valuable minerals are interlocked with other fine-grained mineral or waste material;
- The presence of alteration zones in both the mineralized and the waste zones;
- The tendency for the ore to oxidize once broken; and
- The quantity and quality of the ore reserves and resource with detailed cross sections showing mineral distribution and zones of faulting or any other geologic structure related to the mineralization.

Structural Information

Required physical and chemical structural information includes the following:

- The depth of cover
- A detailed description of the cover, including the
  - Type of cover;
  - Approximate strength or range of strengths;
  - Structural features in relation to the proposed mine development; and
  - Presence of and information about water, gas, or oil that may have been encountered
- The quality and structure of the host rock (back, floor, hanging wall, footwall), including the
  - Type of rock,
  - Approximate strength or range of strengths,
  - Noted zones of inherent high stress,
  - Noted zones of alteration,
  - Major faults and shears,
  - Systematic structural features,
  - Porosity and permeability,
  - The presence of any swelling-clay or shale interbedding,
  - RQD throughout the various zones in and around all of the mineralized area to be mined out,
  - The host rock mass classification (Rock Mass Rating [RMR] or Barton's Q-system),
  - Temperature of the zones proposed for mining, and
  - Acid-generating nature of the host rock
- The structure of the mineralized material, including all of the factors listed previously, as well as the
  - Tendency of the mineral to change character after being broken (e.g., oxidizing, degenerating to all fines, recompacting into a solid mass, becoming fluid, etc.);
  - Siliceous content of the ore;
  - Fibrous content of the ore;
  - Acid-generating nature of the ore; and
  - Systematic fault offsets.

PLANNING RELATED TO PHYSICAL PROPERTIES

The physical nature of the extracted mass and the mass left behind are very important in planning many of the characteristics of the operating mine. Four aspects of any mining system are particularly sensitive to rock properties:

1. The competency of the rock mass in relation to the in-situ stress existing in the rock determines the open dimensions of the unsupported roof unless specified by government regulations. It also determines whether additional support is needed.
2. When small openings are required, they have a great effect on productivity, especially in harder materials where drill-and-blast cycles will be employed.
3. The hardness, toughness, and abrasiveness of the material determine the type and class of equipment that can extract the material efficiently.
4. If the mineral contains or has entrapped toxic or explosive gases, the mining operation will be controlled by special provisions within government regulations.

In countries where appropriate regulations do not exist, best-practice guidelines must be sought.

THE NEED FOR A TEST MINE

From this long list of essential information required for serious mine planning, it becomes evident that not all of this information can be developed from the exploration phase. Nor is it likely that it can all be obtained accurately from the surface. If this is the first mine in this mining area or district, then what is probably needed during the middle phase of the mine feasibility study is development of a test mine. While this may be an expense that the owners were hoping to avoid up front, the reasons for a test mine are quite compelling. They include opportunities to

- Confirm, from a geologic point of view, the grade, ore continuity, ore configuration, and mineral zoning;
- Confirm, from the engineering viewpoint, rock strengths and mass rock quality; verify mining efficiencies; confirm water inflows; and demonstrate waste characteristics;
- Pilot-test the metallurgical process;
- Enhance the design basis for cost estimates, improve labor estimates, build more accurate development schedules; and
- Lower the mining investment risk.

Having a test mine in place will shorten the production mine development and will serve as a training school for the production mine.

LAND AND WATER CONSIDERATIONS

Information needed about the property includes

- Details on the land ownership and/or lease holdings, including royalties to be paid or collected (identified by mineral zones or areas);
- Availability of water and its ownership on or near the property;
- Quality of the water available on (or near) the property;
- Details of the surface ownership and surface structures that might be affected by subsidence of the surface;
- The location of the mining area in relation to any existing roads, railroads, navigable rivers, power, community infrastructure, and available commercial supplies of mine and mineral processing consumables (drill steel, bits, explosives, roof bolts, steel balls and rods for the mills, chemical additives for processing, steel liners for all mining and processing equipment, etc.); and
- The local, regional, and national political situations that have been observed with regard to the deposit.

OTHER FACTORS INFLUENCING EARLY MINE PLANNING

Many operational decisions must be made in planning the mining operation. None is more important than sizing the mining operation. However, it is not an easy or obvious decision to make and several factors must be considered.

Sizing the Production of a Mine

A considerable amount of literature is available on the selection of a production rate to yield the greatest value to the owners, including works by Tessaro (1960), McCarthy (1993), Runge (1997), and Smith (1997). Basic to all modern mine evaluations and design concepts is the desire to optimize the net present value (NPV) or to operate the property in such a way that the maximum internal rate of return is generated from the discounted cash flows. Anyone involved in the planning of a new operation must be thoroughly familiar with these concepts. Equally important is the fact that any entrepreneur who is planning a mining operation *solely from the financial aspects of optimization*, and who is not familiar with the issues associated with maintaining high levels of production at low operating cost per metric ton over a prolonged period, is likely to experience disappointment in years with low (or no) returns.

Other aspects of the problem for optimizing mine production relate to the effect of NPV. When viewed from the purely financial side of the question (i.e., producing the product from the mineral deposit at the maximum rate), optimization that yields the greatest return is the case often selected. This is due to the fixed costs involved in mining, as well as to the present-value concepts of any investment. Still, there are "...practical limitations to the maximum intensity of production, arising out of many other considerations to which weight must be given" (Hoover 1909). There can be many factors limiting mine size, some of which are listed here:

- Market conditions
- Current price of the product(s) versus the trend price
- Grade of the mineral and the corresponding reserve tonnage
- Time before the property can start producing
- Attitude and policies of the local and national government and the degree of stability of existing governments and their mining policies, taxes, and laws
- Availability of a source of energy and its cost
- Availability of usable water and its cost
- Cost and method of bringing in supplies and shipping production
- Physical properties of the rock and minerals to be developed and mined
- Amount of development required to achieve the desired production related to the shape of the mineral reserve
- Amount and complexity of mineral processing required
- Availability of nearby smelting options (if required)
- Size and availability of the work force that must be obtained, trained, and retained
- Availability of housing for employees (in remote locations)
- Potential instability of the government in the future, which might cause a company to develop a smaller, high-grade mine in the beginning until they have received their objective return, then use the income from the existing property to expand and mine out the lower-grade ores

Although all of these factors must be taken into consideration, another approach to sizing the mine is to use the Taylor formulas (Taylor 1977). Taylor studied more than 200 mining properties and then used regression analysis to determine the formulas for sizing a mine. Taylor notes, however, that the formulas are not very applicable to steeply dipping mineral reserves or when mining from deep shafts. The formulas are

$$\text{life of mine} = 0.20 \,\#\, (\text{expected ore metric tons [tons]})^{0.25} = \text{life of mine (in years)} \pm 1.2 \text{ years} \quad (12.1\text{-}1)$$

$$\text{daily production} = \text{reserve ore metric tons (tons)}/\text{expected life/operating days/year} \quad (12.1\text{-}2)$$

Assume 37.2 Mt (41 million tons) of mineable resource:

$$\text{life of mine} = 0.20 \times (37{,}200{,}000)^{0.25} = 15.6 \text{ yr } (\pm 1.2 \text{ yr or } 14.4 \text{ to } 16.8 \text{ yr})$$

$$\text{daily production} = 37{,}200{,}000/16 \text{ yr}/365 = 6{,}525 \text{ Mt/d } (6{,}059 \text{ Mt/d to } 7{,}068 \text{ Mt/d})$$

or

$$\text{life of mine} = 0.20 \times (41{,}000{,}000)^{0.25} = 16 \text{ yr } (\pm 1.2 \text{ yr or } 14.8 \text{ to } 17.2 \text{ yr})$$

$$\text{daily production} = 41{,}000{,}000/16 \text{ yr}/365 = 7{,}020 \text{ tpd } (6{,}530 \text{ tpd to } 7{,}590 \text{ tpd})$$

The two formulas tend to overestimate the production of small-vein-type mining deposits where a lot of vertical development must be completed compared to the daily tonnage that can be extracted. For mineral resources that are steeply dipping, and for deeper mining, the shape of the resource must be considered, as well as how much development is necessary to sustain the desired production. According to McCarthy (1993), for Australian underground narrow-vein mines, approximately 50 vertical meters (165 vertical feet) per annum is currently

economically appropriate for modern mechanized mines. Thus for example, if given certain reserves for mining 10,000 metric tons per vertical meter, then the production would be 500,000 t/a. Properties that were above this "best fit" trend line, McCarthy says, are usually overly capitalized or have higher-than-average operating costs.

Not only does the resource's tonnage affect the mine size, but the distribution of ore grade can certainly affect the mine planning. Unless a totally homogeneous mass is mined, it may make a considerable economic difference as to which portion is mined first or later. Furthermore, no ore reserve has an absolute fixed grade-to-tonnage relationship; trade-offs must always be considered. In most mineral deposits, lowering the mining cutoff grade means that more metric tons will be available to mine. But the mine cutoff must balance the value of each particular block of resource against every type of cash cost that is supported by the operation, including all downstream processing costs, as well as the amortization of the capital that was used to construct the new property.

Even in bedded deposits such as potash or trona, the ability or willingness to mine a lower seam height may mean that more ore can eventually be produced from the reserve. In such cases, the cost per unit of value of the product generally increases. Similarly, narrow-seam mining greatly reduces the productivity of the operation compared to high-seam and wide-vein (or massive) mining systems.

In evaluating the economic model of a new property (after the physical and financial limits have been considered), all of the variables of grade and tonnage, with the related mining costs, must be calculated using various levels of mine production that, in the engineer's judgment, are reasonable for that particular mineral resource. At this point in the analysis, the various restraints of production are introduced. This will develop an array of data that illustrate the return from various rates of production at various grades corresponding to particular tonnages of the resource. At a later stage, probability factors can be applied as the model is expanded to include other restraining items.

Timing Affecting Mine Production

For any given ore body, the development required before production start-up is generally related to the size of the production, as well as the mining method. Obviously, the necessary stripping time for most large porphyry copper deposits is very large compared to the stripping time for even a large quarry. For an underground example, very high production rates may require a larger shaft or multiple hoisting shafts, more and larger development drifts, the opening of more mineable reserves, as well as a greater lead time for planning and engineering all aspects of the mine and plant. The amount of development on multiple levels for a sublevel caving operation or a block caving operation will be extensive compared to the simple development for room-and-pillar operation. In combination, all of these factors could amount to considerable differences in the development time of an operation. In the past, the time for mine development has varied from 2 to 8 years. Two indirect economic effects could result from this:

1. Capital would be invested over a longer period of time before a positive cash flow is achieved; and
2. The inflation rate-to-time relationship in some countries in the past has been known to push the costs upward by as much as 10% to 20% per year, thereby eliminating the benefits of the "economy of scale" of large-size projects.

To aid the engineer in making approximations of the time it takes to develop shaft and slope entries related to the size and depth of the mine entry, the reader is referred to Bullock (1998). For example, sinking and equipping a 6.1-m (20-ft) diameter shaft ranging in depth from 305–914 m (1,000–3,000 ft) will take approximately 64–113 weeks, depending on the production capacity that the shaft must be equipped for. Driving a slope to the same depths will take approximately 52–151 weeks, respectively.

For mines that are primarily developed on one or two levels and have extensive lateral development, the speed of the development can vary considerably. The lateral development on each level of a room-and-pillar mine opens up new working places, and the mine development rate can be accelerated each time a turnoff is passed, provided that there is enough mining equipment and hoisting capacity available. This is in contrast to a vein-type mine that has a very limited number of development faces, as the vein is developed for each level and each level requires deepening the main hoisting shaft or slope. Experience has shown that the mine's development only progresses deeper at the average rate of about 50 m/a. Chapter 4.7 of this handbook discusses several examples of the timing of mine developments.

The timing of a cost is often more important than the amount of the cost. In a financial model, timing of a development cost must be studied in a sensitivity analysis. In this respect, any development that can be put off until after a positive cash flow is achieved without increasing other mine costs should certainly be postponed.

Government Considerations Affecting Mine Size

Government attitudes, policies, and taxes generally affect all mineral extraction systems and should be considered as they relate to the mining method and the mine size. One can assume that a mine is being developed in a foreign country and that the political scene is currently stable but is impossible to predict beyond 5–8 years. In such a case, it would be desirable to keep the maximum amount of development within the mineral zones, avoiding development in waste rock as much as possible. This will maximize the return during a period of political stability. Also, it might be desirable to use a method that mines the better ore at an accelerated rate to obtain an early payback on the investment. If the investment remains secure at a later date, the lower-grade margins of the reserve might later be exploited. Care must be taken, however, that the potential to mine the remaining resource, which may still contain good grade ore, is not jeopardized, whatever the stability situation. There is merit in carefully planning to mine some of the higher-grade portions of the reserve while not impacting the potential to mine the remaining reserve.

Some mining methods, such as room-and-pillar mining, allow the flexibility of delaying development that does not jeopardize the recovery of the mineral remaining in the mine. In contrast, other mining systems, such as block caving or longwall mining, might be impacted by such delays.

Similar situations might arise as a result of a country's tax or royalty policies, sometimes established to favor mine development and provide good benefits during the early years of production; in later years the policies change. Again, as in

the preceding case, the flexibility of the mining rate and system must be considered, but not to the extent of jeopardizing the remaining resource.

PREPLANNING BASED ON GEOLOGY AND ROCK CHARACTERISTICS

In the previous section, the influence of geology from a macro point of view was considered. In this section, the geology from a micro point of view of the rock and mineral characteristics must be considered in mine planning.

Geologic Data

Using geologic and rock property information obtained during preliminary investigations of sedimentary deposits, isopach maps should be constructed for all potential underground mines to show the horizons to be mined and those that are to be left as the roof and floor. Such maps show variances in the seam or vein thickness and identify geologic structures such as channels, washouts (called "wants"), and deltas. Where differential compaction is indicated, associated fractures in areas of transition should be examined. Areas where structural changes occur might be the most favored mineral traps but are usually areas of potentially weakened structures. Where possible, locating major haulage drifts or main entries in such areas should be avoided; if intersections are planned in these areas, they should be reinforced, as soon as they are opened, to an extent greater than that necessary elsewhere. Further details on development opening in relation to geologic structures and other mine openings appear in Spearing (1995), reproduced by Bullock (2001).

Again referring to flat-lying-type deposits, extra reinforcing (or reducing the extraction ratio) may also be necessary in metal mines where the ore grade increases significantly, since the rock mass usually has much less strength. Where the pillars were formed prior to discovering the structural weakness, it will probably be necessary to reinforce the pillars with fully anchored reinforcing rock bolts or cables. It is advisable to map all joint and fracture information obtained from diamond-drill holes and from mine development, attempting to correlate structural features with any roof falls that might still occur.

Characteristics of Extracted Material

The hardness, toughness, and abrasiveness of the material determine whether the material can be extracted by some form of mechanical cutting action, by drilling and blasting, or by a combination of both methods.

The mechanical excavation with roadheaders of the borate minerals from the Death Valley (California, United States) open-pit mine operated by Tenneco, and the later use of the same type of roadheader at the nearby underground Billie mine (California) illustrate the point. Bucket-wheel excavators have been used extensively in Germany and Australia for stripping overburden from the brown coalfields.

Technological advances in hard-metal cutting surfaces, steel strengths, and available thrust forces allow increasingly harder and tougher materials to be extracted by continuous mining machines. The economics of continuous cutting or fracturing, as compared to drill-and-blast, gradually are being changed for some of the materials that are not so tough or abrasive. However, for continuous mining—other than tunnel boring machines—to be competitive with modern high-speed drills and relatively inexpensive explosives, it appears that the rock strengths must be less than 103,400–124,020 kPa (15,000–18,000 psi) and have a low abrasivity. Rock that is full of fractures, however, is also a great aid to mechanical excavation. In one case that was covered in an article about the gradual trend toward mechanical excavation in underground mining (Bullock 1994), a roadheader was being used in a highly fractured, welded volcanic tuff, even though the rock strength was well over 137,800 kPa (20,000 psi).

At times, reasons other than the cost of extraction favor one mining system over another. Using a mechanical excavation machine is nearly always advantageous in protecting the undisturbed nature of the remaining rock where blasting might be prohibited. Likewise, the continuous nature of mechanical excavation can be used to speed mine production. This was seen in the openings driven by Magma Copper in developing the Kalamazoo ore body in Arizona, United States (Chadwick 1994; Snyder 1994) and by Stillwater Mining Company in developing their original ore body as well as for their East Boulder ore body in Montana, United States (Tilley 1989; Alexander 1999). A continuous boring tool may also be desirable for extracting an ore body without personnel having to enter the stoping area. Where their use is applicable, continuous mining machines are certainly much easier to automate than the cyclical drill-and-blast equipment. The automation of the 130 Mobile Miner at the Broken Hill mine in Australia is one case in point (Willoughby and Dahmen 1995). Another more dynamic case is the complete automation of the potash mines of Potash Corporation of Saskatchewan, Canada (Fortney 2001).

PLANNING THE ORGANIZATION

The amount of equipment or numbers of personnel required to meet the needs of all mines cannot always be given in absolute and precise terms. The purpose of this discussion is to mention some of the general problems that may be encountered and actions to mitigate those problems.

Work Force and Production Design

When planning the details of a mining work force, it is necessary to consider several factors:

- Is the supply of labor adequate to sustain the production level dictated by other economic factors? If not, can the needed labor be brought in, and at what cost?
- What is the past history of labor relations in the area? Are the workers accustomed to a 5-day work schedule, and if so, how will they react to a staggered 6- or 7-day schedule?
- Are the local people trained in similar production operations, or must they be trained before production can achieve full capacity?
- Will a camp have to be built and the workers transported in on weekly schedules?
- If long commutes are required to reach the property daily, are company-contracted busses for all shifts an option?
- If long commutes are required, are shifts longer than the normal 8 hours an option?
- Can people with maintenance skills be attracted to the property, or will the maintenance crew have to be built up via an apprenticeship program?

Apprenticeship programs are very slow in terms of producing results. Accordingly, some state laws in the United States restrict the annual number of people who can be trained in such programs. This one item could cause a mine designed

and equipped for a very large daily production to fall far short of its desired goals.

Work-force issues and local community resources need to be investigated at the same time that the property is being evaluated and designed. This will provide adequate time for specialized training, minimize unexpected costs, and also prevent economic projections based on policies that, if implemented, could negatively impact employee morale or community relations. The productivity and profitability difference between an operation with high morale and good labor relations and an operation where such parameters are poorly rated can be drastic. Such matters can make the difference between profit or loss. Of all the items involved in mine design, this one is the most neglected and can be the most disastrous.

Equipment Selection

Field-Tested Equipment

The equipment selected should be produced by manufacturers that field-test their equipment for long periods of time before they are marketed to the industry. Too many manufacturers build a prototype machine and install it in a customer's mine on the contingency that they will stand behind it and make it work properly. Eventually, after both the end user and the manufacturer redesign, rebuild, reinforce, and retrofit this model, a workable machine is obtained. The cost in lost production, however, is imposed on the mine operator, not the manufacturer. The manufacturer can then proceed to sell the "field-tested" retrofitted model to the entire industry, including competitive mines. Beware of taking on equipment in underground mines that has not been thoroughly field tested in severe applications by the manufacturer, unless it is going to be used for an isolated research application.

Equipment Versatility

The equipment selected for the mining operation should be as versatile as possible. Normally, for large surface mines, this is not much of a problem. For small quarries and for most underground mines, however, it can be a problem if the equipment can only be employed on a limited number of mining operations. For example, in one room-and-pillar mining operation (Bullock 1973), the same high-performance rotary percussion drilling machines used for drilling the bluff or brow headings were then mounted on standard drill jumbos for drilling holes for burn-cut drifting and stoping rounds and for slabbing rounds in the breast headings. Because the drills on these jumbos have high penetration rates, they were also used to drill the holes for roof bolts and, in some cases, the holes for the reinforcing pillars. The same front-end loader was used to load trucks in one stope and to perform as a load-haul-dump unit in another stope. By switching working platforms, the same forklift tractors served as explosive-charging vehicles and as utility service units for handling air, water, and power lines. They also served as standard forklifts for handling mine supplies. This equipment philosophy results in the following advantages:

- Less equipment must be purchased and maintained.
- Less training is required for operators and maintenance personnel. In addition, all personnel have a better chance of becoming more efficient at their jobs.
- Having fewer machinery types means having a smaller equipment inventory.

Possible disadvantages of this approach are the following:

- A more efficient machine may be available to do the task currently being performed by the versatile—but less efficient—machine.
- The mine may become too dependent on a single manufacturer to supply its equipment needs.

Equipment Acceptance

Equipment selected should have a very broad acceptance and must be in common use throughout both the mining and construction industries. However, since underground mines impose a headroom restriction not encountered on the surface, this is not always possible. Nevertheless, where headroom is not an issue, selecting a standard piece of equipment means that the components will have endured rigorous testing by the construction industry. Furthermore, equipment parts are normally off-the-shelf items in distributors' warehouses.

Application Flexibility

The selected equipment should be flexible in application. For example, the equipment should be able to accelerate and move rapidly, have good balance and control at high speeds, be very maneuverable, and have plenty of reserve power for severe applications. Both trucks and loaders should have ample power to climb every grade in the mine and be able to accelerate quickly to top speed on long, straight hauls.

PLANNING THE UNDERGROUND MINE SERVICE FACILITIES

Underground facilities such as underground pumping stations, power transfer and transformer stations, underground shops, storage warehouse space, ore storage pockets, skip-loading stations, lunchrooms, refuge chambers, shift and maintenance foremen's offices, and central controlled computer installations and communications all extract a strong influence on engineering study and design. More detailed information appears in Chapter 12.5, where these types of facilities are described and their designed size is discussed.

CHAPTER 12.2

Hard-Rock Equipment Selection and Sizing

Peter L. McCarthy

INTRODUCTION

Whereas underground equipment should be selected to suit the mine, it is equally true that the mine should be designed to suit the equipment. It is impossible to begin mine planning and scheduling without a good idea of the type and size of equipment available and how it might be applied. Design of stopes or panels, mine accesses, development cross sections, ramp gradients, electric power reticulation, ventilation circuits, and so on must be based on an assumed type and fleet of equipment.

GENERAL APPROACH

In practice, equipment selection for a new hard-rock mine starts with the stoping operation. Stoping equipment should be appropriately sized for the characteristics of the ore body and the stope dimensions. Stope development openings should be sized to suit the stope dimensions and the stoping equipment capabilities and requirements.

Equipment should then be sized to mine the required size of stope development. Separate development fleets for access and stope development may be required. If this logic is not applied, big "efficient" development equipment may be acquired for access development, and then used in the stoping areas. The result is that the stope development is sized to fit jumbo drills, rock-bolter booms, or even the haul trucks, and must be far larger than the optimum, causing inefficiencies in stope design, poor geotechnical conditions, or excessive overbreak and development cost.

Of course, it is often necessary to select new equipment for an existing mine, where the constraints including access dimensions, ventilation, and so forth have to be identified and managed. In a shaft mine, for example, the machine size may be limited by the dimensions of shaft compartments and the component sizes in which the machine can be broken down for transport.

Proposed or possible changes to the mine plan, such as a move from a 5-day working week to continuous working, or a change in the decline gradient, will affect the equipment duty and must be considered. Sometimes a new machine may allow a new way of working. For example, replacement of rear-wheel-drive trucks with four-wheel-drive trucks would allow ramps to be steepened. This could reduce overall costs, and it is this larger context that must be analyzed.

Machines should be compared in terms of capital cost, operating cost, specifications, performance, availability, ease of maintenance, service and parts backup, and service life.

Fleet Description

The first step is to describe the key elements of the equipment fleet. For example, in a hard-rock ramp-access mine, this might include

- Two-boom jumbo drills,
- One-boom jumbo drills,
- Rock-bolting machines,
- Long-hole drills,
- Large load-haul-dump units (LHDs),
- Small LHDs,
- Haulage trucks,
- Integrated tool carriers, and
- Road graders.

Many other machines such as personnel transporters, shotcrete machines, air compressors, raise drills, and others may be needed, but the items in the list will be considered in determining stope and development layouts and dimensions.

Equipment Matching

Individual items of equipment, considered together, form a development system or a production system, and thus they must be physically compatible. Jumbo drills must be capable of reaching the limits of the largest excavation required, usually determined for the production drills and the trucks. LHDs must be able to reach and fully load the tubs (boxes or trays) of the trucks in three to five passes.

Sometimes a workaround will enable incompatible units to be used. For example, a "step" in the floor may enable small LHDs to load large trucks.

Electric machines should all operate from the same electric supply voltage. A decision must be made about whether compressed air will be reticulated, and if not, each pneumatic machine must be self-sufficient for compressed air.

Peter L. McCarthy, Chairman and Principal Mining Consultant, AMC Consultants Pty Ltd., Melbourne, Victoria, Australia

When items are obtained from a single manufacturer, the manufacturer will be able to determine how well matched they are. If they come from different manufacturers, some research may be needed, including detailed study of the specifications and discussions with staff of other mines about using the units together.

Choice of Manufacturer or Supplier

Manufacturers of underground equipment range from large, international firms with worldwide representation to small manufacturers that generally serve a local market or a specialized niche. In general, the international firms offer robust, reliable, and well-proven equipment at the upper end of the price range. Equipment is usually priced in euros or U.S. dollars, which may appear prohibitive when converted to a local currency.

Small regional manufacturers can offer attractive pricing and may offer a viable alternative to the name brands. Because their level of research and development is limited, and because they are building to a price, machines from such manufacturers generally have lower availability and may have reduced performance. These factors should be assessed carefully in deciding whether lower capital cost outweighs higher operating costs, including the impact of servicing and breakdown delays on the mining system as a whole.

Other manufacturers offer specialist equipment that is not available from the major suppliers. Examples of the products of international niche manufacturers include narrow-vein mining equipment from France and Canada, rock-bolting platforms from Canada, backfill slinger trucks from Germany, raise climbers from Sweden, and so on.

Equipment with similar specifications from the major manufacturers will generally give similar performance. This is often compared with the choice of buying a car from Ford or from General Motors—both will do the job. It is worth enquiring at other mine sites that use the same equipment, because specific models sometimes have problems that are not really resolved during the model run, whereas competing machines are free of those problems.

Apart from operating performance, equipment analysis should include the ease of maintenance. Some equipment models are easier to maintain, which can have a positive impact on the availability of the equipment.

The most important factor in choosing between otherwise similar machines is the level of backup support provided in a region by the manufacturer. Appropriate questions include the following:

- What training will the manufacturer offer to operators and maintenance personnel?
- Does the manufacturer have service facilities with trained personnel within an hour or two of the mine by road? If not, is it willing to establish such facilities on the basis of an order?
- Will the manufacturer stock a comprehensive range of spare parts in-country for any specific model? What is the likely delivery time?
- Will the manufacturer provide spare parts in the mine store on a consignment basis, so that payment is made only when they are used?
- Which major components are not stocked in-country? How long would it take to obtain them, if needed, and what would be the cost of urgent air freight?
- Will the manufacturer offer maintenance and consumables on a fixed cost per hour or per meter basis, and establish its own maintenance work force on-site?
- What is the reputation of the manufacturer for service and spares backup in the region?
- Are components interchangeable between different pieces of equipment such as the same axles in LHDs and trucks?
- Are the driveline components from the same manufacturer?

After these questions have been addressed, it may be advantageous to source the key fleet items, such as trucks, LHDs, and jumbo drills, from a common supplier. It is also attractive to minimize the number of different models of equipment on the mine site, even if from the same manufacturer, to minimize duplication of stores inventories or maintenance skill sets. Mixed manufacturer fleets, especially trucks, may result in unexpected operational conflicts such as different truck speeds, with slower trucks delaying faster trucks, especially when hauling loads up a ramp.

Appropriate Technology

Any new machine should incorporate a level of technology that can be understood and supported by the operators and maintenance team. Although it may be appealing to engineers to acquire the latest technology, the potential performance will not be delivered if the machine spends much of its time waiting for repairs. At the crudest level, there are mines that operate compressed-air rock drills and do not have the workshop facilities or the skills to maintain hydraulic rock drills. Similarly, many mines do not have the electronics capability to maintain the latest fully computerized jumbo drills and prefer to buy the versions with manual controls.

In general, the longer the supply lines to the mine and the less educated or skilled the work force, the more robust and less innovative should be the technology. It is also difficult to mix different technologies within one operation. For example, a mine developed some years ago in southern Africa tried to combine handheld drills and slushers in the stopes with rubber-tired jumbo and truck development and haulage. The two systems were not compatible: large numbers of walking stope miners impeded the movement of trucks; the rock broken in development was too large for the conveyor feeders; and the maintenance workshops had to service large numbers of stope drills and scraper winches, with which they were familiar, and smaller numbers of hydraulic jumbos and diesel trucks, which were new to them. The mine failed for these and unrelated reasons.

Mine systems should be designed to accommodate the technology to be used. For example, if a conventional mine is to be mechanized, not only must the required infrastructure be provided, but materials-handling logistics need to be thoroughly planned and assessed. For example, this could include transportation and storage underground of diesel, spare parts, and hydraulic oils.

Innovative Models

Innovative new models of machines, even from the most reputable manufacturers, may present operational problems. It often takes 2 or 3 years of operation to resolve design problems in trucks, loaders, and jumbo drills, with trucks giving the greatest problems. Usually the machine gets a bad name in the industry and a revised model with a new code name is

released after the problems are resolved. The problems are not predictable and could be as simple as shearing of wheel studs on a high-powered truck.

The promised performance of a new model may be appealing, and some mine has to be the first to try it. When considering such a machine, it is usually possible to negotiate a performance guarantee with the supplier. This should take the form of an operating availability guarantee, possibly with a minimum performance expressed as metric ton–kilometers per hour, meters drilled per hour, or similar. Financial compensation applies if the machine does not deliver the guaranteed performance.

It is usual for the manufacturer and supply agent to be very interested in the success of a new product, and they may provide high standards of operator training and assume responsibility for maintenance for an extended period. The duration of these above-normal levels of service should be ascertained.

Examples of new equipment that have proved disappointing in the past include

- Some high-powered 50–80 t (metric ton) capacity trucks;
- Some combined drilling and cable-bolting machines;
- Some rock-bolting jumbos;
- Many models of scaling machines;
- Undersized impact breakers; and
- Novel surface or soft-rock crushers and sizers, when applied underground in hard-rock mines.

Equipment Replacement

All equipment has a service life, after which it becomes uneconomical and should be replaced. For some items the service life may be equal to or exceed the mine life, in which case replacement is not necessary. Generally, major items such as headframes, winders (hoists), crushers, ball mills, and so on are designed to last the life of the mine and, in practice, may outlast several mines. Worldwide, a number of operations are still getting satisfactory performance from crushers and winders that were built in the 1930s.

Most portable and mobile equipment has a finite service life. Typically, new mobile equipment will operate at low maintenance costs for approximately 10,000 hours or 2 years, after which the cost increases steadily. If the use of the machine is lower than around 5,000 h/yr, this "honeymoon period" may be extended. This cycle may be repeated following one or two major rebuilds, although the subsequent maintenance costs are rarely as low as for a new machine.

If the working environment changes, a machine may be deemed obsolescent and need to be replaced. Examples include a change to the stoping method, requiring a larger machine, or a change in the ventilation standards that requires a cleaner engine. If there is a substantial improvement in the available technology, a machine may be replaced, even though it is still delivering to its original specification. For example, new rear-dump haul trucks with much-improved power-to-weight ratios may displace older, slower units.

A decision to replace an existing machine must consider the entire physical and financial environment. For example, in a struggling mining company, capital may simply be unavailable no matter how well a replacement can be justified. In such circumstances, the equipment life can be extended almost indefinitely but with a much-increased operating cost. To extend useful life, many operations cycle their equipment through two or more duties. For example, haul trucks may be converted to water trucks, or production LHDs become development LHDs, where they are used more intermittently.

A particular problem arises in shaft-access underground mines. The difficulty involved in dismantling and reassembling large mobile units for shaft transfer leads to inflexibility in maintenance, and major overhaul periods may be extended. Operators tend to retain old equipment as backup units long after they have reached the end of their economic life. This creates an environment of low usage and excessive maintenance costs. For example, one Australian shaft mine was able to reduce its mobile equipment fleet from 50 to 11 units after establishing a service decline from the surface.

Service life and maintenance costs also depend on a company's maintenance policy and the level of onboard monitoring installed.

Making Financial Comparisons

The benefit of investment in a new machine should be quantified in advance, and in most companies this is a requirement of the capital approval process. The economic benefit is best measured by comparing the net present values (NPVs, or usually net present costs) of the alternatives. If the expected service lives of the alternatives are different, the analysis becomes complicated. For example, two machines with service lives of 5 and 7 years would need to be compared (artificially) over a period of 35 years to get a meaningful comparison, or an accurate estimate be made of the residual value of the longer-life machine after 5 years. To overcome this problem, costs should be annualized using an approach known as the annual average cost or the equivalent annual value method.

Equipment replacement decisions are not exclusive to mining, but apply throughout all business activities. Detailed discussions of the methods can readily be found in textbooks on engineering economics and on the Internet, and suitable financial modeling software can be downloaded and purchased for a small sum.

Many mining companies require that the internal rate of return for the investment exceed a hurdle rate, a minimum acceptable rate of return that is set from time to time by the administration and is based on the company's cost of capital or desired rate of return on all of its investments. Although this may simplify decision making, it often leads to suboptimal decisions because it prohibits many investments that add some value to an operation, and, in particular, it ignores the many benefits that cannot be quantified in a simple financial analysis. Companies may also limit the timing of capital approvals within the annual budget cycle and take a dim view of "out of budget" applications.

Nonfinancial measures of performance may be important. For example, improvements in workplace safety or environmental quality may not be economically measurable but may be highly desirable. Provision of a new machine with an air-conditioned cab may improve industrial relations even if the machine specifications suggest there will be no increase in productivity.

At many mines, particularly at remote sites, there is a large benefit in reducing labor numbers. Increased mechanization will aid this, and can become a matter of policy even if it is difficult to quantify the gains from a particular decision on an NPV basis. Labor costs are typically >50% of total costs, but when the cost of extras such as airfares and site accommodation are included, they may be higher yet.

Conversely, the social–political climate in some areas may dictate that reduction in labor by introduction of more productive machines is politically undesirable. An example is the large amount of hand labor on ramp roadway maintenance seen in many Mexican mines when a grader would be more efficient.

Information Required for Financial Analysis

The capital cost of a new machine should be estimated including the cost of spares, which can be 20% of the purchase price for a mobile unit. This will depend on whether spares are available on consignment; that is, they can be held in the store and paid for when used. Estimators should use the final or likely negotiated price rather than the manufacturer's list price, which is usually somewhat higher.

If an item is sourced overseas, estimators should check what currency will be used for the transaction and what protection (if any) is available against exchange rate variations. Any payable import duties and the transport and unloading costs including in-country transport to the mine should be checked. For a shaft mine, the transport cost will include shaft transfer and reassembly, which can be substantial for bigger items.

Operating costs can be estimated from

- Detailed cost records and performance of similar equipment,
- Cost records for the new item from another operation,
- Manufacturer's cost and performance estimates, and
- A database of costs from a range of operations.

To support ongoing decision making, good record keeping and cost allocation are required over the life of each unit. The mine accounting system must be able to track each piece of major equipment and not report a combined cost for all LHDs, trucks, jumbos, and so on. Records should include engine hours and, for rock-drilling equipment, percussion or hydraulic pump hours, as well as outputs such as metric tons loaded, metric ton–kilometers hauled, or meters drilled.

Caution must be used when comparing costs from different operations, where different operating conditions may apply and the basis of reported costs may not be well understood. Engineers should be particularly wary of manufacturer's estimates, as they are inevitably optimistic. This is an area where consultants can be very helpful, as a good consultant should have an extensive cost and performance database.

The salvage value may sometimes be important. For mobile equipment it will depend on the age of the unit, its condition, and the operating hours since a major rebuild. A rebuilt 10,000-hour underground mobile item could be worth 60%–70% of new cost. The rebuild itself might cost 20%–30% of the original purchase price. An older unit will generally be saleable for about 20% of new cost, if it is operable. Machinery merchants are generally willing to provide an estimate of value for a used item, and for common items may not require an inspection.

The cost of removing the old item from the mine, particularly if it is a shaft mine, may negate the salvage value, in which case the unit should be pushed into a stope and backfilled.

Taxation effects and the method of financing the new item may affect the analysis.

Leasing and Contracting

Besides outright purchase, other forms of equipment finance are available:

- An operating lease is similar to rental, is usually for short-term requirements, and can be cancelled without penalty. It is relatively expensive, because the lessor assumes the risk of re-leasing and technological obsolescence, but is fully deductible as an operating expense. It does not affect the lessee's balance sheet.
- A finance lease is a contract, whereby payments are made over much of the useful life of the asset. During this time the lease cannot be cancelled, although it may be paid out if the item is disposed of or destroyed. The cost includes capital (less salvage) cost, interest, a risk premium, and the commercial cost of providing the service. Typically 60%–70% of the purchase price is financed, with the balance payable as a residual. The item appears on the lessee's balance sheet.

As an alternative to leasing, a contractor (and contractor's equipment) could be used. Applications include, for example, truck haulage, production drilling, surface crushing, and the entire mine development or production program. Contracting is often appropriate where a small additional increment of capacity is required for 1 or 2 years. It also makes sense where specialist skills such as cable bolting are required for a limited time, or where the necessary expertise is not available in the vicinity of the mine and there is insufficient time to train a work force.

Estimating the Average Annual Cost

The average annual cost is the sum of depreciation, interest, and operating cost. Consider a truck that has an initial cost of $1.0 million and a salvage value of $0.2 million after an estimated 4-year service life. The depreciation is thus $0.8 million over 4 years or $0.2 million/yr.

The interest expense arises, because owning an asset ties up capital. This is true whether all or part of the purchase price is borrowed or existing cash is used. In the latter case, there is an opportunity cost because that money could have been invested elsewhere. The average investment is

$$(\$1.0 \text{ million} + \$0.2 \text{ million})/2 = \$0.6 \text{ million}$$

If the company has a cost of capital (or cost of borrowing) of 10%/yr, the annual interest expense is $0.1 \times \$0.6$ million or $60,000 for each of the four years.

The annual operating cost may be calculated from the estimated hourly operating cost of $200/h (which includes operator, fuel, tires, maintenance, etc., and the cost of a major rebuild at 12,000 hours) and the expected use of 5,500 h/yr, which is a total of $1.1 million/yr. From this, the average annual cost is

$$\$0.2 \text{ million} + \$0.06 \text{ million} + \$1.1 \text{ million} = \$1.36 \text{ million}$$

A similar calculation can be made for each of the trucks under consideration. The equipment selection decision can then be based on these results, together with all of the other important considerations outlined in this chapter.

Courtesy of Atlas Copco.
Figure 12.2-1 Articulated rear-dump truck

A more accurate calculation can be made, if required, to include consideration of tax effects. The capital tax factor (CTF) is used to adjust capital costs for tax effects. It is determined by

$$CTF = 1 - (td / (i + d))$$

where
t = corporate tax rate
d = annual depreciation rate allowable by the taxation authority (average)
i = cost of capital or interest rate

For example, if $t = 30\%$, $d = 20\%$, and $i = 10\%$, then

$$CTF = 1 - (0.3 \times .20)/ (.10 + .20) = 0.8$$

The CTF is applied to capital costs and salvage values, whereas interest and operating costs are adjusted using $(1 - t)$ to get the after-tax cost. In the example,

annual depreciation = \$0.2 million $\times$ 0.8
= \$0.16 million

annual interest cost = \$0.06 million $\times$ 0.7
= \$0.042 million

annual operating cost = \$1.1 million $\times$ 0.7
= \$0.77 million

Hence, the average annual cost (after tax) is \$0.972 million.

Of course, all the trucks must be evaluated in the same way, either before or after tax, and experience shows that the rankings rarely change. Although more-accurate spreadsheet-based evaluations are possible, taking into account the time value of money, the average annual cost is only one of the considerations in selecting the most-appropriate equipment.

HARD-ROCK EQUIPMENT SELECTION

The key items of mobile equipment are loaders, trucks, jumbo drills, and production drills, each requiring a different approach to selection. Specific selection criteria apply to each item of ancillary equipment. In all cases the considerations discussed in the previous sections should be addressed.

Selecting a Truck

Trucks used underground fall into three categories: rigid-body rear-dump trucks adapted from surface mining units; articulated rear-dump trucks that may be adapted from surface mining units but usually are purpose designed to have a low profile (Figure 12.2-1); and tractor–trailer units, some with separately powered trailers, usually side-dumping, which can be assembled as an underground road train (Figure 12.2-2). All have diesel engines except for trolley-electric trucks, which require special infrastructure.

Where trucks are required to travel through development openings, the truck cross section will fix the dimensions of the opening, or vice versa. Allowance must be made for clearance from the load to any pipes, ventilation duct, or other services; and clearance to side walls, which may be a statutory requirement. A typical design profile is shown in Figure 12.2-3.

The clearance to ventilation ducts is influenced by the following:

- The shape of the tunnel profile, whether flat, arched, or shanty-backed, which is determined from the geology and ground-support requirements.
- The duct diameter, which depends on the airflow required. Sometimes oval-shaped ducts are used to improve clearances but at the cost of greater resistance and fan power consumption.
- The type of duct, whether rigid or flexible. Flexible ducts may be more mobile and require greater clearances.
- The size, number, and position of ducts within the cross section. The position could be in the crown or in one corner of the profile. In wider headings, vent ducts could also be along a sidewall.
- The size and number of ducts depends on the planned distance of forced ventilation (before connecting to a return airway) and the ventilation volume required to service the heading. A forced ventilation heading may typically require one loader and one truck. The ventilation volume is usually a relationship based on a factor relative to the

Courtesy of Powertrans Pty Ltd.
Figure 12.2-2 Underground road train

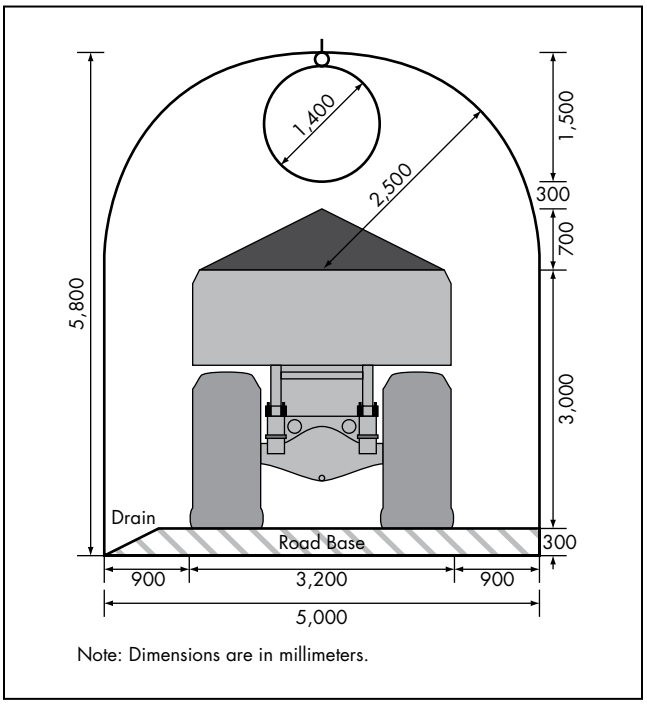

Figure 12.2-3 Typical mine development profile for haul truck

engine power. Duct diameter is then related to required ventilation volume and duct resistance. Duct diameter may become quite large (>1.2-m diameter) for significant forced ventilation lengths, which may require duplication or a mix of types (forced and push–pull systems).

- The expected load profile in the truck. Sometimes trucks are not fully loaded during the development phase, but can be fully loaded after the development is completed, when a ventilation circuit is established and the ventilation ducts have been removed.
- The initial thickness of road base material and any subsequent buildup of road base dressing material that is not removed by grading, and allowance for road spillage that a truck may accidentally ride over.
- The layout of turnouts from the main drive and the way ventilation ducts make the transition through corners.

Sidewall clearance is required to minimize impact damage and for safety reasons. There must be room for pedestrians to walk past a stationary truck and for recovery work to be done in the event of a breakdown or tire failure. It is not acceptable for trucks to pass pedestrians.

Trucks require a minimum turning radius, which generally will not be <20 m due to truck requirements (capability and maintenance) and development issues on grade (overbreak on development rounds). Widening of the heading and/or flattening the gradient may be necessary on bends to maintain required clearances or reduce longitudinal torsion of the truck frame.

Road trains require additional attention to radius and wall clearances due to the variable tracking path of the powered trailers. Development loops are also required for the road trains as they are not designed for reversing, and tipping is usually sideways.

The operating cost per metric ton–kilometer decreases as the truck capacity increases. Thus, there is an incentive to maximize truck capacity, with diesel trucks of up to 60-t capacity being available for underground applications. A trade-off study is required to assess the benefit of the low truck operating cost against the disadvantages that come with size. Factors to be considered include the following:

- The volume of waste rock broken increases with the cross-sectional area of the heading. For example, a 5.5 × 5.5 m drive will produce 53% more waste rock than a 4.5 × 4.0 m drive. If the cost of development breaking and disposal is \$130/m^3 and 10 km of primary development is planned, the cost difference of more than \$1.2 million must be recovered from a reduced trucking cost for all of the ore and waste rock from the mine.
- Ground-support costs generally increase with the square of span.
- Larger, more powerful trucks require more ventilation per truck but not per ton moved.

A larger mine opening with larger trucks will have a greater total production capacity in metric tons per day or per year.

Equipment manufacturers provide comprehensive manuals of specifications of their products, and many provide detailed approaches to equipment selection. The key considerations for an underground truck are

- Physical dimensions and load capacity;
- Exhaust gas and exhaust particulate quality;
- Safety features including falling object protection system and rollover protection system, and whether these comply with local standards;
- Air conditioned, enclosed cabin;
- Ergonomic cabin and seat;
- Power-to-weight ratio, and hence speed on grade;

- Engine braking capability or hydraulic retarder;
- Whether fitted with spring activated, hydraulic release fail-safe brakes;
- Whether the torque converter locks up to provide better power transfer and longer transmission life;
- Centralized lubrication; and
- Centralized fire protection system.

The truck load can be calculated from the truck body volume, the broken density of the rock to be carried, and a fill factor that typically varies from 85% to 95%. The stated tonnage capacity of the truck is typically quoted as "SAE heaped" (where SAE refers to the Society of Automotive Engineers), which has the top surface of the load rising one length unit vertically for every two length units horizontally from the top edge of all sides of the tray. This is rarely achieved in practice, particularly for up-ramp haulage. It is not unusual to find that a 50-t-capacity truck achieves an average payload of 43 t, particularly if there is any problem with back clearance on the haul route. Capacity is maximized by using a well-matched loader and with the use of an onboard weightometer.

The manufacturer's tables will provide torque-speed curves, speed-on-grade curves, and other information to allow cycle times to be estimated. In general, it is sufficient to determine the cycle as the sum of

- Loading time (including any wait for loader), which will depend on the loader capacity and the distance from the muck pile to the loading point;
- Travel time (at an average speed on grade) from the loading point to the dump point, usually including level and uphill segments;
- Dump time (including any delay waiting for other trucks to dump); and
- Travel time (at an average speed on grade) back to the loading point.

The average speed, when loaded, will depend on the condition of the roadway, including the presence of spillage or water, the clearance to the tunnel walls, the road gradient, the number of curves or bends, and any mine-imposed or statutory speed limit. The empty travel speed, if downhill, may be limited for safety reasons to less than the general mine speed limit. Similarly, there may be load or gradient limits for loaded travel downhill.

A typical cycle time calculation for a 50-t-capacity truck in an efficient decline-access mine might appear as follows:

Loading	2.5 minutes
Travel loaded	3.5 km at 7 km/h = 30.0 minutes
Dumping	1.0 minutes
Travel unloaded	3.5 km at 9 km/h = 23.3 minutes
Total cycle time	56.8 minutes
Efficiency factor	90%
Cycle time	63.1 minutes

Thus, if the truck can be loaded to an average 46-t payload, the productivity will be 43.7 t per effective operating hour. If traffic congestion is expected to interfere with the trucking cycle, then a further congestion factor may be introduced to increase the estimated cycle time. One simple way to estimate this factor is to assume that a truck returning empty must pass every other truck on its loaded haul out of the mine. If, as is typical (but not necessarily efficient) practice, empty trucks wait in passing bays for full trucks to pass them in the opposite direction, the cycle time could be increased by the time it takes for a full truck to travel half the average distance between passing bays multiplied by the number of trucks operating, less one.

After the cycle time has been determined for a particular haulage route, the tonnage to be moved, the effective time per shift, and the truck availability must be considered to determine how many trucks are required. It is almost always the case in underground mining that the best outcome is achieved by having an excess of loading capacity, so that truck use is maximized. In other words, it is better to have loaders waiting for trucks than have the trucks waiting for loaders. Often the loaders can spend the time between truck arrivals moving the muck up to a temporary stockpile at the loading point to minimize the loading time and turn the truck around quickly.

If there is in fact little or no queuing of trucks at loaders, the cycle time could theoretically be reduced by having slow full trucks wait for faster empty trucks to pass, rather than the more typical rule noted previously. If this were done, the average delay time in passing bays would be reduced. However, there are other practical operating reasons for why this would not usually be done.

In the example, assume a continuous 24-hour operation with two 12-hour shifts per day. Realistic allowances might include

Fuel up, safety meeting, and travel to job	1 h/shift
Meal breaks	1 h/shift
Job inspections	0.5 h/shift
Planned maintenance (8 h/week)	0.6 h/shift
Breakdowns/unplanned maintenance	0.5 h/shift
Job or efficiency factor	90%
Effective hours per shift (8.4 h × 0.9)	7.56
Effective hours per year (7.56 h × 730 shifts)	5,500
Annual truck production (5,500 h × 43.7 t)	240,350 t

If the target production is 1.5 million t/yr of material brought to surface, then the number of trucks required would be

$$1{,}500{,}000/240{,}350 = 6.2 = 7 \text{ trucks}$$

Traffic congestion occurs when the number of trucks required is high relative to the length of haul, so efforts should be made to provide effectives traffic management through the use of radio communications, block lights, and well-spaced, efficient passing bays. The problem is exacerbated for mixed-fleet systems (different capacity, different loaded speeds).

The difference between the efficiency factor introduced within the cycle time calculation and the job or efficiency factor discussed here is that the former increases the operating engine hours required and, hence, the annual operating cost, whereas the latter reduces the operating engine hours available. A useful check is to see that the annual hours required from the truck are consistent with experience at similar sites. There can be a large difference in annual operating hours for underground haulage trucks ranging from around 2,000 hours up to 5,600 hours depending on the management strategy and mine layout.

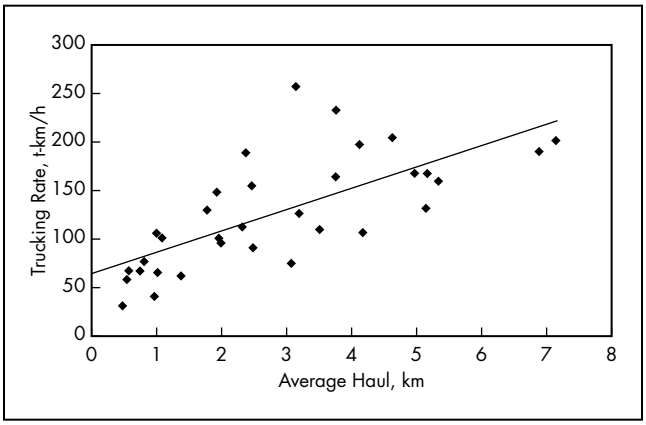

Figure 12.2-4 Truck productivity as a function of haul distance

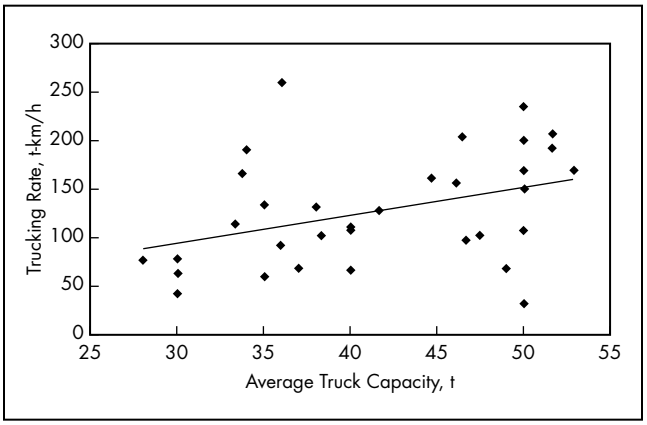

Figure 12.2-5 Truck productivity as a function of truck capacity

Because haulage routes vary, it is often useful to compare truck performance on a metric ton–kilometer basis. This assumes that hauling 1 t for 10 km requires about the same truck capacity as hauling 10 t for 1 km. In the previous example, a 50-t truck hauled 43.7 t/h over a distance of 3.5 km, an output of 153 t-km/h. Actual truck performance, as recorded from 32 operating mines, is shown in Figures 12.2-4 and 12.2-5.

The metric ton–kilometer approach should be used cautiously, because it ignores roadway gradient, which can vary substantially. Whereas some costs, such as tires, vary with load and distance traveled, others, such as fuel, are more closely correlated with engine hours and engine power setting.

When calculating the number of trucks required, allowance must be made for the haulage and disposal of waste rock from development. Often this rock will be backfilled into stopes, requiring a shorter cycle time than a haul to the surface. However, backfilling often causes delays while waiting for a loader or bulldozer to clear the dump point, so that the advantage may not be great. Where trucks must dump fill rock into stopes under a limited back height, ejector-tray trucks may be used. These have an ejector blade, something like a bulldozer blade, which pushes the load from the truck body without having to elevate it into the tipping position.

Ejector-tray trucks have a reduced payload compared to the equivalent standard model, and because of the increased weight in the truck body, they are less fuel efficient. They also have more moving parts to maintain and can suffer damage if large rocks wedge between the sidewall and the ejector.

Trolley-wire electric trucks have been available for many years but have limited application because

- The system has a high capital cost when the trolley-wire installation is considered;
- Although there is no diesel exhaust, they require substantial ventilation for cooling;
- If the mine generates its own power from diesel on the surface, there is no operating cost saving;
- A very high standard of road maintenance is required; and
- Without auxiliary power, trucks cannot travel beyond the fixed trolley wire into actively developing areas.

Despite these limitations, trolley-wire trucks may offer advantages for a mine using low-tariff grid power with a fixed loading point, such as the bottom of an orepass system.

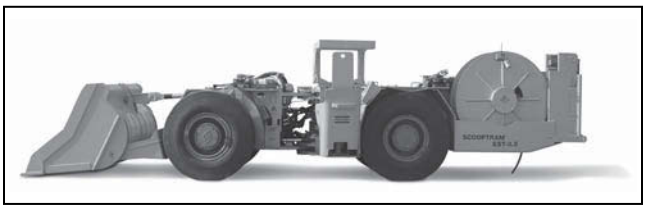
Selecting a Load-Haul-Dump Machine

LHDs are known variously as loaders, muckers, or boggers and differ from front-end loaders in that they have a lower profile and are designed to carry a load in the bucket efficiently for up to 200 m between the muck pile and the truck or orepass that they are loading into. Thus, an LHD spends more time traveling than does a front-end loader, and is engineered accordingly.

A mine may use different-sized LHDs for stoping and for development. Often two or more sizes of LHD are used for stoping, to suit the ore-body width and mining method at different locations within the mine.

Standard models are available in bucket capacities ranging from around 3 to 11.6 m^3. Special machines designed for narrow-vein mining can be as small as 0.5 m^3. Corresponding payloads range from 1 to 25 t. Extremely low-profile machines are also available for working in flat-dipping narrow-vein ore bodies with as little as 1.6 m of headroom.

LHDs may be diesel or electric powered. The diesel units are versatile and can tram quickly from one location to another (Figure 12.2-6). The electric units (Figure 12.2-7) carry a cable drum and rely on a trailing electric cable, so they are tethered to a location during normal production. Electric LHDs have low noise levels and zero emissions, so they require less ventilation. They are highly productive in situations such as block caving, where ore is transported from a series of drawpoints to a fixed orepass location.



The ergonomic and safety considerations for selecting an LHD are similar to those for trucks, as listed previously. In the past, some operators sustained back injuries due to poor operator location and poor seating. The best operating position is midway between the front and rear wheels, and particular attention should be paid to the quality of the seat suspension.

LHDs often operate in situations with limited forced ventilation, so an enclosed, air-conditioned cab is desirable, and the engine should be the latest-generation, low-emission type. Fail-safe brakes are highly desirable. LHDs can operate effectively in headings as steep as 20% (1 in 5), although they perform best if the gradient is limited to around 14% (1 in 7) or less.

The size of a selected LHD must fit within the planned development and stope openings, and the bucket must be able to reach above and fill a truck efficiently.

Figure 12.2-6 Diesel load-haul-dump unit

Courtesy of Atlas Copco.
Figure 12.2-7 Electric unit showing cable drum

The bucket load can be calculated from the bucket volume, the broken density of the rock to be carried, and a fill factor, which depends on the fragmentation of the rock and may be different for development rock and for broken ore in stope drawpoints. As with trucks, the nominal capacity quoted is typically for SAE-heaped loading, which is also typically difficult to achieve in practice. However, a high fill factor can be achieved with well-blasted rock. For example, an 8-m^3 bucket with a 90% fill factor and broken ore of bulk density 2.2 t/m would carry 15.5 t.

The manufacturer's tables will provide speed on grade and other information to allow cycle times to be estimated. Some manufacturers provide estimates of productivity in metric tons per hour for various haulage distances.

In general, it is sufficient to determine the LHD cycle as the sum of the following:

- Loading time, which depends on the power of the LHD, the muck pile condition, the floor condition, and fragmentation of the broken rock. The presence of large rocks, which require individual attention, can slow the loading cycle considerably.
- Travel time (at an average speed on grade) from the loading point to the dump point.
- Dump time (including any delay waiting for trucks), which is usually faster when tipping into a pass because no attention to the shape of the load is required. However, depending on the fragmentation of the rock and the size of the pass, grizzlies or other methods of size restriction to limit the size of rocks in the pass may constrain the tipping rate into a pass.
- Travel time (at an average speed on grade) back to the loading point.

A more complex cycle may apply. For example, it is usual to cut stockpile (remuck) bays every 120–250 m along a development heading. After blasting, the LHD quickly moves the muck from the round into the stockpile bay to allow ground support and drilling to proceed, after which the LHD loads trucks from the stockpile. It may be necessary to consider the LHD performance to estimate times for the two loading cycles within the overall development cycle.

The average speed, when loaded, will depend on the condition of the roadway, including the presence of spillage or water, the clearance to the tunnel walls, the road gradient, and the geometry of the tramming route. A typical cycle time calculation for an 8-m^3 LHD that is loading trucks might appear as follows:

Loading	30 seconds
Tramming loaded	200 m at 7 km/h = 103 seconds
Dump into truck	30 seconds
Travel unloaded	200 m at 7 km/h = 103 seconds
Delays, waiting	60 seconds
Total cycle time	5.4 minutes
Efficiency factor	90%
Cycle time	6.0 minutes
Cycles per hour	10
Metric tons per hour	155 (using 15.5 t/bucket from previous calculation)

As in the truck example, the effective hours must be determined. For a continuous 24-hour operation with two 12-hour shifts per day, realistic allowances might include the following:

Fuel up, safety meeting, and travel to job	1 h/shift
Meal breaks	1 h/shift
Inspect job, wash down, bar down	0.5 h/shift
Planned maintenance (8 h/week)	0.6 h/shift
Breakdowns/unplanned maintenance	1.0 h/shift
Job or efficiency factor	80%
Effective hours per shift (7.9 h × 0.8)	6.32
Effective hours per year (6.32 h × 730 shifts)	4,614
Annual LHD production (4,614 h × 155 t)	715,170 t

If the target production is 1.5 million t/yr of ore, the number of production LHDs required would be

1,500,000 / 715,170 = 2.1 = 3 production LHDs

The number of production LHDs required could be higher if

- LHDs are locked into production areas, or the tramming distance between production areas is excessive;
- More redundancy is required to ensure that production targets are met in the event of a major breakdown;
- There are periods of time in the stoping cycle when there are insufficient active drawpoints to use the available loaders; and
- LHDs are operated on remote control for stope cleanup, which reduces productivity.

A separate calculation is required to determine the number of development LHDs required.

Some LHD models are available with ejector buckets for discharging under limited headroom, which can reduce the

need for back stripping at loading points, and can be useful for tight backfilling.

Remote Control and Automation of LHDs and Trucks

Remote control of loading units is desirable where conditions at the face or in the stope are hazardous, or where the ground overhead has not been secured. Radio remote control of LHDs has been available for many years, having evolved from cable-remote control of compressed-air-powered loading units. Line-of-sight remote control has proven to be hazardous and has fallen out of favor. Despite training and strict operating rules, operators tend to move into the path of the loading unit and hence are exposed to injury.

Teleremote control, using television cameras mounted on the LHD, allows the operator to be seated in a safe, air-conditioned environment underground or even to operate the machine from the surface. Current developments include employing the operator in a city office, remote from the mine, thus making the job more attractive while greatly reducing on-site costs.

The productivity per hour of an LHD is typically less under teleremote control than with an operator on board, because the teleremote operator does not have the full range of audible, visual, and physical inputs to enable optimum performance. However, most teleremote operations currently use two-dimensional video screens for providing visual information to operators. Such things as three-dimensional (3-D) visual presentation and virtual-reality helmets, available in other industries, have been trialed in mining operations but have not come into widespread use. It is conceivable that in the future, provision of real-time 3-D virtual-reality visual and audio information to remote operators may reduce the difference in productivity between remote control and direct operation. Also, teleremote operation offers the possibility of operating for a greater part of the working shift because delays such as travel time do not apply and because operators can be rotated in a surface office to keep the machines at maximum use.

The major manufacturers now offer autonomous LHDs that can operate with minimal or no human intervention. These machines have sophisticated onboard computers and typically use lasers to scan their environment and determine position. Such a machine can load, tram, and dump autonomously so that a human supervisor can manage two or more LHDs.

The loading part of the cycle requires the muck pile to be well broken. The current generation of autonomous machines is not as effective as humans at assessing the position of large rocks and maneuvering the bucket to displace and lift them. The LHD can be damaged if used autonomously with large rocks, so a common compromise is to load the LHD on teleremote and then switch to autonomous for the remainder of the cycle.

The use of surface teleremote and autonomous LHDs requires a good broadband communications backbone to be installed in the mine, and a high standard of training for maintenance personnel. For safety reasons these machines can only be used in an area that has been locked off from human entry, so the opportunities for their use are limited. They are suited to block caving and some sublevel caving operations where production activities can proceed for a significant time without the need for other activities around them. In many other mines, activities such as development, geological sampling, surveying, and so on interact with production loading, so that it is impractical to create a nonentry zone.

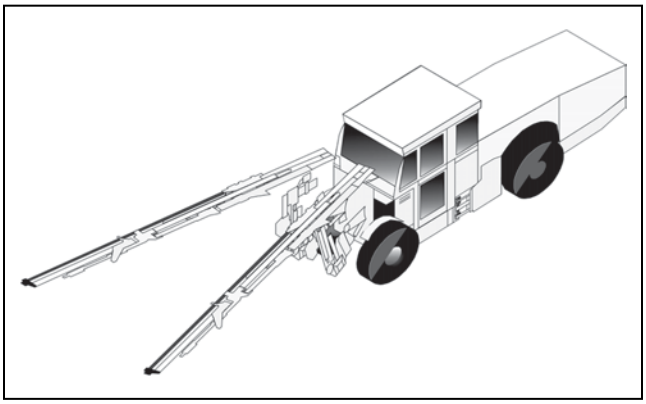

Figure 12.2-8 Two-boom jumbo

For autonomous operations, the mine must be designed to accommodate the level of technology. Where automation has been adapted to an existing mine layout, the results have generally been unsatisfactory. Design of operations needs to include interaction between activities; dealing with spillage, drainage, and road maintenance; blast damage; planned and unplanned maintenance activities; surveying; geological mapping and sampling; and so on.

Autonomous haulage trucks are also available but are not yet widely used. Autonomous trucks must operate on a dedicated haulage route that is locked off from other traffic and from pedestrian traffic, which can rarely be arranged in existing mine layouts. In most cases, duplicate development of a dedicated haulage roadway would be required and may not be justified.

Selecting a Jumbo Drill

A modern jumbo drill has an articulated diesel-powered carrier and an electrically powered hydraulic pump, which operates the boom rams and hydraulic rock drill(s) when the machine is in drilling mode. The jumbo may have one, two, or three booms, depending on the size of openings.

The diesel engine enables the jumbo to tram between working places. It is rare for the diesel engine to provide hydraulic power for drilling because it is inefficient, and because there is usually insufficient ventilation to operate the engine at the face. Some models have a "fast tramming" option that is useful in a large mine where the work places are far apart.

Single-boom jumbos are suited to face areas from 6 to 30 m^2, whereas twin booms may fit in an opening as small as 8 m^2 but can extend 100 m^2 or more. Two booms are sufficient to cover the face area in most mines, with three-boom jumbos being more popular in civil engineering works. Where a three-boom jumbo would, in theory, provide a faster drilling cycle, in practice, the operator is fully busy managing two. A valuable application of the center boom is drilling the large diameter reliever holes in the cut. Many jumbos have a third boom with a basket. A single boom is used in small headings or narrow veins, where there is insufficient room to operate a two-boom machine (Figure 12.2-8).

The manufacturer's data will show the capability of the jumbo to cover the proposed face area. The blast design will determine the hole diameter, generally in the range of 33 to 89 mm, although larger holes can be drilled at greatly reduced penetration rates. Depending on the duty, rock drills (drifters)

with impact power in the range of 10 to 30 kW are available. The length of round to be drilled and fired will determine the length of the drill steel and the boom. In general, longer, heavier booms require a larger carrier.

It is important that the jumbo has adequate reach to enable back holes to be drilled parallel with the axis of the excavation. If an undersized machine is used to drill large profile excavations by angling the back holes out (not parallel to the direction of advance), the result may be a sawtooth profile, excessive overbreak, and unsatisfactory conditions for ground control.

High-powered drifters may require a high-voltage system (1,000 V) to deliver sufficient energy to the hydraulic pumps. The voltage also impacts the trailing cable diameter and, hence, trailing cable length and power extension requirements. This is of relevance for countries where lower-voltage systems (~450 V) are the norm.

An important consideration is whether the jumbo will also be used for rock bolting and meshing, either consistently or occasionally, and the type of rock bolts to be used. For rock bolting, it must be possible to turn the booms at 90° to the axis of the carrier, and to drill holes into the walls and back. The boom length cannot exceed the available width and height. In these situations a split-feed boom may be required, which effectively telescopes the boom to full length as required. This adds complexity, maintenance, and weight and may lead to inaccuracy as parts wear, so the benefit must be weighed against these considerations.

A jumbo may also be used for scaling or "rattling" the tunnel walls and back, as part of the development cycle, in lieu of barring down or using a dedicated scaling machine. This is never recommended by the drill manufacturers because it can cause a lot of damage to the booms from falling rock. Nevertheless, it is a common practice as operators have learned that the convenience and safety benefits can outweigh the increased maintenance. For this application, a robust and well-protected boom should be selected.

The face advance that can be achieved from a jumbo drill depends on the number of faces available to it. In a single-heading situation, such as during the development of a main decline from the surface, a twin-boom jumbo can typically average 45–50 m of advance per week, including the main heading and stockpile bays. This means that the main face will advance, on average, about 40 m/week. This rate can be exceeded for periods of several months if in good ground, but most mines present a range of conditions, including zones of poor ground or faults, which slows progress, so that over a 2-year development program the 40-m/week rate would apply.

A higher advance rate can be achieved using the latest "long round" technology. For example, during the development of Newcrest Mining's Cadia East project in New South Wales, a record for 6.0 m × 5.5 m mine development with full ground support was set with an advance of 283 m in a single month (including stockpile bay development) (Willcox 2008). Long round development has limitations on curve radius and turnout or crosscut development, so is not generally applicable to underground mine development. Higher development rates exceeding 400 m/month have been achieved in civil tunneling works, but the Cadia East performance is a good example for mine development.

The process of estimating the performance of a two-boom jumbo drill is set out in Tables 12.2-1 through 12.2-3, which are based on actual measurements from a mine where each jumbo had at least five faces available to it for drilling, and so could be kept continuously at work. Causes of delays were recorded in detail on shift reports. The jumbo drills were conventional units without computer alignment and were not the latest generation of high-frequency drifters.

Table 12.2-1 Physical development parameters

Parameter	Measurement
Width, m	5.0
Height, m	4.5
Area, m^2	22.5
Rock density (wet), t/m^3	2.8
Overbreak, %	5
Metric tons per meter (including overbreak), t/m	66.2
Drill factor, charged holes/m^2	2.20
Number of charged holes	50
Number of 100-mm cut holes	4
Hole depth, m	3.05
Pull, %	90
Advance per round, m	2.75
Metric tons per round, t	181.6
45-mm-diameter face holes, meters drilled, m	151.0
100-mm-diameter cut holes, meters drilled, m	12.20
Total face meters drilled, m	163.18
Rock bolt length, m	2.4
Friction bolt holes per round	5
Resin bolt holes per round	8
Rock bolt meters drilled per round, m	31.2
Total small-diameter meters drilled per round, m	182.2
Face meters drilled per meter advance, m	59.4
Total meters drilled per meter advance, m	70.8

After this analysis is completed, using performance parameters for the jumbo drill under consideration, the required number of jumbos can be estimated. If the target is 800 m of development per month, then, in this example, three jumbos would be required. Of course, if sufficient faces cannot be made available to fully use the drills, this problem is not solved by adding more drilling capacity. Instead, the materials handling capacity must be addressed.

Selecting a Rock-Bolting Machine

Rock bolting may be done using a handheld rock drill from the muck pile, a work basket, or a scissor-lift platform. Purpose-built articulated, four-wheel-drive scissor lifts are available with or without a bolting boom attached. Alternatively, the development jumbo drill can be used to install rock bolts and mesh with minimal exposure of the operator to the area being supported.

Purpose-designed machines are available for drilling holes and installing both conventional rock bolts and cable bolts. A rock-bolting machine resembles a jumbo drill and may use the same carrier. The working boom carries a rock drill and a carousel that can handle a range of rock-bolt lengths and typically 10 rock bolts. A separate hydraulic arm may be fitted to maneuver and place screen mesh.

A rock-bolting machine may be capable of installing mechanical- or friction-anchored bolts as well as cement- or resin-grouted bolts. Machine selection should address the following points:

Table 12.2-2 Jumbo cycle time

Component	Measurement
Setup	
Tramming speed, k/h	4.0
Average distance between faces, km	1.0
Tramming time, min	15.0
Setup and markup time, min	25.0
Total setup time, min	40.0
Setup time (=engine hours) per cut, h	0.7
Drill meters per engine hour, m/h	272.0
Drilling Cycle	
Instantaneous penetration rate, 45-mm holes, m/min	1.40
Instantaneous penetration rate, 100-mm holes, m/min	0.7
Meters drilled, 45-mm holes, m	182.2
Meters drilled, 100-mm holes, m	12.2
Drilling time, 45-mm holes, min	130.1
Drilling time, 100-mm holes, min	17.4
Total drilling time, min	147.6
Total drilling time, h	2.5
Holes drilled (all types)	67
Boom setup time per hole drilled, s	55.0
Total boom set-up time, min	61.0
Total boom set-up time, h	1.0
Total set-up and drill time (2 booms), h	3.5
Average penetration rate per boom, m/min	0.71
Jumbo drilling time, h	1.74
Ground Support Using Jumbo	
Change centralizers, min	10.0
Rattle backs, min	15.0
Installation time per rock bolt, min	1.0
Total rock bolt installation time, min	5.0
Total ground-support time, min	30.0
Total ground-support time, h	0.5
Total jumbo time per face, h	2.9

Note: Calculations are given in seconds or minutes, and the results are rounded to hours. The final result of jumbo time per face in hours is the sum of setup time plus jumbo drilling time plus ground support time.

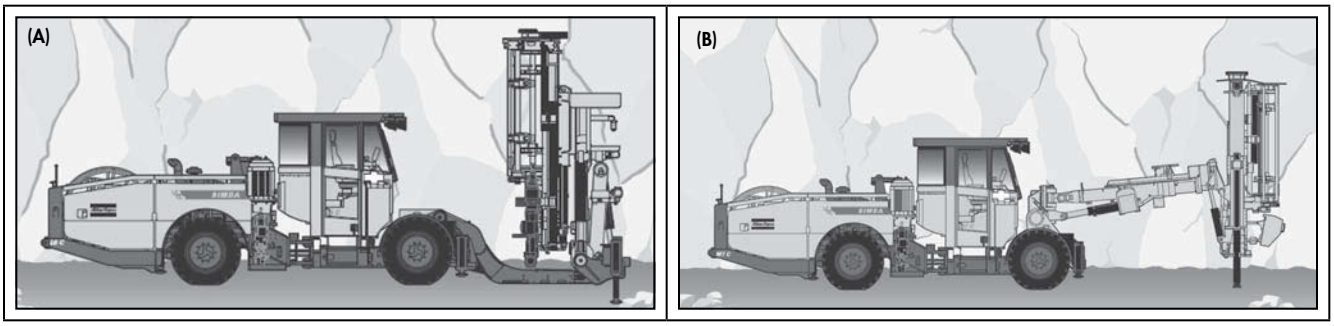
Face advance per shift, m	5.01
Face meters drilled per shift, m	298
Total meters drilled (including rock bolts) per shift	354.7
Meters drilled per month, m	19,356
Face advance per working day, m	15.0
Face advance per month, m	325.6

- Can the desired type and length of rock bolt be installed?
- Can it handle screen mesh?
- Will it fit into the required minimum back height?
- Can it reach the required maximum back height?
- Is the cab enclosed to protect the operator from resin fumes?
- Is a remote control option available for hazardous situations?

The rock-bolting machine size should be matched to the required heading size, which in turn depends on the purpose of the heading. It is unfortunately quite common to find that limited availability of rock-bolting boom lengths forces headings to be larger than they need to be for the purpose for which they were designed. At best, this might merely produce more development waste than necessary. At worst, it can make the use of the heading for its intended purpose more difficult, more costly, or more time-consuming than it would have been if correctly sized.

Rock-bolting machines are subject to impact damage from falling rock and require tight tolerances on working parts, so that the rock bolt can be indexed to the drilled hole. It is useful to enquire from other operators about their experience with maintenance on the model being considered.



Rock-bolting machines tend to be slower and less mobile than jumbos. A check should be made to ensure that the rock-bolting machine can travel between development faces within the cycle time required.

Selecting a Production Drill

Production drills are used for drilling stope blastholes and service holes. Top hammer drills are generally available in sizes from 5 to 127 mm in diameter, whereas in-the-hole hammer (ITH) drills range from 95 to 178 mm in diameter. The drill-and-blast design will determine the optimum diameter and length of the hole. The selected drill must be able to quickly drill the hole, at minimum cost, with acceptable deviation. Deviation will limit the smaller hole sizes to around 12–15 m in length, whereas holes of around 100-mm diameter with tube drills can be up to 40 m long. Longer holes require larger diameters, favoring ITH drilling.

Skid-mounted, crawler-mounted, and trolley-mounted rigs have generally been replaced by highly mobile diesel-powered rigs. Top-hammer rock drills are hydraulic, using electric hydraulic power packs, whereas ITH drills use compressed air from a stand-alone or booster compressor. High-pressure water-powered hammers are also available.

For narrow-vein mining, production drills that can operate in vein widths of 3.0 m or slightly less are available. In the larger sizes, fully automated operation is possible so that a complete ring of blastholes can be drilled without human

Courtesy of Atlas Copco.
Figure 12.2-9 Production drill rigs

intervention. Considerations in selecting a production drill include

- The performance, including penetration rate, of the drifter at the desired hole diameter;
- Whether the desired hole inclinations can be drilled;
- Parallel hole coverage capability;
- Feed pivoting system (rigid with sliders—more accurate holes or totally variable—highly variable hole alignment);
- Whether reticulated compressed air or an onboard compressor will be used;
- Whether centralized lubrication is fitted;
- Whether automated rod handling is available;
- Whether carousel capacity is adequate for planned hole lengths;
- Whether remote control is available (umbilical cord system for misfire drilling management);
- What onboard surveying system is used for hole positioning;
- Whether cab is closed and air conditioned;
- The level of automation required (for increased use);
- Operator visibility of hole collar and lighting conditions; and
- The ability to collar the hole close to the wall, particularly in narrow-vein applications.

Drill string selection (rods, in-hole stabilizers, tubes) and feed stabilization (front- and/or rear-feed stingers) are also important considerations for managing drill-hole deviation.

Figure 12.2-9 shows production drilling rigs with hydraulic top-hammer rock drills. Both are designed for long-hole ring and parallel hole drilling upward or downward. In Figure 12.2-9A the drill unit faces the canopy and is suitable for holes in the range of 89 to 127 mm. The drill in Figure 12.2-9B is boom mounted for maximum reach and flexibility in both production drilling and bolt-hole drilling and is suitable for holes in the range of 51 to 89 mm.

Other Underground Equipment

The considerations outlined in the opening sections of this chapter apply to a wide range of underground equipment. Specific considerations include the following:

- Integrated tool carriers are based on wheel loaders for greater load-carrying capacity, versatility, and stability than conventional forklifts. Operator visibility and automated quick coupling are important features.
- Robust scalers are becoming more effective in headings between 4 and 6 m high. Backhoes fitted with a scaling pick or lightweight impact hammer and very large scalers have proved less successful. Some limestone mines use a rotary head on an excavator very effectively.
- Shotcrete (or Fibercrete) machines may be designed for wet or dry mix material. Mobility, boom reach, and remote-control capability are important in underground operations. The machine should have a remote-controlled boom nozzle to remove the operator from the unsupported area.
- Explosives charge-up machines may be used for cartridge, emulsion, or ammonium nitrate and fuel oil, and the charging process may be manual or mechanized. As with jumbo drills and rock-bolting machines, the charge-up machine must be sufficiently mobile to service the faces required within the development and production cycle. The reach and load capacity of the basket and the explosives carrying capacity must be suited to the proposed duty.
- Road maintenance equipment, such as graders (with or without rippers), bobcats, water trucks, and rollers need to be fully assessed for the suitability of the road surface medium and dimensions of the underground workings.
- A wide range of four-wheel-drive vehicles are suitable for underground mining, although many of the lower-cost models may not stand the rough conditions of a typical mine and may have a very high maintenance cost. It is a good strategy to buy the best rugged model available secondhand, with around 100,000 highway-kilometers. In corrosive or rough mine environments, the best vehicle life may be around 2 years. Estimators should not underestimate the cost of fitting a vehicle for underground operation, which might include crash bars, engine isolator, and removal of unwanted interior fittings.
- Handheld (airleg or jackleg) drills, rope scrapers (slushers), and rail equipment may still be used in some circumstances, although their use is rapidly diminishing. Proper selection of rail equipment, in particular, requires careful consideration based on cycle times, gradients, and locomotive capability. It is best to consult old textbooks including earlier versions of this handbook to gain an appreciation of the selection process.

CHAPTER 12.3

Soft-Rock Equipment Selection and Sizing

Jeremy Busfield

INTRODUCTION

Soft-rock mining predominantly applies to coal mining but is also applicable to other bedded soft mineral deposits. Therefore, although this chapter primarily focuses on underground coal mining, certain aspects are relevant to mineral deposits such as potash.

Underground coal mining methods currently fall into the following principal categories:

- Longwall (full-extraction) operations
- Room-and-pillar (partial-extraction) operations
- Room-and-pillar (first-workings) operations

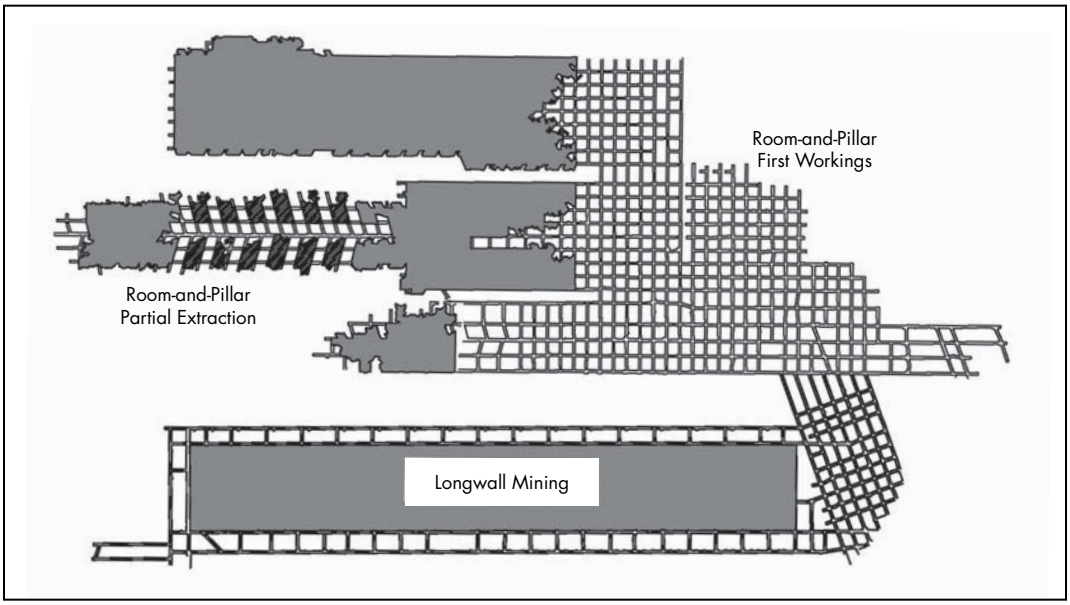
These methods are discussed in the following sections of this chapter. Figure 12.3-1 provides examples of the three categories.

LONGWALL MINING METHODS

Because of its mechanized process, longwall mining generally achieves the highest productivity and reserve recovery and is typically the primary choice for new mines being developed, unless geological, surface, or capital constraints dictate otherwise.

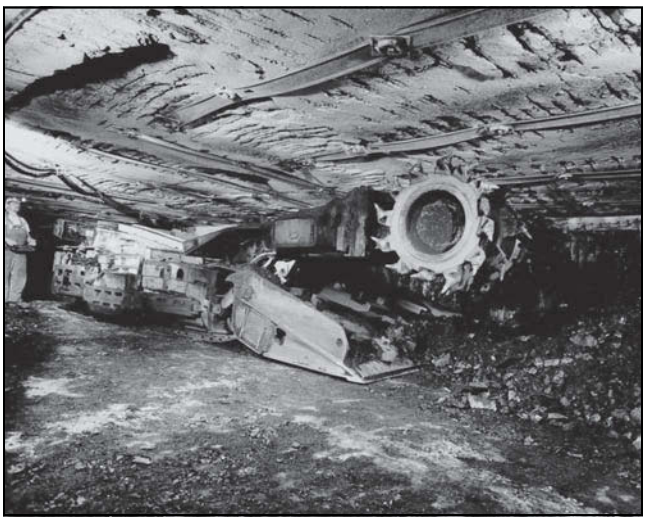
In longwall mining, a set of roadways is driven out from the main entries down each side of the longwall panel to block out a portion of reserves. The mechanized longwall equipment is then retreated through the panel to extract the entire panel of coal. The roads used for traveling and the roads used for coal clearance during panel extraction are termed the *maingate* (or *headgate*) entries, whereas the tailgate entries are generally used for return air. Where possible, a set of parallel adjacent panels is extracted sequentially to allow reuse of one gate road (i.e., the maingate for the first panel becomes the tailgate for the next panel, and so forth). Working in this way maximizes coal recovery, while keeping the quantity of roadway drivage to a minimum. The number of roadways that comprise a maingate varies around the world, with single entries being common in Europe, two roadways common in Australia and China, and three roadways common in the United States. The number of roadways influences the style of coal clearance and the mobile equipment used.

Longwall mining methods vary slightly according to the seam height, which can range from as low as 1.0 m to in excess of 15 m. The height influences the longwall equipment used. Single-pass seam extraction is undertaken in seam heights of up to approximately 5.5 m, for which conventional longwall equipment is used. For seams in excess of 5.5 m, either multislice or top coal caving methods can be used. Top coal caving requires a different style of roof support and an armored face conveyor (AFC) configuration. In very thin seams, the longwall plough system can be used, which uses a different coal-cutting machine (a plough as opposed to a shearer).



The longwall panel width can vary up to more than 400 m, and this influences the longwall equipment (quantity of roof supports, quantity of AFC pans, hydraulic power, electrical power, etc.). Panel length can be dictated by geology, surface subsidence restrictions, equipment limitations, or other mining constraints. Very short panel widths in the order of 25 to 50 m are typically termed *mini-wall longwalls*, and these use a specific type of AFC arrangement.

ROOM-AND-PILLAR MINING METHODS



Until the advent of high-production longwall techniques, the majority of underground coal extraction used room-and-pillar (R&P, also termed *development* or *bord-and-pillar*) mining techniques. In many parts of the world this is still the case, with many mines achieving high production rates from R&P methods. The use of the R&P method is often favored because of its low capital requirements compared to the longwall system. The R&P method is also used in small or irregular-shaped deposits, deposits with surface subsidence restrictions, and deposits where geological constraints (such as faulting) preclude the economic use of longwall mining.

R&P methods range from first workings, where only roadways are driven (forming pillars), to second workings, where the pillars are then later either fully or partially extracted. R&P methods are generally deployed in seam heights ranging from 1.5 to 4.5 m. In seam heights of less than 2.1 m, the roof is often excavated periodically or continually to provide an adequate working height. Low seam heights can restrict equipment options, particularly bolting equipment. With greater

Figure 12.3-2 Continuous miner in a room-and-pillar operation

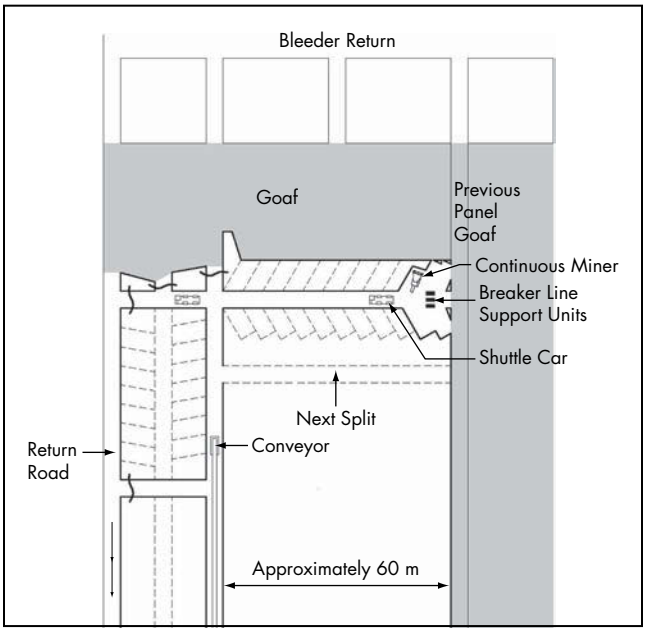
seam heights, some mines extract the floor as a second working, thus allowing up to 6-m seams to be partially extracted. In these cases consideration is required for roadway gradients and equipment capabilities in regard to negotiating steep grades. In first workings, a benefit can be gained by increasing the roadway width to up to 7.5 m (or more), depending on the spanning ability of the roof. In potash mines, roadway spans typically exceed what can be achieved in coal, with the roadways formed by wide-head continuous miners (CMs) taking several passes. A CM in an R&P operation is shown in Figure 12.3-2.

Secondary extraction methods generally fall into pillar-splitting or stripping methods or fall into split-and-fender methods, for example, Wongawilli extraction in Australia (Figure 12.3-3).

In the standard pillar-splitting technique, the main development roadways are driven toward the boundary of the mining area, forming coal pillars to support the roof. When the limit of reserves or the mining boundary is encountered, the coal pillars can either be split or stripped, thus forming smaller pillars that are then left to support the roof or that collapse in a controlled manner on retreat. This method of mining requires specific equipment that can extract coal and retreat in a nimble and rapid manner.

Split-and-fender mining involves the formation of main access roads into a particular district and the subsequent "blocking out" of an area of coal, typically 60 to 80 m in width and up to 1.5 km in length. A roadway or "split" is driven through to the end of the block using a CM, leaving a thin coal "fender" that is extracted as the CM retreats back toward the access roadways, allowing the roof to collapse behind. When the fender is fully extracted, the mining equipment is retracted, and the entire sequence is repeated until the whole coal block is mined out. Although similar equipment can be used for this method, the use of powered roof supports (mobile breaker line supports) is often used to increase safety and allow for a greater level of roof control.

LONGWALL MINING EQUIPMENT



This section begins with a discussion of standard longwall equipment, followed by discussions of longwall equipment variations, selection, specifications, and sizing.

Standard Longwall Equipment

The standard longwall face equipment consists of roof supports; a shearer; an AFC; a beam stage loader (BSL), including crusher and boot end; a monorail; a pump station; and system electrics. Figure 12.3-4 is a schematic of a longwall system showing the relative locations of each piece of equipment.

Roof Supports

Roof supports (sometimes referred to as shields or chocks) hold the exposed roof as the coal is mined, allowing the roof strata to cantilever over the support fulcrum and then break off into the goaf (or gob). In this manner, the operators are

Courtesy of MineCraft Consulting.
Figure 12.3-3 Wongawilli extraction panel

shielded from falling goaf as the face is advanced and the immediate face area is destressed. As the shearer cuts along the face, the AFC is snaked across the new face line using the double-acting sequence rams fitted between the supports and the AFC pans. As the AFC is snaked, the roof supports are lowered and pulled across to the advanced position by the sequence ram and reset to the roof, referred to as the lower-advance-set cycle. In this way the face is automatically advanced as each longwall slice is taken through the panel. The immediate roof falls behind the support, forming a goaf.

Roof supports can be operated in either "conventional mode" or in "immediate forward support" (IFS) mode. Conventional supports cannot be advanced to support the roof until the AFC is advanced (i.e., the roof is exposed and unsupported for some distance behind the shearer), whereas in IFS mode the supports are advanced immediately after the shearer has passed. IFS support is generally needed in weak roof conditions and is the most popular mode of support currently used. IFS supports require longer canopies than "conventional" supports with corresponding larger leg cylinders and hydraulic systems.

Modern longwall supports have been built to operate to approximately 5.8 m in height. Support capacity depends largely on support configurations, although the largest supports available have a capacity of approximately 1,750 t (metric tons), equating to a support density of approximately 125 t/m^2 and weighing up to 65 t.

The roof supports used at the gate ends are configured slightly different to the "run-of-face" supports, in that they have longer canopies so as to extend over the maingate drives. In addition, the gate end supports have higher rated capacity relay bars to enable pushing the maingate drive frames and BSL. Typically, there are five gate end supports at the maingate and three at the tailgate.

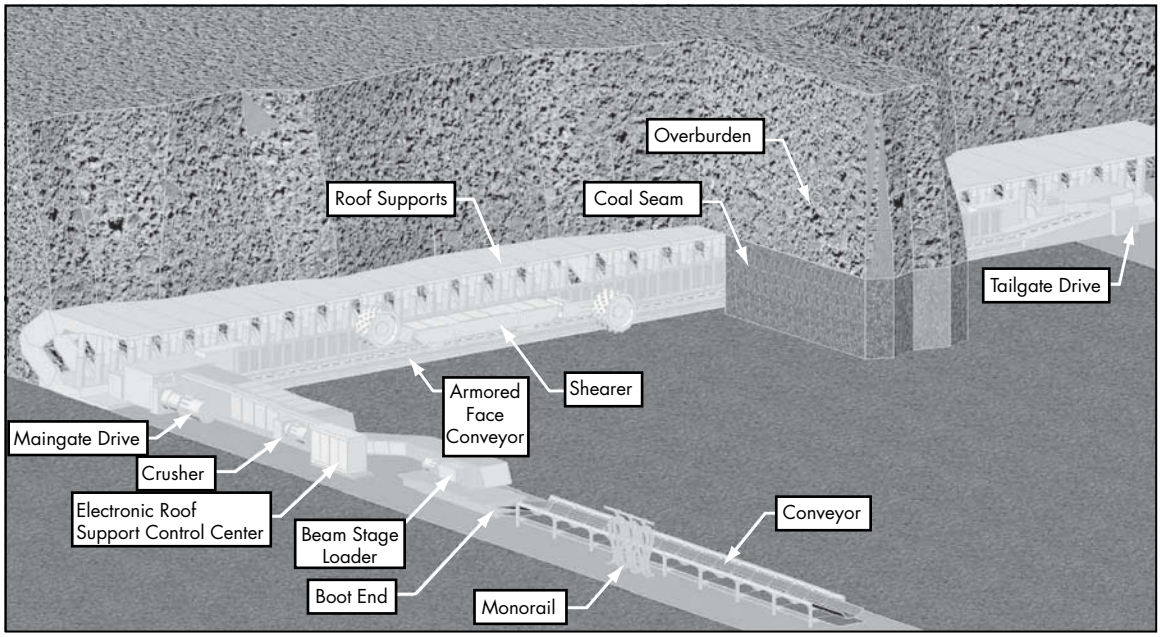
Originally operated by valves fitted to each support (lower, advance, and raise), modern supports are controlled by electrohydraulic systems, whereby solenoids operate the valves and the supports can be operated automatically in sequence mode or from adjacent or nearby supports. This automatic sequence also can operate with a positive set mode, whereby each support is set against the roof to a minimum pressure (often between 70% and 80% of the yield pressure), thus guaranteeing effective support when in automatic mode.

When specifying roof supports, various options are available, including the following:

- Four-leg versus two-leg supports (because of advancements in cylinder technology and capacity and because of lemniscate design, two-leg supports are now more popular)
- Front walkway, rear walkway, or both (rear walkways are often used in thick seams to offer more protection against face spall)
- Side shields on one or both sides (used to push supports uphill)
- Face sprags or flippers (used to prevent face spall in thick seams)
- Base lift systems (used to raise shield prior to advance when in boggy floor)

A longwall roof support with face sprag and base lift fitted is shown in Figure 12.3-5.

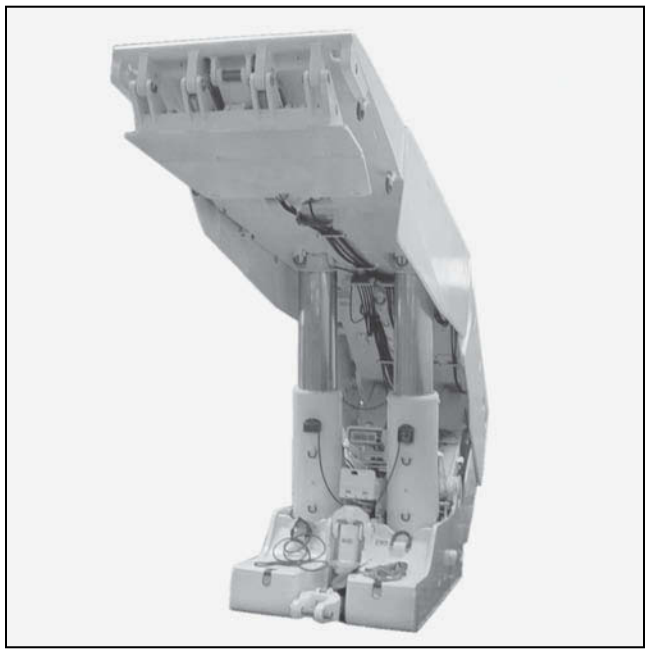
Shearers



Modern longwall double-ended ranging drum shearers have two cutting drums, one at each end mounted on hydraulically raised ranging arms that are in turn connected to the shearer body (Figure 12.3-6). The shearer is driven by onboard traction units that drive a sprocket wheel that connects to rack bars mounted on the walkway side of the AFC. The face side of the shearer slides along the top (or toe) of the AFC sigma section. The shearer operators control the speed of the shearer and the position of the cutting drum using handheld controls (either radio remote or tethered cable) to maintain a suitable cutting horizon within the seam and minimizing dilution.

Modern heavy-duty shearers are fitted with up to 2,000 kW of available power at the cutting drums, enabling maximum cutting rates of more than 5,000 t/h to be obtained. Shearers can be up to 14 m in length and weigh up to 100 t.

Armored Face Conveyor



The longwall AFC is used to convey cut coal along the face to the maingate, where it is connected to the BSL and outby conveyor system. Steel AFC pans are constructed in sections typically 1.75 or 2.0 m long to match the width of roof supports. Flexible (dog bone) connectors are used to join the pans together. A clevice bracket is fitted to each pan, by which the roof support relay bar (hydraulic ram) attaches. As each slice is taken on the longwall, the AFC pans are advanced or "snaked" into the newly cut area behind the shearer by activating the relay bars in sequence.

The AFC supports the shearer body as it runs along the face, and the cut coal is conveyed along the AFC by flight bars attached to AFC chains driven by motors at both the maingate and tailgate face ends (Figure 12.3-7). Inspection pans that feature a removable decking plate will typically be fitted as every fifth pan to allow for access to the bottom chain. Transition pans are used at the gate ends to transition the AFC onto the drive frames and BSL. Maintaining tension in the AFC chain is important with a chain-tensioning device fitted at the tailgate drive frame. Often automated using an appropriate control

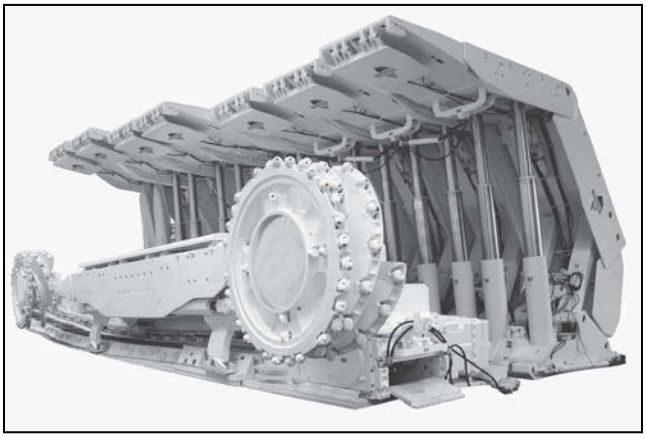
Figure 12.3-5 Longwall roof support with face sprag and base lift fitted

system (reed rods, etc.), the tensioner operates by extending a hydraulic ram (1-m stroke) fitted to the tail sprocket assembly. While the tensioner provides fine adjustment on a day-to-day basis, coarse adjustment is achieved by removing links from the AFC chain.

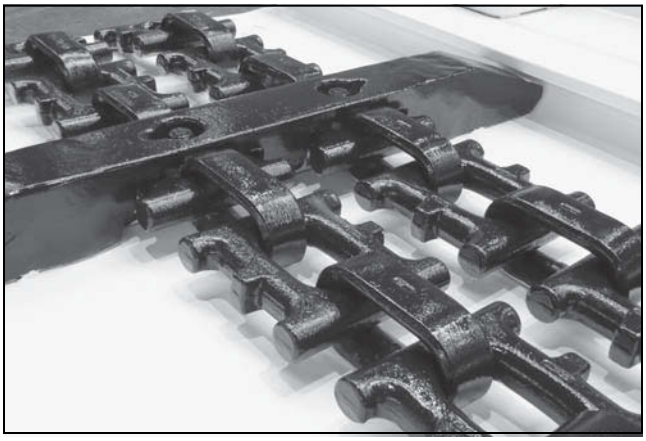
Important aspects of the AFC include the following:

- The drive motors must be able to start the AFC when fully loaded.
- The AFC speed must be sufficiently faster than the shearer's cutting rate to allow coal to be cleared when cutting from tailgate to maingate.
- The AFC chain must be of sufficient strength to handle the applied tensions.



Modern AFCs can be supplied with up to 3,000 kW of installed power in AFC pan sections with 1,300-mm raceways. Coal can be transported at rates in excess of 4,500 t/h. The current limiting factor for face length is the AFC (chain strength versus installed power). Modern chains are being developed so as to allow longer faces.

Currently, the two main AFC drive systems are controlled-slip transmission (CST) systems and fluid-coupling systems. CST systems incorporate clutch systems in the output stage of the AFC gearbox (Figure 12.3-8) with the motor directly coupled to the gearbox. Fluid-coupling systems are fitted between the motor and gearbox and incorporate valves to change the fill volume of the coupling, thus changing the level of torque. Both systems allow for controlled starting and load sharing between drives. An AFC maingate drive frame is shown in Figure 12.3-9.



Beam Stage Loader, Crusher, and Boot End

The BSL transfers the coal from the AFC to the conveyor belt and includes a chain conveyor running over deck plates, a crusher, a gooseneck, and a boot end. The BSL is capable of handling a higher volumetric capacity than the AFC to ensure that coal removal from the face occurs without accumulation at the maingate corner (AFC/BSL intersection).

The crusher sizes the cut coal to ensure that oversize lumps are not carried onto the conveyor, and they consist of a high-inertia rotating drum fitted with large "hammers" to break up large lumps of coal that may have slabbed from the face or large pieces of stone from the roof. The gooseneck is an elevated section that raises the coal so it can be transferred onto the belt.

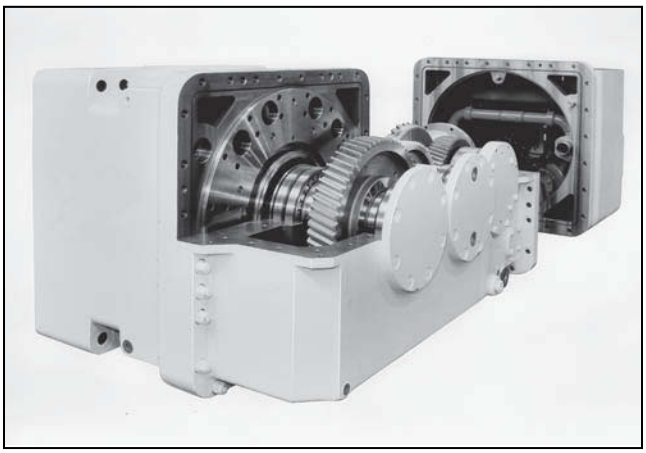
Courtesy of Bucyrus.
Figure 12.3-6 Double-ended ranging drum shearer

Courtesy of Bucyrus.
Figure 12.3-7 AFC chain and pan

The boot end consists of the tail pulley for the conveyor belt fitted to a sliding frame so that the BSL can be retracted a certain distance (up to 3 m) without moving the tail pulley location. The boot end is fitted with tracks or pads for movement and features hydraulic rams so that the tail pulley can be leveled and adjusted for belt tracking.

Monorail

The monorail system provides a flexible services link between the operating longwall face and the pump station and transformer equipment. Services, including electricity, hydraulic fluid, water, compressed air, communications, and control, are carried along the monorail system as either hoses or cables. The purpose of the monorail is to allow the longwall to independently retreat typically 200 m (two pillars) before the need to relocate the services equipment further outby.



The monorail equipment comprises long-length runs of hosing and cables mounted to trolleys supported by roof-mounted monorail beams located adjacent the gate conveyor in the belt heading.

Pump Station

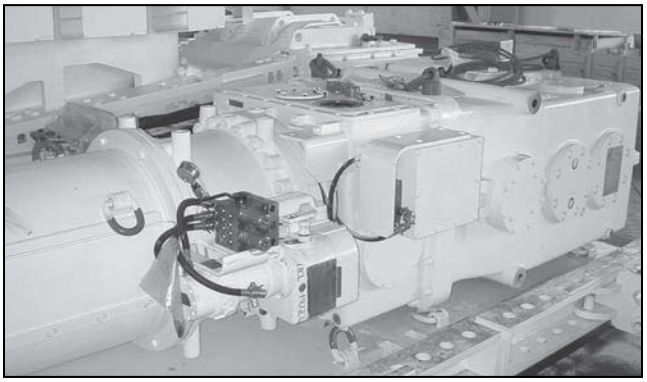
The pump station provides the high-pressure hydraulic fluid required to operate the longwall face equipment, including the hydraulic emulsion supply for the roof supports and water for shearer cooling, dust suppression, and other auxiliary systems as required. The pump station consists of sleds containing typically up to three pressure pumps, including one high-pressure set pump (if used), a high-pressure water pump for the shearer, a reservoir for the closed emulsion fluid system, and the pump control units. The pump station is typically located in the mine roadways (on a steel-framed sled) or in cut-throughs (trailer mounted to assist movement around the mine). Hydraulic fluid can be either fed from a surface-mounted emulsion-mixing farm (via poly pipe to the pump station) or from mixing tanks located on the sled.

Electrical System

A track-mounted transformer located outby (with the pump station) reduces the panel's incoming power to the required face voltage prior to supplying the distribution and control board (DCB) equipment, which is normally located on the BSL. The DCB provides isolation, control, and monitoring capabilities to the longwall face electrical equipment. The face voltage is typically specific to the country (e.g., 3.3 kV in Australia and 4.4 kV in the United States).

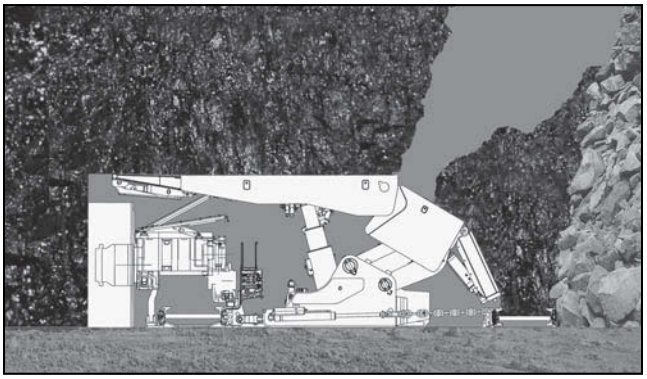
Courtesy of Bucyrus.
Figure 12.3-8 AFC gearbox

The control and monitoring equipment, which is the electrical control center for the longwall system, is typically located on the maingate corner and provides an interface for operators with the longwall equipment.



Longwall Equipment Variations

Alternate equipment configurations are available for alternate mining methods and/or methods of operation.



Top Coal Caving

The roof supports for top coal caving feature a hinged rear canopy shield that, when hydraulically lowered, will allow coal that has fallen from the roof to flow onto a rear AFC and thus be collected (Figure 12.3-10). Although this feature can successfully allow for the recovery of coal from thick seams, the caving methodology and sequence (lowering of the canopy) requires careful integration into the overall longwall sequence to ensure that the productivity of the entire operation is not compromised.

Top coal caving requires a rear AFC, which is a second AFC located behind the roof supports along the edge of the goaf and protected by the hinged rear canopy. The rear AFC

Courtesy of Bucyrus.
Figure 12.3-9 AFC maingate drive frame

Courtesy of Bucyrus.
Figure 12.3-10 Top coal caving schematic

is connected to the roof support by a hydraulic relay bar and chain. The rear AFC transfers the coal onto the front AFC at the maingate end of the face. Hence, it requires a short transfer loader that crosses the main front walkway. In addition, the rear AFC drive unit must be located in the maingate area. To fit all this equipment into the maingate area requires a special roof-support configuration (Figure 12.3-11).

Longwall Ploughs

Longwall ploughs are used in place of shearers in thin-seam longwall applications. A plough consists of a vertical steel frame housing a series of cutting picks that sits on top of the AFC and is driven at high speed (2.5 to 3.6 m/s) the length of the face by a chain drive system (Figure 12.3-12). The plough cuts a thin slice of coal (150 to 250 mm) in either one or both directions with the coal falling onto the AFC to be cleared. The longwall supports and AFC are advanced after each cut in a staged manner. Because of the low seam height applications, plough faces are generally fully automatic with the equipment being operated and monitored from the maingate.

Longwall Automation

The longwall mining method is highly mechanized, which lends itself to various aspects of automation. This has been progressively developed over time. A longwall face in operation is shown in Figure 12.3-13.

Until approximately 2003, the level of longwall automation was limited and consisted primarily of inner-equipment automation (e.g., roof support sequencing) and intra-equipment automation (e.g., shearer initiated support advance). Recent Australian industry-funded studies have advanced the capability of longwall automation to now include the following capabilities:

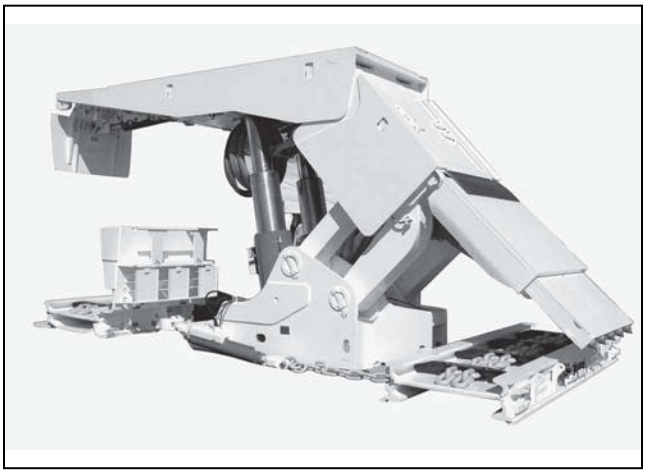
- Face alignment control (use of an inertial navigation system)
- Horizon control (improved memory cut)
- Shearer-state-based automation (shearer speed control based on position)
- Automated fly and straightening cuts
- Automated gate road support operation
- Open communication systems (more user-friendly software systems)

Several mines are now testing these capabilities, and they have been reporting improved productivities.

Longwall Equipment Selection

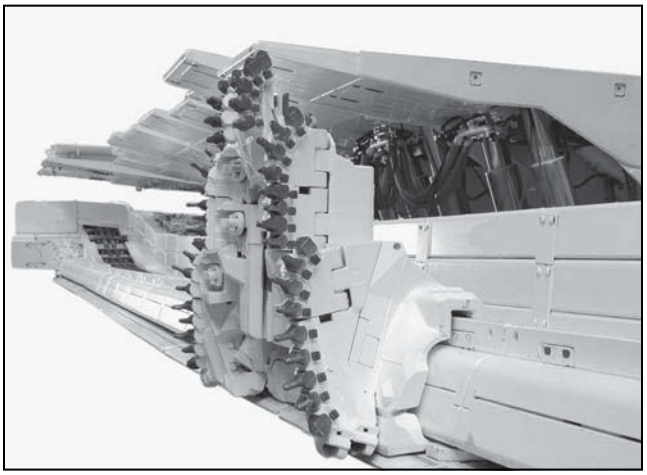
The detailed specification of a longwall system needs to be determined at the time of tender preparation and is based on the results of detailed studies carried out during the feasibility studies. These studies include detailed mine planning, geotechnical characterization, caving studies, and engineering analysis. Key specification aspects include face length, web depth, nameplate capacity (NPC), and support density.

Face Length



Because of improved technology, longwall face lengths have progressively increased from 200 m in the mid-1980s to 440 m today. Long faces in the world include 400 m at Ulan in Australia, 385 m at Cumberland in the United States, and 440 m at Prosper in Germany. The current limiting factor for face length is the AFC (chain strength versus installed power). Hence, there is a trade-off between face length and NPC. Modern chains are being developed so as to allow longer faces. Current technology indicates that a 400-m face length with 4,500-t/h NPC is the current limit.

Web Depth



The depth of cut made by each pass of the shearer can range up to 1,200 mm and commonly ranges from 800 to 1,000 mm. There is a significant productivity benefit from having a deep cut, as this translates to more coal per pass of the shearer. However, the greater the web depth, the greater the required shield canopy length to achieve the required tip-to-face distance. Hence, the cautioning aspect to web depth is the risk of face instability. A detailed geotechnical study is required to establish an appropriate web depth that balances the need for high productivity with the need for face stability. Another approach is to use a half-web (or partial-web) system, whereby only half the web depth is cut during each pass, which can lead to better ground control in particular situations. A half-web system requires faster shearer speeds to maintain productivity. However, this has been very successful (e.g., Twenty Mile mine in the United States). If a half-web operation is envisaged, then the longwall specification will need to include partial push capability of the relay bars (half stroke).

Nameplate Capacity

NPC is the rated capacity of the AFC and is a measure of the coal output during the main cutting run of the shearer. The most important aspect of NPC is that it directly impacts the capacity of the entire underground coal clearance system. The longwall

Courtesy of Bucyrus.
Figure 12.3-11 Top coal caving roof support

Courtesy of Bucyrus.
Figure 12.3-12 Longwall plough

belt conveyor must match the longwall NPC, or the longwall will not be able to operate at designed capacity. This is commonly seen in practice for various reasons. Consequently, the shearer speed is commonly restricted to compensate.

Similar to face length, nameplate capacities have steadily increased in line with increasing technology up to the maximum of 4,500 t/h in Australia and 5,200 t/h in the United States. Although high NPCs can theoretically directly translate to higher productivities, this is not always seen in practice, with many of the highest-producing longwalls in the world rated at 3,500 t/h. This is because NPC is not the only aspect of the determination of productivity.

In general terms, an NPC of 4,500 t/h will require 6,000- to 6,500-t/h trunk belts (2,000- to 2,200-mm belt widths), while an NPC of 3,500 t/h will require 5,000- to 5,500-t/h belts (1,600- to 1,800-mm belt widths).

Support Density

Support density is the rated capacity of the roof shield and is expressed in units of metric tons per square meter of canopy area, usually after the shearer has made its pass (after cut). Again, improving technology has allowed this capacity to increase over time, with capacities up to 130 t/m^2 now available. Typical support densities are between 90 and 110 t/m^2. Variables such as support width (1.75 m versus 2.0 m), shield geometry, and leg cylinder diameter have an impact on support density. The required support density is determined using geotechnical techniques such as ground response curve modeling or Fast Lagrangian Analysis of Continua (FLAC) modeling. Modern supports typically have a support density rating between 95 and 115 t/m^2. Typically, the ratio of setting pressure to yield pressure will be specified at 80%. However, there is an increasing trend toward 90% set, which requires use of a high-pressure set hydraulic supply system.

Longwall Equipment Specifications

There are several longwall equipment suppliers throughout the world, many of which offer complete systems. The typical process of selecting suppliers is to conduct a formal prequalification process involving the following:

- **Expression of interest:** All suppliers are requested to formally express their interest in supplying the equipment. The expression of interest may be advertised in a suitable media. However, in most countries, equipment suppliers maintain close relationships with organizations, so they are aware of forthcoming tenders.
- **Technical prequalification:** An indicative technical specification is issued to interested suppliers who are requested to prequalify by submitting a response as to whether they can meet the equipment technical requirements, provide examples of where they have supplied before, and provide sufficient equipment description to satisfy the prequalification.
- **Commercial prequalification:** Often attached to the technical specification, the commercial prequalification requests answers to various questions of a commercial aspect relating to security of supply, financial strength of the supplier, warranty provisions offered, and a budget price for the supply of the equipment.
- **Short listing:** Following the prequalification process, a short list of two to four suppliers can be selected. These suppliers would then be subjected to a formal tendering procedure for the supply of the equipment.

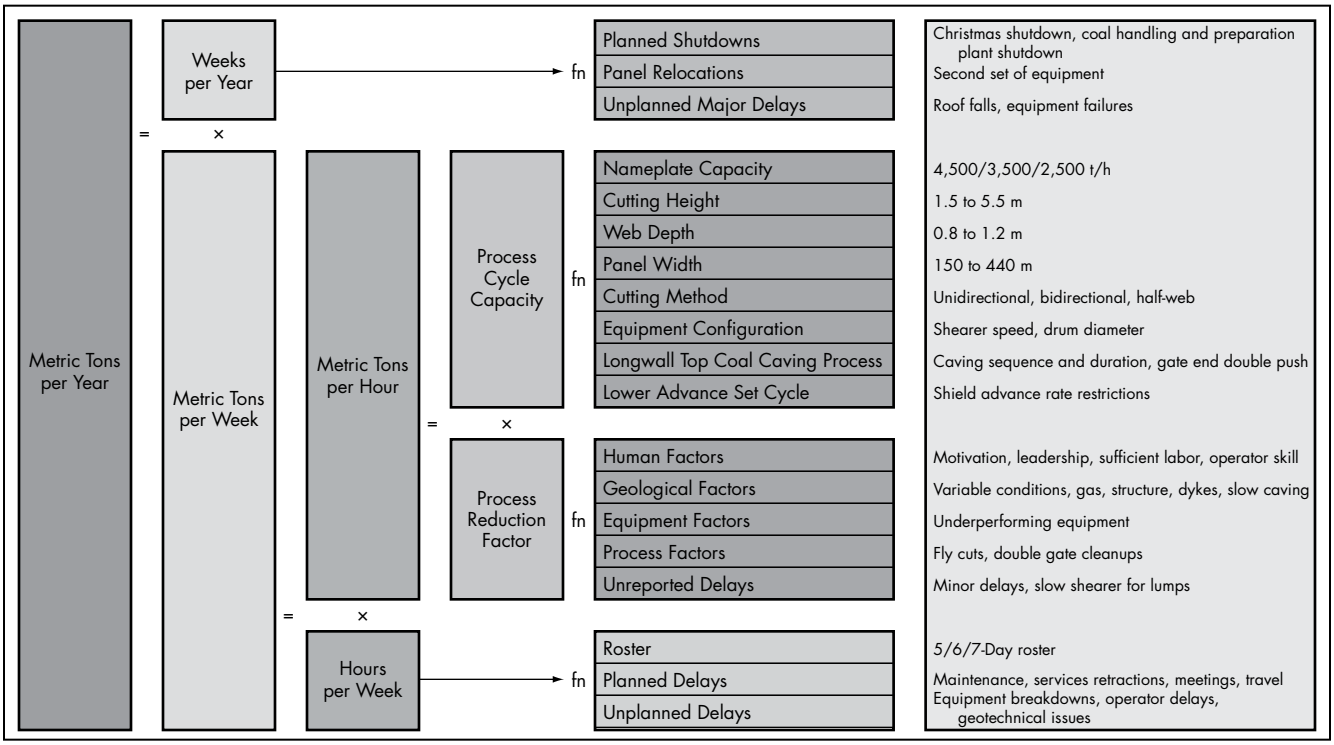
Figure 12.3-13 Longwall face in operation

Examples of a typical longwall requirements and specifications are included in Tables 12.3-1 and 12.3-2.

Table 12.3-1 Example of a longwall system's general requirements



Parameter	Requirement
Mining method	Conventional retreat longwall
Number of maingate roadways	Two
Panel width	305-m centers
Mining extraction range	Nominal 4.5 m, minimum 3.5 m, maximum 4.8 m
Face cross grades	Flat to 1:10 downhill
Panel lengths	1,500 to 4,000 m (total of 16 panels)
Longwall retreat	~50 km and ~100 Mt over the life of the mine
System cutting process capability	Bidirectional and unidirectional sequence mandatory; half-web optional
Automation capabilities	In accordance with the capabilities expected to be supplied at the time of ordering (approximately 2010)
Extraction web depth	Nominal 1,000 mm
Nameplate capacity	3,500 t/h
Process cycle capacity	3,000 t/h

Courtesy of MineCraft Consulting.

Table 12.3-2 Example of longwall equipment preliminary specifications

Equipment	Requirement
Roof supports	• Two-leg immediate forward support (IFS), 2.0-m nominal width roof support • Operating height range, 2.8 to 4.0 m • Single-piece rigid construction IFS-type canopy with single moveable side shield and automated face sprags • Support density, 100 t/m^2 • Tip to face distance of 400 mm before cut • Set to yield ratio of 80% • Rigid catamaran-type base fitted with base lift and telescopic relay bar • Full electrohydraulic system, including filtration • Closed height, 2,200 mm; maximum extension height, 300 mm higher than maximum extraction height • Run of face roof support typical mass, 35 t; gate end, 37 t • In-service life of 45,000 lower advance set (LAS) cycles without loss of function and 45,000 to 60,000 LAS cycles with up to 25% withdrawn from service for maintenance; maximum life, 80,000 cycles
Shearer	• Double-ended ranging arm/drum multimotor shearer • Ranging arms individually powered by electric motors • Haulage via indirect drive sprocket arrangement and track type to suit AFC pans • Drum diameter and arrangement to be optimized to provide acceptable coal loading and equipment undercut/cut-out capabilities; sprays incorporated • Shearer typical mass, 80 t without drums fitted
Armored face conveyor (AFC)	• Power rating to suit 3,500 t/h over full length of conveyor and volumetric capacity to suit 4,000-t/h short-term peaks • Drive units incorporating soft-start and load-sharing capabilities • Automatic chain-tensioning system • Capable of greater than 150-t reserve chain pull for face overload events • AFC pans of length to suit 2.0-m nominal width roof supports fitted with services trough and bretby* trough arrangement
Beam stage loader (BSL)	• Power rating and volumetric capacity to suit 4,000-t/h short-term peaks • Automatic chain-tensioning system • Fitted with ancillary equipment, including spray system, wet scrubber, and monorail removal platform
Crusher	• Power rating, motor inertia, and volumetric capacity to suit 4,000-t/h short-term peaks • Output material sizing to <300 mm
Boot end	• Skid-type advancing boot end with steering, side shift, and leveling capabilities • Travel to suit two BSL advances • Trough and skirting to suit 1,600-mm belt-width gate conveyor belting
Monorail system	• Nominal 200-m services retraction frequency, plus 40-m reserve compression (240 m total) • Located in belt road heading, with capacity to house all services required to support the longwall system • Materials management system to suit 100-m cut through spacing and 1,600-mm belt-width gate conveyor structure
Pump station	• Track-mounted pump and tank stations; cut-through located • Services to be supplied include roof support hydraulic supply, shearer water, roof support dust suppression, plus miscellaneous auxiliary systems • Output capacity to suit hydraulic power requirements plus a reserve of not less than 20% of maximum demand requirements • 350 bar standard pressure, 420 bar high-pressure set • Equipment transport configuration design to suit typical mine size and constraints
Electrical system	• Track-mounted transformer; cut-through located • BSL/monorail-mounted distribution and control board unit and AFC-mounted control and monitoring equipment unit • Incoming supply at 11-kV, 3-phase, AC 50 Hz; longwall motors typically 3.3 kV

Figure 12.3-14 Longwall productivity factors

Longwall Equipment Sizing

Longwall equipment size is generally referred to as its nameplate capacity. Selecting the longwall equipment size relates to the required levels of productivity. Hence, it is important to understand the relationships between the longwall system, its NPC, and its productivity. The relationship between the longwall system and annual productivity is shown in Figure 12.3-14. Two important productivity key performance indicators (KPIs) are the average metric tons per operating hour and the operating hours per week. For an operating mine, these statistics can be collected as part of the production monitoring data. For a new longwall operation, these KPIs need to be derived, which requires a combination of modeling and benchmarking.

To model longwall productivity, the following definitions are used:

- **Nameplate capacity (NPC):** NPC is the rated instantaneous capacity of the longwall (e.g., 2,500 t/h). This is the load that is carried by the AFC during its main cutting run and will occur somewhere in the cycle for between approximately 10 and 20 minutes. In some instances the NPC is determined (restricted) by the coal clearance system.
- **Process cycle capacity (PCC):** PCC is the average capacity achieved during one full cycle at maximum efficiency. This is equal to the metric tons produced in cutting maingate/tailgate and tailgate/maingate divided by the time taken (e.g., 1,800 t/h).
- **Actual productivity:** This is the actual operating rate achieved at the mine over an extended period, as determined from the statistical reporting system (e.g., 1,000 t/h). Depending on the analysis period, the actual productivity will fluctuate from very low levels up to, but not exceeding, the PCC.
- **Productivity reduction factor (PRF):** PRF is the difference between the actual operating rate and the PCC. It is a measure of efficiency and reflects various issues such as adverse mining conditions, operator skills, motivation, and organization. For new mines, this can be derived by benchmarking against similar operations and will generally range between 55% and 75%.
- **Operational availability:** This is a measure of the average number of hours in a shift that the longwall is producing divided by the total hours in a shift (e.g., 56%). It is calculated by dividing the actual operating hours recorded over an extended period by the planned operating hours. The difference between the two measures is the amount of unplanned downtime that occurs, either due to equipment breakdowns or process delays. For new mines, the operational availability can be derived by benchmarking against similar operations and will generally range between 50% and 70%.

The longwall model will calculate the PCC, assuming everything operates to its design capacity.

However, in reality, the longwall does not always operate in this manner. Numerous operational issues, such as operator skill and attention, the presence of geological anomalies, taking fly cuts (straightening cuts), slowing for lumps on the AFC, and gate end cleanups, all slow and impact the cycle. The PRF takes this into account and is a measure of how efficient the longwall cycle is performed. The PRF will fluctuate from very low levels up to very high levels but can be measured over an extended period for use as a benchmarking tool.

In addition, numerous unplanned breakdowns (mechanical/electrical) and operational delays occur, which reduce the total amount of operational time available within a shift. This is termed *operational availability* (also called utilization).

PCC is calculated as follows:

- PCC equals the cycle metric tons per cycle time, where cycle metric tons equals metric tons cut from the maingate to the tailgate and the tailgate to the maingate. This is a function of face length, extraction thickness, web depth, and wedge cuts at gate ends.
- Cycle time equals the time taken for the shearer to cut from the maingate to the tailgate and the tailgate to the maingate. This is a function of NPC, shearer speed, shearer acceleration, snake length, cutting mode (bidirectional and unidirectional), and face length.

When calculating the PCC, it is important to conduct some operational reality tests regarding issues such as the following:

- Excessive shearer speed
- Sufficient shearer underframe clearance
- Excessive drum rotational speed
- Adequate ranging arm power
- Adequate AFC power

Typically, the engineer should have some operational experience with the longwall method to perform these calculations.

Longwall Top Coal Caving

Calculating the productivity of the longwall top coal caving (LTCC) method creates an additional level of complexity. However, the same principle can be applied. It is important to accurately model the LTCC process, particularly the caving cycle, as to when this occurs in the process. Typically, the main cut and the cave cannot occur at the same time as the BSL, and the section conveyor cannot handle the dual output. Therefore, the cave either occurs while the shearer is stationary at the gate end or while the snake is occurring. Therefore, the caving cycle is generally the rate-determining step for the process cycle, with several factors to consider, including the capacity of the rear AFC, the number of caving drawpoints, the time required to cave each support, and the method of caving (manual or automatic).

The key benefits of LTCC are resource recovery (more of the coal seam is recovered) and improved development ratio (more longwall metric tons per development meter). However, this can often be at the expense of productivity when compared to a conventional high-capacity longwall, and care is required when designing and modeling the process.

Other Longwall Equipment Considerations

Other engineering considerations when selecting a longwall system include the following:

- **AFC power demand calculations:** These calculations are performed to ensure that sufficient AFC drive power is installed so that one can be able to start a fully loaded AFC with sufficient reserve chain pull.
- **Electrical load flow study:** This study is performed to ensure that adequate electrical power is available to cater for both normal loads and for starting under adverse conditions.
- **Hydraulic flow simulations:** These simulations ensure that the hydraulic system is sufficient to meet the roof support requirements, including routine LAS cycle (up to three supports moving at once), high-pressure set, gate end advance, and to cater for adverse loading events.

ROOM-AND-PILLAR MINING EQUIPMENT

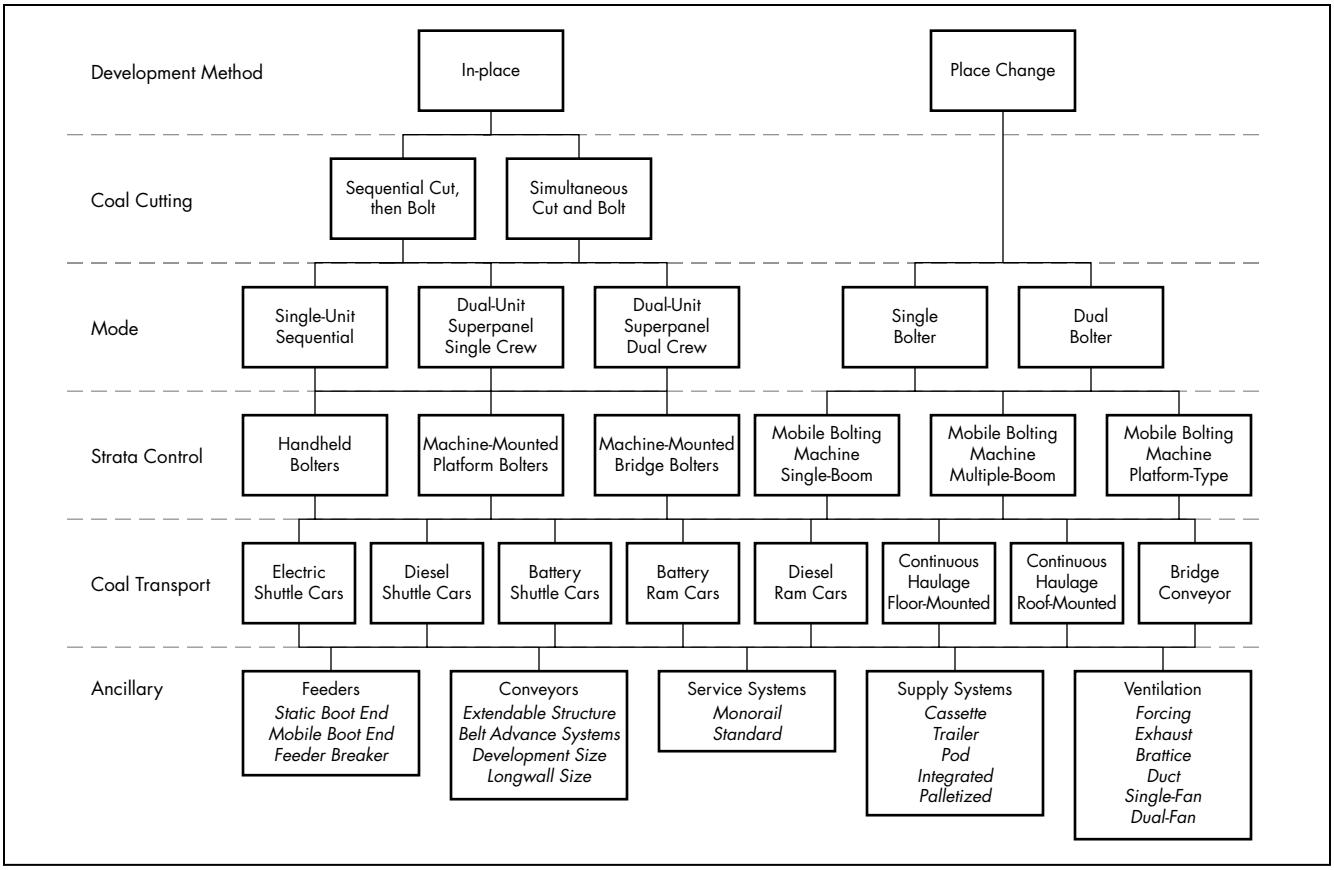
R&P mining can be divided into two categories: first workings (development) and second workings (extraction). Both processes require equipment to cut and gather the coal at the mining face, convey and discharge the cut coal onto a section conveyor, and install ground support at the mining face. Ancillary support equipment is required to provide ventilation and power. There are numerous options of equipment that can be used as shown in Figure 12.3-15.

Standard R&P Mining Equipment

Standard R&P equipment and systems include CMs, roadheaders, haulage units, feeder breakers, mobile bolters, electrical power, ancillary equipment, and mobile roof supports.

Continuous Miners

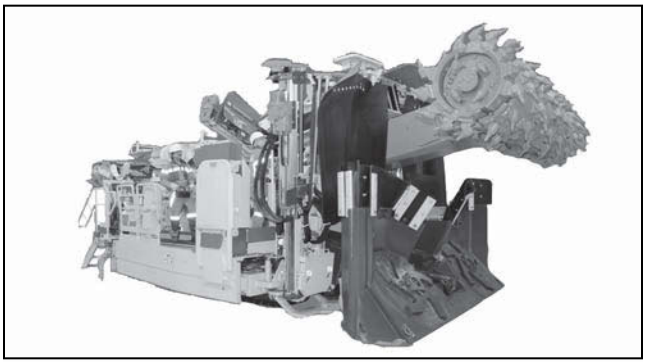
A CM is a large electrohydraulic machine that extracts the coal to form a rectangular profile roadway or tunnel. It features a rotating cutterhead (drum) laced with rock picks at the front. The cutterhead is driven into the coal face, thus breaking out the coal. The broken coal falls to the ground and is loaded onto a centrally located chain conveyor using a loading apron and gathering arms, spinners, or east–west conveyor. The coal is conveyed through the body of the CM and loaded into coal haulage units (typically shuttle or ram cars), which come to the rear of the CM to be loaded.



Modern CMs are fitted with hydraulic drill rigs that drill and install the primary ground support as the roadway is formed (roof and rib bolts). Platforms are provided for the drill rig operators to stand on while the CM is cutting coal. Commonly, the drill platforms feature hydraulically operated temporary support mechanisms to protect the operators from roof or rib collapse. The CM is fitted with caterpillar tracks to allow it to be propelled forward and backwards (skid steering). CMs are also commonly operated by handheld radio remote-control units, although older units have pendant controls (cable-connected) or operator cabins.

The three main types of CMs are as follows:

1. **Simultaneous cut and bolt:** This type features a full roadway width cutting head (e.g., 5.2 m) that can sump into the coal face while the body of the CM remains stationary, resulting in the ability to use the drill rigs at the same time as cutting coal (Figure 12.3-16).
2. **Sequential cut and bolt:** This type features a full roadway width cutting head. However, the body of the CM moves forward when cutting coal, and thus drilling cannot occur at the same time.
3. **Place change (or cut and flit):** These CMs are not fitted with drill rigs, often have a narrower cutting head (e.g., 3.5 m), and are used for the place-changing method of mining. Other machines are used to install the ground support in these applications (Figure 12.3-17).



Roadheader

A roadheader can be used as an alternative to the CM. A roadheader is a large electrohydraulic machine that extracts the coal to form an arched profile roadway, often extracting a portion of the stone roof. Roadheaders are fitted with a pineapple-shaped

Figure 12.3-17 Place-change continuous miner

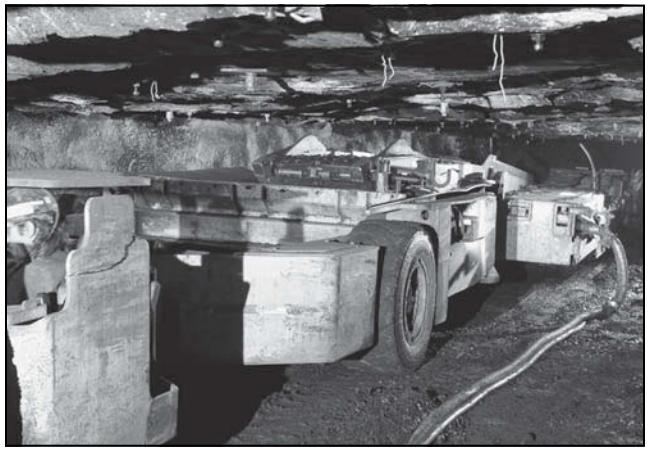
cutting head attached to a slewing boom. Similar to the CM, the cut material falls on a loading apron equipped with gathering arms or spinners that directs the material to a central chain conveyor that discharges from the rear of the roadheader.

Coal Haulage

Coal haulage units are required to convey the cut coal from the CM to the gate conveyor loading point. Key requirements include a large payload and rapid and flexible maneuverability. Three types of units are available, namely, electric-powered shuttle cars (SCs) with a tethered trailing cable, battery-powered ram cars, and diesel-powered ram cars.

Cable electric SCs (Figure 12.3-18) are commonly used for longwall roadway development and offer the benefits of being fumeless, do not require refueling or battery replacement, do not generate large amounts of heat, and do not require turning around (shunting) to discharge. Their disadvantages include attention to cable handling (cable damage) while in operation and a limited travel distance of approximately 200 m (the length of the trailing cable). Ram cars offer

Courtesy of Sandvik.
Figure 12.3-18 Electric shuttle car



Courtesy of Sandvik.
Figure 12.3-19 Battery ram car

unlimited travel distance. However, they require regular refueling and require shunting to discharge. If battery ram cars are used (Figure 12.3-19), then a battery charge station is required, which is commonly placed some distance from the working face because of their construction and ventilation requirements. A ram car in operation is shown in Figure 12.3-20.

Several SCs can be used behind each CM. However, most Australian mines use a single car in longwall gate roads because of the short shuttle distance, the congestion caused by two SCs, and the need for an additional person in the crew. If ram cars are used, then at least two units are required to provide service while one is being refueled. For pillar extraction methods, several SCs need to be used (between two and four) to rapidly clear the coal when a pillar split has commenced.

As an alternative to coal haulage units, various techniques of continuous haulage have been developed over time, including flexible conveyors, bridge conveyors, and ADDCAR systems. Careful panel design is required for continuous haulage to gain the benefits of this technology. Consideration is required for roadway width and height, cutting sequence, clearances, face ventilation, cut-through angles, access to the face by vehicle, and conveyor extension process. Continuous haulage has been successfully used in several non-longwall coal mines and potash mines throughout the world.

Courtesy of Bucyrus.
Figure 12.3-20 Ram car being loaded at the face

Feeder Breaker

Feeder breaker units are typically required for large-capacity coal-haulage units. These consist of coal hoppers that accept the rapid discharge from the haulage units and then size and discharge the coal at a steady rate onto the section conveyor belt. Feeder breakers are fitted with crawler tracks so that they are self-advancing during panel extensions. However, they are typically left stationary during the mining process.

An advantage of feeder breakers, when using large haul units, is their ability to protect the gate conveyor boot end from knocks/collisions, which otherwise will misalign the conveyor. For a high-capacity development system, a basic requirement is the ability to quickly drive the haulage unit up to the discharge point and rapidly discharge the load. Feeder breakers can provide this requirement, whereas boot ends require a slower approach to avoid damage.

Some suppliers offer mobile boot ends that are a feeder breaker with a tail pulley and sufficient power to extend the conveyor belt (pull belt out of the loop take-up) when they advance. This can assist the belt-extension process. However, care is required to ensure the mobile boot end can withstand the belt tension as the panel extends. Staking props are often fitted to the mobile boot ends to anchor against the roof so that the belt tension does not pull them back.

Mobile Bolters

When the place-changing (cut-and-flit) method is used, roof support is installed by an independent bolting unit that trams into the heading when the CM is flitted out. Modern mobile bolting units are electrohydraulic powered; are fitted with up to four roof bolting rigs, two rib bolting rigs, temporary roof, and rib protection canopies; and have provision for the storage of consumables.

Electrical Power

Electrical power to a development panel is reticulated at the country-specific mine supply voltage (e.g., 11 kV in Australia) to a section transformer via an isolator switch located at the start of the development panel. The transformer, located within 600 m of the working face, steps the voltage down to typically between 950 V (United States) and 1,000 V (Australia) and is then fed to a distribution control box located within 200 m of the face. The distribution control box features up to

seven outlets to which trailing/flexible cables feed the various devices at the face (CM, SCs, fan, feeder, pump, etc.). Cable sizes reflect the various power demands of the equipment, with the CM cable typically 120 mm^2 and other cables typically 35 mm^2. The section feed cables are typically 150 mm^2.

Ancillary Equipment

Auxiliary fans are required to provide immediate face ventilation. Typically, these are centrifugal exhaust fans mounted on relocatable sleds or trailers placed in close proximity to the operating face in conjunction with either lightweight fiberglass or steel ducting (600 to 750 mm in diameter). These fans effectively place the fan's negative pressure suction inby of the CM operators, minimizing dust and methane buildup at the face. The fans commonly feature variable inlet vanes (to control airflow) and methane degassing valves (to prevent high gas levels from passing over the fan blades). The number of fans required for each working face depends on the number of roadways being developed, the method of working, and the level of activity. Commonly, between one and three fans are required.

An alternative method of face ventilation is by forcing ventilation in conjunction with dust scrubbers mounted on the CM. In this case, relocatable axial or centrifugal fans are located in close proximity to the face, with air directed using flexible or rigid ducting or brattice sheeting.

Panel dewatering is typically through pneumatic diaphragm pumps, as these pumps are able to operate in this arduous environment with minimal attention. Because of their relatively low output flow rate and their pressure-head capability, they normally report to a nearby electric pump pod. The electric pump pod units are capable of the greater pumping duties required to reach the central mine dewatering station before delivery to the surface.

Because of the high solids content associated with mine dewatering, system design and pump selection requires sound detail to avoid the settling of solids in the reticulation system (causing pipe blockages).

Mobile Roof Supports

For some of the secondary extraction methods (e.g., Wongawilli), mobile roof supports that are also called breaker line supports are used to provide a level of protection along the goaf (gob) edge. These are electric-powered, four-legged hydraulic roof supports mounted on caterpillar tracks with pendant controls. Typically, three units are used in a section. Breaker line supports are often used during longwall takeoffs to provide roof support as the roof supports are removed.

R&P Development Equipment Selection

The detailed specification of the R&P equipment needs to be determined at the time of tender preparation and is based on the results of detailed studies carried out during the feasibility studies. These studies include mining method analysis, panel configuration design, development process studies, productivity requirement studies, ground support specification, and engineering analysis.

Key specification aspects include mining strategy (development for longwall, first workings R&P, secondary extraction pillar splitting, etc.), face mining method (place change, in-place sequential, in-place simultaneous), type of CM, coal clearance method (continuous haulage or cars), bolting method (mobile bolters, CM-mounted rigs), and panel configuration.

Development Equipment Specification

The key aspects in selecting the most appropriate development arrangement and equipment specification include the following:

- Mining method: development or extraction
- Panel design: number of headings, pillar width, angle of cut-throughs, and roadway width
- Cutting method: in-place or place-change
- Cutting machine: roadheader or CM
- Type of CM: sequential, simultaneous, or place-change
- System of coal haulage: SC, ram car, or continuous haulage
- Number of SCs: one or two
- Number of bolting units: one, two, or three
- Method of face ventilation: method used

Table 12.3-3 summarizes a typical development arrangement for a longwall mine, and Table 12.3-4 summarizes a typical general specification for the development equipment for a first workings development system.

R&P Development Equipment Sizing

Development productivity is fundamentally measured in meters advanced per week or in metric tons per week (for which the conversion is relatively simple). Therefore, development equipment is typically sized to match a desired advance rate (e.g., 8 m/h) or output (e.g., 250 t/h). Unlike a longwall, where the equipment is completely integrated into a highly mechanized system, development is a collection of equipment that requires the mining engineer to integrate it into a process. The key process requirements are cutting, coal clearance, and ground support, and these are conducted by separate and independent items of equipment.

Development productivity can be calculated in a similar manner as longwall productivity, as shown in Figure 12.3-21. However, for development calculating the process advance rate is more complex, as itvneeds to take into account that the CM is continually moving from a fixed conveyor discharge point.

Two example development productivity cases are given in the following discussion. The first example, shown in Table 12.3-5, is for a conventional two-heading gate road entry for a longwall panel using a simultaneous miner bolter with a single shuttle car (100-m cut-through spacing). The second example, shown in Table 12.3-6, is for a three-heading development using the place-change method (60-m cut-through spacing). This example compares three mines with slightly different plunge depths.

Definition of the terms used in development productivity modeling include the following:

- **Nameplate capacity (NPC):** NPC is the peak cutting and loading rate of the CM (e.g., 950 t/h). It is often quoted by the equipment supplier and can be used to determine the time taken to load a shuttle car or to load onto a continuous haulage system.
- **Nameplate advance rate (NAR):** NAR is a measure of the peak advance rate of the CM. It is the time taken to cut and load one car, drive the car to the boot end, discharge its load, and then return, divided by the cut-out distance of the CM (e.g., 0.5 m). NAR is a useful factor when sizing the section conveyor belt.

Table 12.3-3 Development system—general arrangement

Parameter	Requirement
Roadway cross section	Nominal 5.2 m wide by 3.4 m high; rectangular profile
Working grade	Up to 1 in 10 (maximum)
Quantity of development panels	One main (up to seven headings) and two gate roads (two headings)

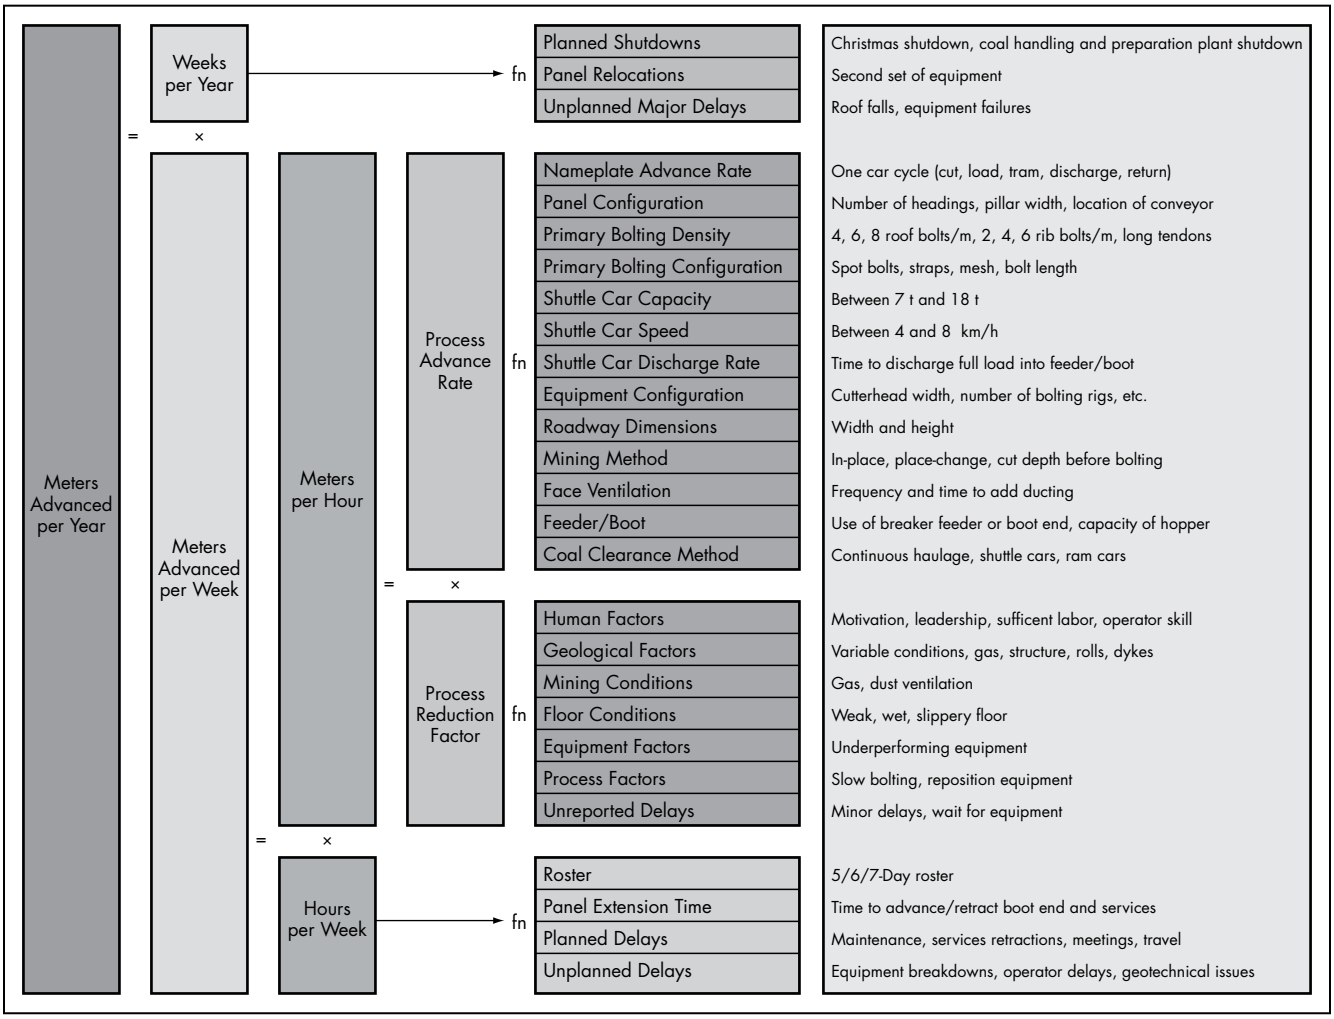
Table 12.3-4 Development equipment—general requirements

Equipment	Requirement
Continuous miner	• Single-pass wide-head track mounted; one per panel; either simultaneous or sequential cut-and-bolt configuration • Fully remote operation with manual override • Four roof and two rib automatic-type bolters; to suit standard or long tendon bolts • Data communications, including real-time bidirectional between equipment and mine communication system • Onboard ventilation system • Dust-suppression system fitted; preferably with wet head design • Hydraulic system with capacity to suit simultaneous operation of all bolting equipment • Onboard roof support materials storage-and-handling equipment • Methane-detection monitors fitted • Fitted with integrated temporary roof-and-rib support systems
Coal haulage	• Electric shuttle car with trailing cable; one per panel • Nominal 15-t capacity; with feed-out rate of 1,400 t/h • Capable of travel speeds up to 8 km/h
Feeder breaker	• Track-mounted mobile feeder breaker; one per panel • Controlled via remote umbilical cable system • Nominal 22-t capacity with a feed-out rate 300 to 1,000 t/h (coal sizing to <200 mm)
Ancillary equipment	• Auxiliary fan; typical output 23 m^3/s • Ventilation ducting; nominal 720-mm diameter; range 610 to 760 mm • Pumping: pneumatic diaphragm face pumps and electric pump panel pods

Courtesy of MineCraft Consulting.

- **Process advance rate (PAR):** PAR is a measure of the maximum advance rate during the cycle, assuming that all activities are completed at their peak rate with no delays. The importance of this factor is that it can be determined by modeling and using actual measurements observed at the mine (or from benchmarking). Therefore, it is a scientific means of calculating productivity. The PAR will be less than the NAR, as it takes into account bolting, extending the ventilation ducting, and any other process-related activity such as repositioning the miner and lowering the canopy. The PAR will only be evidenced in practice over short durations at the mine (e.g., 2 to 6 hours), as it is rare that the process flows at their peak rate over an extended time in the development process.
- **Actual advance rate (AAR):** AAR is the advance rate achieved at the mine over an extended period (e.g., 3.6 m/h). AAR is measured from the mine statistical reporting system for an operating mine. For a new mine, this would be calculated from the modeled process advance rate (AAR = PAR × PRF).
- **Process reduction factor (PRF):** PRF is the difference between the AAR and the PAR. It is a measure of efficiency and reflects various issues such as adverse mining conditions, operator skills, motivation, and organization, and the complexity of the mining process. For new mines, this can be derived by benchmarking against similar operations and will generally range between 45% and 70%.
- **Operational availability:** This is a measure of the average number of hours per week that the development section is operating divided by the total planned operating hours in a week (e.g., 56%). It is calculated by dividing the actual operating hours recorded over an extended period by the planned operating hours. The difference between the two measures is the amount of unplanned downtime that occurs, either due to equipment breakdowns or process delays. The time to extend the panel is not included in planned operating hours. For new mines, the operational availability can be derived by benchmarking against similar operations and is generally between 50% and 70%.



COAL CLEARANCE EQUIPMENT

The coal clearance system provides the means for transporting run-of-mine (ROM) coal from all mining units operating in the underground mine to the surface ROM stockpile. The coal clearance system consists of various types and sizes of belt conveyors, which are designed specifically for the various duty requirements associated with each mining unit. The loading pattern from each production face varies depending on the mining method. For example, longwall mining will produce a fairly constant flow for 15 to 20 minutes while the main cut is taken, punctuated by 10 to 20 minutes of irregular flows as the snake is taken. First workings development will produce very short duration high flows of 1-to-2-minute duration as each SC is discharged with a frequency between cars of 10 to 20 minutes. Occasionally, underground surge systems are used (bins, bunkers, etc.) to smooth the flow and allow for lower-capacity outby conveyors to be used.

The required duty of a coal clearance system depends on the mining system. For example, if the mine employs a 3,500-t/h NPC longwall system and up to three development units operating simultaneously (i.e., one unit completing mains development and two units completing gate road development), then the coal clearance system volumetric capacity duty would be as follows (simple method):

- Longwall gate conveyor: 3,500 t/h (matched to NPC of longwall)
- Development gate conveyors: 1,000 t/h (loading rate reduced to approximately 500 to 600 t/h by use of feeder breaker)
- Main headings trunk conveyor: 5,000 t/h (to allow for longwall plus three development units)

Detailed conveyor calculations are required to refine these duty requirements, which are undertaken during the mine feasibility study. These calculations take into account the panel gradients and panel lengths over the mine life and provide key specification data such as belt rating, power requirements, and the need for tripper drives (mid-panel booster drives). Specialist conveyor duty software is available to perform

Courtesy of MineCraft Consulting.

Figure 12.3-21 Development productivity factors

these calculations. However, some practical experience is required to audit the outputs and to ensure that realistic specifications are produced.

Where conveyors are required to run downhill, braking units are required. Because gate road conveyors are extended as the panel is developed and then retracted as the panel is extracted, care is required in the calculations to ensure that the maximum duty case is calculated. This is especially prevalent where undulating seams are encountered (both up- and downhill sections).

Because the development conveyor duty is commonly significantly lower than the longwall conveyor duty, the following options are available when developing the gate roads:

- Install a small development conveyor (e.g., 1,050 mm) for development and then fully replace this conveyor prior to longwall extraction.
- Install the longwall conveyor drive head and structure (e.g., 1,600 mm), but with a narrow belt (1,200 mm) and minimal drive units, and then replace the belting prior to longwall extraction and fit additional drive units.
- Install the longwall conveyor drive head, structure, and belting (e.g., 1,600 mvm), but twith minimal drive units, and then fit additional drive units prior to longwall extraction.

Preliminary Specification

Table 12.3-7 is an example of the general requirements for the coal clearance equipment for a new longwall mine. Specific details would also be required in regard to requirements for related aspects, including the following:

- Dust control and belt scrapers
- Transfer chute design
- Detection systems for belt wander, belt alignment, belt tear, chute blockage, belt slip, and belt tension
- Belt monitoring, emergency stop, communication systems, gas/fire monitoring (e.g. carbon monoxide detectors)

ANCILLARY EQUIPMENT

Ancillary equipment used in underground coal mines must comply with the local statutory regulations, which are intended

to ensure that these vehicles are safe to operate in potentially hazardous environments. The following comments relate to Australia, which has strict vehicle requirements.

Mobile Equipment

Mobile equipment refers to the diesel vehicles that are typically used in underground coal mines. They are categorized as personnel carriers, material transporters and utility vehicles, or special-purpose vehicles. Typically, these vehicles were developed over the years into purpose-designed vehicles to suit the rugged environment of the underground coal mine. Statutory regulations require that these machines comply with diesel engine exhaust-emission limits, be flameproof, have wet braking systems, and be fitted with various shutdown monitors (high temperature, low scrubber water, etc.). Recently, nonflameproof personnel carriers (modified Toyota Land Cruisers) have been successfully introduced into some Queensland mines. However, these suffer some restrictions in their ability to travel into working faces, depending on methane levels and statutory zones.

Personnel Carriers

Transport of personnel from the surface to the work site and back is through the use of personnel carriers having typical carrying capacities of up to 14 people, including the driver. Several models are available from suppliers, with some companies requiring additional safety features such as forward facing seats and seatbelts. Some personnel carriers are converted into maintenance utility vehicles with a rear flat tray for carrying tools and spares.

Material Transporters and Utility Vehicles

Material transporters and utility vehicles include a range of vehicles for duties such as equipment and materials transport and other work duties around the mine. Typical configurations include the following:

- **Load-haul-dump vehicles (LHDs):** LHDs are used with attachments including fork tines, loading plates, buckets, jib cranes, elevated work platforms, augers, hydraulic drilling rigs, stone dusters, pipe installation platforms, cable reelers, and trailers. LHDs are typically the workhorse of the modern mechanized mine and are commonly fitted with a quick-detach system. Typically, there are one or two of these vehicles, with a capacity between 7 and 10 t, at every panel. The mine will also have some higher-capacity LHDs, with capacities of between 10 and 15 t. These are used for roadwork and other heavy-duty requirements. A utility loader with a 10-t capacity is shown in Figure 12.3-22.
- **Multipurpose vehicles:** Multipurpose vehicles are specifically designed to pick up and carry modular pods and tubs.
- **Bobcats:** Occasionally, mines will use small LHDs such as bobcats for light cleanup duties.

Special-Purpose Vehicles

These are purpose-built vehicles that perform only one or a few specific duties on a periodic basis, with typical configurations including the following:

- Heavy-duty LHDs (40 to 50 t): Used for transport of longwall equipment and some belt conveyor equipment (Figure 12.3-23)
- Roadway graders and rollers: Used for road construction and maintenance
- Roof support trailers: These are used in conjunction with an LHD to transport longwall roof supports
- Specific shield haulers: Used for larger roof supports
- Shearer transporter: Used to transport the longwall shearer
- Mine dozer: Diesel powered, heavy-lift machine for moving longwall equipment
- Mule: Electric-powered, heavy-lift machine for moving longwall equipment
- Mobile generator: Used for CM flits
- Mobile bolters: Used for outby roof support
- Drilling rigs: Used for gas drainage and/or exploration

Some of this equipment is used infrequently, and there are often a number of leasing companies available to service the mine requirements. The majority of mines in Australia rent this equipment during longwall moves, although if the mine purchases equipment that is not typical (e.g., roof supports weighing more than 35 t), then the mine may be required to purchase its own longwall move equipment. The general

requirements for the mobile equipment are summarized in Table 12.3-8.

ELECTRICAL EQUIPMENT AND DISTRIBUTION

Electrical power is typically reticulated in and about an underground mine at the mine supply voltage, which will be derived from the surface main mine substation. Locally positioned substations are then used to transform the electrical power to a voltage suitable for utilization by the various electrically powered equipment. This includes the equipment used in the following areas:

- Development panels
- Longwall panel
- Conveyor systems

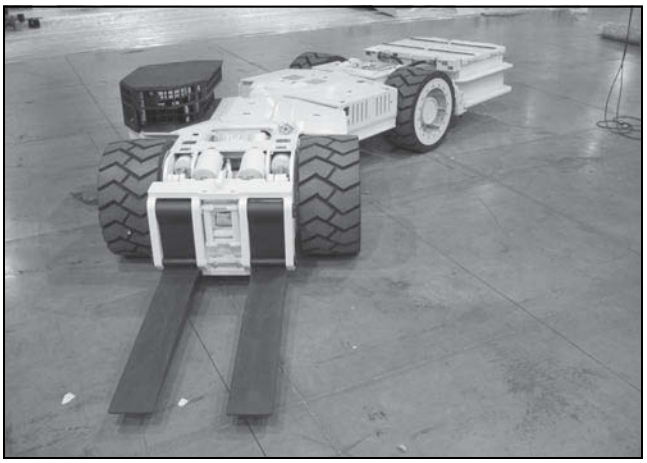

Table 12.3-7 Coal clearance equipment—general requirements

Equipment	Requirement
Construction conveyors	Conveyors are installed during the construction phase of the mine, catering for the lower outputs from the development units, and installed in a suitable location to allow construction of the permanent conveyors. The construction conveyors include a trunk and surface radial stacker conveyor. General specifications of the construction trunk conveyor include the following: • Conveyor length to suit mains development progress to a final length of approximately 1,250 m • A volumetric capacity of 1,800 t/h and a power capacity of 600 t/h, 1,200-mm belt width operating at 3.0 m/s, and solid woven 8,000 belting • Head end drive unit (1 × 500 kW) with transformer/starter unit • Electric auto winch take-up system General specifications of the construction radial stacker conveyor include the following: • Same volumetric capacity and belting width as the construction trunk • Nominal 11-m vertical height discharge rotating through 45°, providing ~5,000-t stockpile capacity On installation of the permanent conveyors, the temporary conveyors are decommissioned and removed.
Ramp conveyor	Conveying ROM coal to surface ROM stockpile. General specifications include the following: • Conveyor length of 710 m with a lift of 108 m from tail to head • Volumetric capacity of 5,900 t/h and a power capacity of 5,550 t/h • 1,800-mm belt width operating at 4.5 m/s, EP2500/5-ply belting • Head end drive station (3 × 750 kW) with transformer/starter unit • Nominal 35-m vertical height gantry structure for ROM stockpile discharge to provide ~100,000-t conical stockpile capacity • Gravity take-up system The complete conveyor is installed during the project phase construction.
Trunk T1A conveyor	Used for conveying ROM coal to the ramp conveyor tail end. General specifications include the following: • Conveyor length of 1,575 m with a lift of 151 m from tail to head • A volumetric capacity of 5,900 t/h and a power capacity of 5,000 t/h • 1,800-mm belt width operating at 4.5 m/s, EP2000/4-ply belting • Head end (2 × 750 kW), tripper 1 (2 × 750 kW), and tripper 2 (1 × 750 kW) drive stations with transformer/starter units as required • Electric auto-winch take-up system The complete length conveyor is installed during the project-phase construction, including both tripper stations. The tripper 2-drive unit and associated transformer/starter is not installed during the project phase because the additional power is not required until panel 2 longwall coal is being produced.
Trunk T1B conveyor	Used for conveying ROM coal to the Trunk T1A conveyor tail end. General specifications include the following: • Conveyor length of 2,000 m with a lift of 136 m from tail to head • A volumetric capacity of 5,900 t/h and a power capacity 4,600 t/h • 1,800-mm belt width operating at 4.5 m/s, EP2000/4-ply belting • Head end (2 × 750 kW) and tripper (2 × 750 kW) drive stations with transformer/starter units as required • Electric auto-winch take-up system A nominal 300-m conveyor length is installed during the project-phase construction, in line with expected mains progress at that time. Only one of the head end 750-kW-drive units is installed due to the low loading requirements, accepting coal from mains and gate road MG103 development units. The second head end 750-kW-drive unit and tripper drive stations, plus remaining structure and belting, is installed in line with mains development progress and conveyor duty requirements.
Trunk T2 conveyor	Used for conveying ROM coal to the trunk T1B tail end. General specifications include the following: • Conveyor length of 1,360 m with a lift of –38 m from tail to head • A volumetric capacity of 5,900 t/h and a power capacity of 5,050 t/h • 1,800-mm belt width operating at 4.5 m/s, EP2000/4-ply belting • A head end (1 × 500 kW) drive station with transformer/starter unit as required • A conveyor braking station located at the conveyor head end is required to ensure suitable conveyor stopping times • Electric auto-winch take-up system This conveyor is installed during the project phase construction.
Gate conveyor—longwall duty	Used for conveying ROM coal from the longwall system to the trunk conveyor system. General specifications include the following: • Conveyor lengths ranging from 1,620 to 6,200 m with lifts ranging from 77 to 103 m from tail to head • A volumetric capacity of 4,200 t/h and a power capacity of 4,000 t/h • 1,600-mm belt width operating at 4.0 m/s and solid woven 10,000 belting • Power requirements up to tripper 1 (2 × 500 kW), tripper 2 (2 × 500 kW), and head end (3 × 500 kW) drive stations, with transformer/starter units as required • A conveyor braking station located toward the tail end of the conveyor is required to ensure suitable conveyor stopping times • Electric auto-winch take-up system This arrangement of power and braking is for the worst-case longwall gate conveyor. Other conveyors with shorter length and less lift may require less drive units and no braking requirements.
Gate conveyor—development duty	Used for conveying ROM coal from the development system to the trunk conveyor system. General specifications include the following: • Conveyor lengths in accordance with "Gate Conveyor–Longwall Duty" section of this table • A volumetric capacity of 550 t/h and a power capacity of 200 t/h • 1,600-mm belt width operating at 2.0 m/s and solid woven 10,000 belting • The longwall duty head end and take-up equipment is used for development duties; however, belt speed is reduced to 2.0 m/s with a single 500-kW-drive unit and a transformer/starter being employed • A conveyor braking station located on the return belt is required to ensure suitable conveyor stopping times

Table 12.3-9 provides an example of the various power supplies utilized in the underground electrical power distribution system for an Australian mine. For other countries, the voltage and frequency will differ (e.g., the United States uses 60 Hz and 950 V for the development face and 4.2-kV for the longwall face). The applicable standard may revert to international standards as opposed to Australian standards.

All underground power circuits operate using an impedance-earthed system (IT earthing system code in accordance with AS 3007.2-2004). The purpose of this is to limit the magnitude of an earth fault and, hence, the resultant touch-potential, thus reducing the risk of electric shock from indirect contact. Also, because most electrical faults occur as a result of cable damage, cables used underground are generally constructed with an earthed screening around each phase conductor, so that the initial type of fault is a low-energy earth fault rather than a high-energy short circuit. Controlling the energy dissipated during an electrical fault in this way reduces the risk of injury to personnel, fire, ignition of methane or dust, or damage to equipment as a result of an arc flash.

The performance of the underground electrical power-distribution system has a significant impact on the performance

Table 12.3-8 Mobile equipment—general requirements

Equipment	Requirement (Nominal Quantities)
Personnel carriers	• Three production vehicles (14 seat) for longwall and development crews • Three support vehicles (14 seat) for maintenance and outby support crews • Two spare vehicles (14 seat) that are used when the others are in maintenance • Two utility vehicles (6 seat) for maintenance crews
Material transporters	• Three-panel supply LHDs (7 to 10 t) for longwall and development • Three outby LHDs (7 to 10 t) • Two spare LHDs (7 to 10 t) • Two roadwork and outby LHDs (15 t)
Special-purpose vehicles	• One grader—roadwork • One mobile generator

*IT earthing system code in accordance with AS 3007.2–2004.

and reliability of the electrically powered mining equipment. Consequently, the design for the underground power supply system needs to account for the following key power supply performance parameters:

- Fault level
- Thermal capacity
- Voltage regulation
- Transient motor starting capability (particularly with respect to the large longwall AFC motors)

Other factors that may influence the quality of the power supply and require detailed study include transient stability and harmonic distortion.

All electrical equipment must comply with the relevant parts of AS/NZS 4871:2002. In addition, equipment for use in an area designated as an explosion risk zone must be certified as being explosion-protected by complying with the relevant parts of AS/NZS 60079.10:2004.

Underground Reticulation

The underground reticulation system is typically comprised of the following components:

- Power supply (11 kV) from the surface to underground (via either cables in the mine entry roadway or via cased boreholes)
- Underground switchboard (11 kV)
- Underground reticulation cables (11 kV) (mounted along the roof of the development roadways)
- Section circuit breaker (isolators)

For a new mine, the power supply from the surface to underground typically occur in the following two stages: the initial development phase and the operational phase.

The power supply for the initial underground development is typically via the mine access portals and is achieved by means of an overhead power line installed overland from the surface main mine substation (e.g., 132/11 kV) to a site in close proximity to the portals (this could be to the top of a highwall if the entry is via an open cut or trench). A cable then connects to switchgear located at the portal entry switch room, which will control the power supply entering the mine and will be interlocked with the mine ventilation fans, to trip the underground power in the event of a ventilation failure.

This feeder will initially provide a power supply for the following loads:

- Initial underground power supply
- Development equipment
- Temporary drift conveyor
- Temporary ventilation fans
- Pumps and other ancillaries

In the longer term, this feeder will also provide the permanent power supply for the drift conveyor, pumps, and other loads located in the portal area.

Prior to the commencement of the longwall, the power supply to the underground operations will require upgrading, typically by using borehole feeder cables originating from the surface main mine substation (132/11 kV). Two 300-mm^2, 12.7/22-kV, cross-linked polyethylene (XLPE), single-point suspension borehole cables provide the power supply to an underground switchboard (11 kV) located in the main headings at the bottom of the boreholes. The underground switchboard is configured with two incomers, one bus tie, and four outlets for the control and distribution of the power supply to the following loads:

- Longwall feeder
- Development and conveyor feeder
- Pit bottom feeder
- One spare

The underground-cable selection process is a balance of the following considerations:

- Achieving acceptable performance parameters
- Minimizing the number of different types and sizes used underground
- Practical sizing for the purposes of handling the cables underground

All 11-kV reticulation cables must comply with Australia/New Zealand safety standards (AS/NZS 1972:2006), while cable couplers must comply with AS 1300-1989.

Load-flow modeling of the underground reticulation system is required to accurately specify the required cable types and sizes. A typical specification is listed in Table 12.3-10.

Although paper-insulated lead-covered (PILC) cable has traditionally been used for underground reticulation cabling, the use of XLPE cable is often recommended because it offers superior current-carrying capacity for the same size cable (approximately 50% increase in capacity over the PILC type). This is important to provide adequate current rating, while keeping the cable size as small as possible for cabling handling purposes.

Table 12.3-10 Underground 11-kV reticulation cable sizes

Application	Cable Type	Cable Size, mm^2
Development/conveyor feeder in the main headings	12.7/22 kV, XLPE	150
Development feeder in the gate roads	12.7/22 kV, XLPE	95
Longwall feeder in the mains headings	12.7/22 kV, XLPE	240
Longwall feeder in the gate roads	12.7/22 kV, XLPE	150
Longwall conveyor tripper drives in the gate roads	12.7/22 kV, XLPE	95

Courtesy of MineCraft Consulting.

Section circuit breakers are used to sectionalize the underground reticulation system (11 kV) and to control the power supply entering the various areas of the mine. Section circuit breakers are required at each gate road entry to control the power entering that development or longwall panel. The section circuit breakers incorporate the following features:

- Incoming and through-going supplies
- Two switched outlets
- Circuit breakers and protection relays for each outlet
- Isolation and earth switches for each outlet
- Programmable logic controller (PLC), network, and control equipment
- IP56-rated (minimum) enclosures (IP56 is an International Electrotechnical Commission weatherproof standard)
- Arc fault rated enclosures (using arc fault control methods)
- Base frame, wheels, draw bar and stabilizing/leveling legs

Development Panels

The electrical equipment for the development panels includes the following items: panel substations, panel distribution and control boxes, and panel trailing cables.

The power supply equipment up to the input connection of the development substation, which includes the 11-kV cables and section circuit breakers, forms part of the underground reticulation system.

The panel substations transform the incoming power supply (11 kV) to a 1,000-V (nominal) supply for distribution to the development machines and ancillary equipment. The current growing trend in the industry is for 2-MVA- (megavolt-ampere) rated substations to accommodate the increased power requirements of the development equipment. Generally, these substations are not flameproof, as they are located far enough outby of the working face to be in a nonhazardous zone. The panel substations typically incorporate the following features:

- Incoming and through-going high-voltage supplies
- High-voltage circuit breaker and protection relays
- Isolation and earth switches for the transformer section
- 2.0-MVA, 11/1.05-kV transformer
- Four-outlet low tension end
- 1,000-V switchgear and protection relays
- PLC, network, and control equipment
- Communication components for the CM
- IP56 (minimum) rated enclosures
- Arc-fault-rated enclosures (using arc-fault-control methods)
- Base frame, wheels, and draw bar

The panel DCB receives the 1,000-V power supply from the panel substation via a 150-mm^2 trailing cable and provides

Table 12.3-11 Panel trailing cable requirements

Application	Cable Type (AS/NZS 1802:2003)	Cable Size, mm^2	Cable Length, m
Panel 1,000-V feeder cable	241.1	150	110
Continuous miner cable	241.1	120	150
Shuttle car cable	275.1	35	275
Auxiliary cable (fan/feeder/pump)	241.1	35	110

Courtesy of MineCraft Consulting.

separate outlets for the distribution control and protection of the 1,000-V power supplies to the various development panel machines. The panel DCB incorporates the following features:

- Flameproof enclosures certified to the relevant parts of AS/NZS 60079.10:2004
- Incoming and through-going supplies
- Six to seven 1,000-V outlets with plug receptacles
- 1,000-V switchgear and protection relays
- Arc-fault-rated enclosures (using arc fault containment methods)
- PLC, network, and control equipment
- Communication components for the other development equipment
- Base frame with either wheels or fork tine boxes for transport

In Australia, all trailing cables must comply with AS/NZS 1802:2003, while the cable plugs must comply with AS 1299-1993. The plugs must be fitted and the cable assemblies tested in accordance with AS/NZS 1747:2003. Table 12.3-11 summarizes the recommended cable requirements for each development panel. All cables are normally supplied assembled complete with plugs, labels, and dust covers. Back-to-back couplers are required for the connection of the individual lengths of cable.

Longwall Panel

The electrical equipment for the longwall panel includes longwall substations; longwall DCB(s); monorail and face trailing cables; and control, monitoring, and signaling equipment. The power supply equipment up to the input connection of the longwall substation, which includes the 11-kV cables and section circuit breakers, forms part of the underground reticulation system. The longwall electrical equipment is normally included in the scope of supply for the longwall equipment package.

Underground Conveyors

The electrical equipment for the conveyor systems includes conveyor substations, conveyor starters, power and control cables, and control and signaling equipment. The power supply equipment up to the input connection of the conveyor substation forms part of the underground reticulation system (11 kV). The conveyor electrical equipment is normally included in the scope of supply for the respective conveyor system package.

Dewatering Pump Stations

The electrical equipment for the dewatering pump stations includes substations, pump station starters, power and control cables, and control and monitoring equipment. Generally, the dewatering pump stations will obtain their power supply from a substation conveniently located nearby, such as a conveyor substation or starter. However dedicated substations may be required for more distant pumping locations such as the pit bottom area to provide a power supply for pumping, an equipment tramming facility, and general power for the area.

Underground Lighting

Underground lighting is typically required in the following locations:

- Electrical equipment locations such as switchboards, section circuit breakers, substations, and DCBs
- Conveyor drives, loop take-ups, and transfer points, including the walkways in between
- Pump stations
- Transport access portal
- Other areas where a particular risk exists and which can be mitigated by lighting
- Initial 50 m (approximately) of the mine access drifts to assist the transport vehicle operators in the transition from daylight to darkness (and vice versa)

CHAPTER 12.4

Underground Horizontal and Inclined Development Methods

Michael A. Tuck

INTRODUCTION

Two types of development exist in mining: primary and secondary. The main difference between these two types is the life expectancy of the development.

Primary implies long life and includes such items as shafts, declines, and other mine accesses; main tunnels, haulages, crosscuts, ore- and waste passes, crusher chambers, and other large chambers. Thus primary development is the development of the more permanent features of a mine. These do not have to be developed early in a mine life, but they need to have a relatively long life span.

Secondary development is more temporary in nature and tends to be associated with the needs of a particular production unit or units. In many cases this type of development is consumed as production proceeds. Thus a typical lifetime for this type of development is 1 or 2 years and is often less than this.

Development is a necessary part of mining as it provides the infrastructure with which production of ore can be undertaken. Development is essential but represents an additional cost. In most situations this cost is not recoverable until mining operations—such as preparing to excavate secondary development undertaken within the ore body itself—begin. However, in some situations (e.g., coal mine development of revenue-generating material and some payback is obtained during development. Primary development is normally almost entirely undertaken in waste external to the ore body; the exception to this is the mining of bedded deposits where some ore in primary development can sometimes be taken.

Development requirements are influenced by a number of parameters; the following list is far from exhaustive:

- Ore-body type
- Ore-body depth
- Mining method selected
- Economics
- Ore-body extent

The mining method selected is a significant influence, especially with regard to secondary development but also with respect to primary development, as it is important to the layout and size of the primary mine infrastructure to be able to handle the production of waste and ore over the lifetime of the mine. It is also important to account for possible variations in production over the mine life as well. Given the cost of development and the usual need for mining companies to generate income relatively rapidly, due to the long lead times between exploration and eventual production, the aim in most cases is to bring production on stream as quickly as possible. However, the long-term capabilities of a mine are dictated by the capabilities of the primary mine infrastructure, the need for accurate geological information, environmental considerations, and numerous other factors. During the mine planning stage, the primary infrastructure and secondary development are investigated. It is essential at this stage that a thorough economic, technical, and sensitivity analysis of all possible mine production systems be undertaken to evaluate the project on a logical basis.

Mine development serves a number of purposes, which include

- Accessing the mineral deposit;
- Provision of accurate geological information to aid the production process; and
- Providing accurate information on other technical needs such as geotechnical characteristics of the rock, water inflow rates, ventilation pollutant inflow rates, and so on.

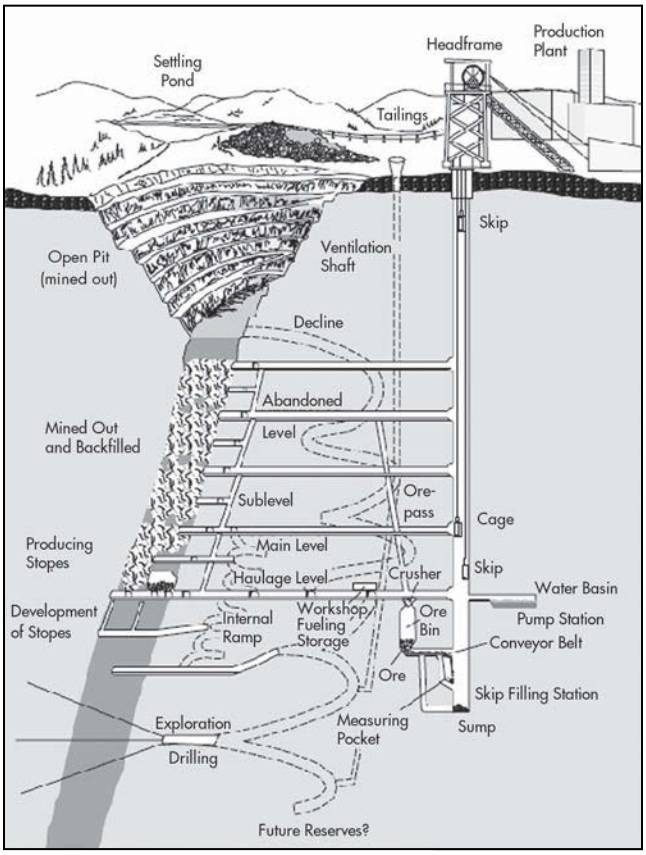

Figure 12.4-1 illustrates some of the openings whose construction will be discussed in this chapter.

EXCAVATION METHODS

Development openings in mines can be excavated in one of two ways, either by drilling and blasting or by mechanical excavation. Both techniques are used and are discussed in the following sections for various types of development openings. Both have their advantages and disadvantages; mechanized mining has the following advantages compared to drilling and blasting methods:

- Higher advance rates/development rates
- Smooth development profile and superior rock stability (tunnel boring machine and mobile miner circular profile in particular)

Michael A. Tuck, Associate Professor of Mining Engineering, University of Ballarat, Victoria, Australia

Source: Atlas Copco 2010.

Figure 12.4-1 Basic infrastructure of an underground mine

- Minimized ground support
- Reduced overbreak
- Less surface disturbance
- Less noise
- Lower running costs
- Continuous haulage system, such as conveyor
- Automated haulage systems
- Less labor required
- Automation
- Precise direction control (laser guidance)
- Safety (no explosives)

However, there are disadvantages also, including

- Cost,
- Difficultly dealing with variable ground conditions, and
- In hard, abrasive rocks, high rates of wear on the cutters can lead to high operating costs and long periods of downtime for cutter replacement and other maintenance.

Shafts

According to *The Mining Glossary* (AusIMM 2007), a shaft is defined as "a primary vertical or non-vertical opening through mine strata used for ventilation or drainage and/or for hoisting of personnel or materials; connects the surface with underground workings." Although this is a good definition, shafts can also be internal within a mine connecting vertically separate workings as well as levels.

In some ways, a better definition of a shaft is a vertical or subvertical opening in a mine that is excavated from the top downward, as opposed to a raise, which will be discussed in a later section of this chapter.

Shafts are the most important capital openings for deep mines. Shafts provide all the services for underground operations including

- Fresh air,
- Transport of ore and supplies,
- Personnel transport,
- Power,
- Communications,
- Water supply, and
- Drainage.

The depth of the shaft has a direct influence on the total time to develop a mine prior to first production; in some cases, shaft sinking can account for up to 60% of the total development time. Consequently, proper selection of the shaft-sinking method to minimize sinking time and ensure uninterrupted operation is of great importance.

Determining the shaft diameter and hoisting depths requires consideration of future mining needs. It is generally better to overdesign the shaft in the initial stages of the project life span than prevent feasible increases in production later by the creation of a bottleneck.

Designing the excavation requires data to be gathered and solutions to elements within the design to be determined. In order to design the excavation the following need to be taken into account:

- Site geology, including a description of the geological column, usually in a table form identifying the rock strata, their geotechnical parameters, groundwater levels (including water heads, inflow rates, and chemical contamination, if any)
- Determination of the shaft diameter
- Choice of shaft-sinking technology
- Description of the shaft lining (should include a list of lining sections with their thicknesses detailed)
- Shaft foundations, including their location and dimensions
- Shaft collar depth, foundations, thickness, and materials to be used (the type and number of openings with a description of their function, dimensions, and elevations should also be detailed)
- Shaft sump, including depth, structural characteristics, pumping arrangements, and cleaning system
- Surveying data
- Calculations, including ground and water pressure acting on the shaft lining, the resulting lining thicknesses, shaft insets and their dimensions, and airflow capacity
- Timetable of construction
- Cost specifications
- Engineering drawings

Shaft Shape and Diameter

Numerous factors regarding the shape and diameter of a shaft need to be considered, such as

- Shaft duties and purpose, such as rock hoisting, ventilation, and worker and materials transport. Is the shaft to be used for a single purpose or for a variety of purposes? What are the quantities involved?
- The amount of water to be handled, number of pipes, and the diameter of the pipe are important parameters, as is the method of hanging these within the shaft.
- Ground conditions
- Size of mining equipment to be handled by the shaft. Is the equipment to be handled in single or multiple parts? For transportation of oversize elements is suspension underneath the shaft conveyance possible?
- The expected lifetime of the shaft

The majority of shafts in modern mining are circular in shape; however, rectangular cross sections were common in the past. Although rectangular shafts were more popular within metalliferous mines, most modern shafts tend to be circular. Other shapes are used such as square or elliptical. Circular shapes have inherent strength and have the advantage that for a particular cross-sectional area the minimum perimeter results. Elliptical shafts tend to be used in areas where a significant horizontal stress field acts in a particular direction; the major axis of the ellipse is aligned to this direction to enhance the shaft strength.

Shaft Linings

Shaft linings basically serve to support the shaft equipment and the walls of the excavation. The minimum lining usually required to support shaft equipment is about 200 mm. Thicknesses required for wall support are generally higher. In modern projects where round or elliptical shafts are employed, concrete lining is used almost exclusively. Such shapes reduce airflow resistance, make sinking easier and allowing the full advantages of concrete to be employed. The placement of concrete can be mechanized, allowing high sinking rates as well as lower costs. The strength of the concrete can be adjusted as required and watertightness can be ensured within aquifers of moderate head. Where heads exceed the strength of concrete, cast iron linings are employed.

In order to calculate the required thickness of the lining material, a number of factors need to be considered. First, the ground pressure acting on the circular shaft needs to be determined.

The vertical or hydrostatic stress, σ_v, is proportional to the weight of the overburden and can be calculated from

$$\sigma_v = \sum \gamma \times h$$

where

γ = density of the rock strata multiplied by the acceleration due to gravity
h = thickness of the rock stratum

The next stage is to evaluate the horizontal stresses. Horizontal stresses vary substantially from one location to another. The minimum value can be calculated using elastic theory employing Poisson's ratio to a maximum value derived from active or residual tectonic stresses. A good average ratio to employ at 500-m depth would show that the horizontal stress is two to three times the vertical stress.

For conventional shaft sinking, the technical limit for shaft water inflow is approximately 500 L/min. However, even the smallest inflow of water can cause problems and will require special arrangements to control it. Water seepage into a finished shaft may cause corrosion of steel installations such as buntons and reinforcing, and will lead to costly and troublesome replacement. Therefore, water inflow to the shaft should be controlled; this is especially true for the buildup of hydrostatic pressure behind a shaft lining. Numerous methods can be employed as described by Unrug (1992). Examples include the use of polyethylene or other shaft liners installed at the rock–lining interface.

The thickness of a shaft lining can be determined using

$$d_i = a\left(\sqrt{\frac{R_c}{R_c - np\sqrt{3}}} - 1\right)$$

where

d_i = shaft lining thickness (m)
a = shaft radius
R_c = allowable stress in the concrete (MPa) (see Figure 12.4-2)
n = coefficient of lining work conditions (see Figure 12.4-3)
p = calculated outside pressure acting on the lining (MPa)

Shaft Collars

The shaft collar is the upper portion of a shaft, which is anchored to the first footing as a minimum and to the bedrock (if required). Overall, the dimensions of the collar depend to a large degree on its depth, cross section, thickness, the function of the shaft, the overburden rocks, hydrologic conditions, the ground pressure (on a diurnal and annual basis), sinking method, and additional loading conditions. A simple collar design is illustrated in Figure 12.4-3.

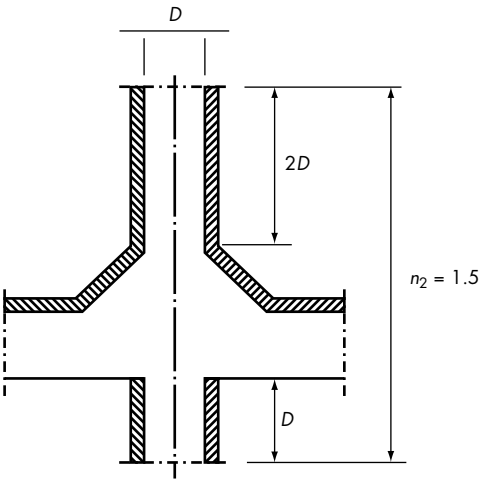
The size of the shaft collar depends to a large extent on the loads in the immediate surrounding areas from the shaft and associated equipment. Examples of these loads include winding equipment and its associated dynamic loading, loading impacting on the shaft collar area from other surface facilities, and so on. The shape, thickness, and choice of shaft collars depend on numerous factors, but in essence depend on structural factors. Some typical collar shapes are illustrated in Figure 12.4-4.

Shaft Insets and Sumps

Shaft insets should be designed to minimize airflow resistance. Model and/or computational fluid dynamics models can be used to ensure this.

Sumps at the base of a shaft and at intermediate levels to minimize pumping heads must be of sufficient depth or size to cope with the water flow requirements. Obviously, suitable dewatering arrangements must be provided. In addition, periodic cleaning must be designed into the system to account for sedimentation, which will reduce the holding capacity of the sump.

Technology of Shaft Sinking



The main classification between traditional shaft sinking and other specialist methods is based on the engineering and hydrogeological conditions of the individual site.

The conventional method of sinking is summarized in Figure 12.4-5 and involves repeating cycles of face advance and lining erection without any previous ground stabilization. Such methods are applicable to good- to fair-quality rocks with limited water inflow into the shaft (<500 L/min).

Symbol	Type	Magnitude	Remarks
n_o	Influence of tectonic forces	In-situ measurements	n_o
n_1	Influence of shaft diameter D	$n_1 = \frac{1}{2}\sqrt[3]{D+1}$	
n_2	Influence of the shaft station	$n_2 = 1.5$	n_2
n_3	Influence of the strata dip x	$n_3 = 1.0$ if $x < 30°$ $n_3 = 1.25$ if $x > 30°$	n_3
n_4	Influence of the weak strata of thickness h	$n_4 = 1.0$ if $h > 1.3$ m $n_4 = 0.7$ if $0.8 < h < 1.3$ $n_4 = 0.3$ if $h < 0.8$	n_4
n_5	Influence of the water filtration through the lining	$n_5 = 1.0$ for watertight lining $n_5 = 0.1$ for formation grouting $n_5 = 0.1$ to 0.2 for water drainage n_5 = for preliminary lining	n_5

Remarks:

n_2

n_o—apply coefficient if $\sigma_h/\sigma_v > 1$

n_3 applies for cohesive soil and rock without water
n_4 applies for calculation of $H_{critical}$ in rocks
n_5 applies for calculation of water pressure

Figure 12.4-4 Typical shapes of shaft collars

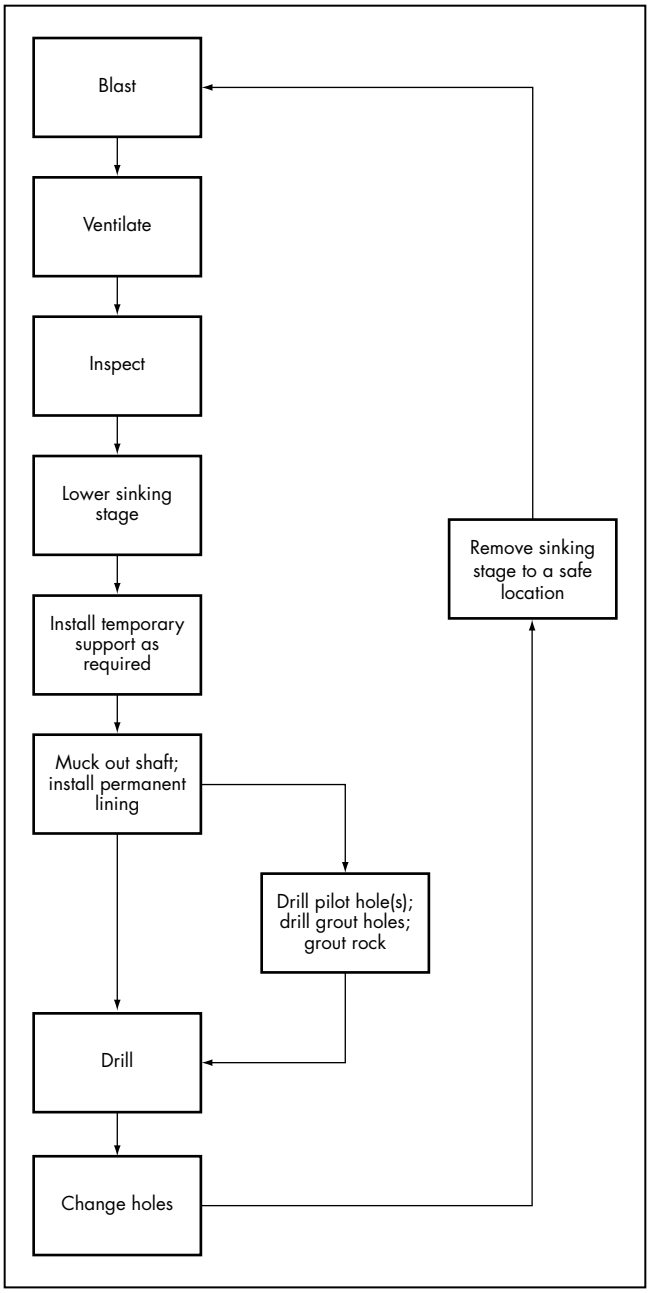

Figure 12.4-5 Typical drill–blast shaft-sinking cycle including a possible grouting sequence for rock strengthening

Specialized methods of shaft sinking include those applied to

- Strong rocks that have an extensive fracture pattern resulting in a strong water inflow (such as the South African goldfields);
- Coherent, weak, plastic flowing ground such as permafrost areas; and
- Loose water-bearing grounds.

Conventional Drill-and-Blast Shaft Sinking

The main components within a traditional drill-and-blast shaft-sinking operation are illustrated in Figure 12.4-5. Additionally, the following classifications of traditional shaft sinking can be made based on the order of the main components of the operation:

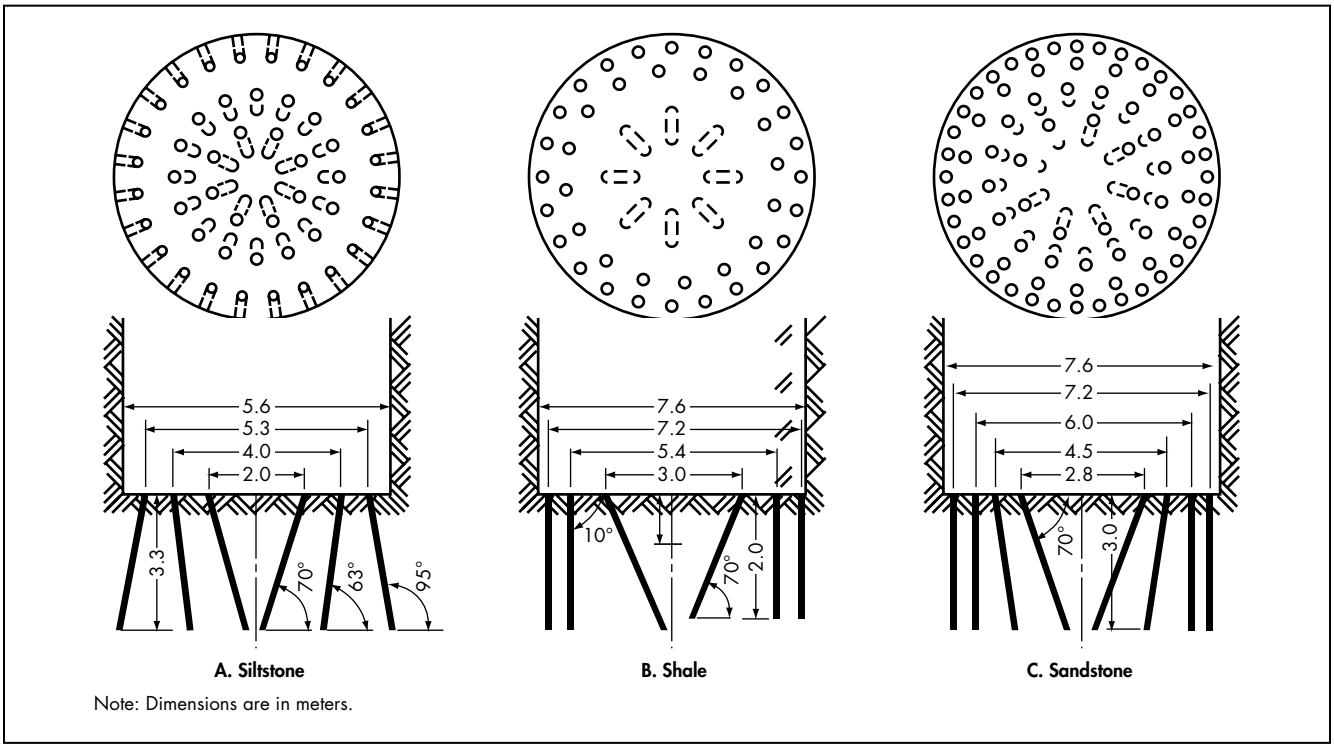
- *Series system*, in which sinking occurs with nonsimultaneous face advance and erection of the permanent lining. The shaft is sunk in sections. The length of the section depends on the rock quality. In a particular section of the shaft, the face is advanced first with a temporary lining. When sinking is suspended, the permanent lining is constructed. Fast sinking rates are not ensured; however, high capital expenditure is not required. This method is commonly applied to the sinking of small-diameter shafts at shallow to moderate depths.
- *Parallel system*, in which sinking with simultaneous face advance and lining erection at certain distances behind the face occurs. In this method, a temporary lining is required as with the series system. It is applied to the sinking of large-diameter and deep shafts where the high capital cost can be paid off over the life of the project.
- *Simultaneous system*, in which advancing the face and erection of the lining in the same shaft section occurs. This method can be further subdivided into series, simultaneous, and parallel simultaneous methods. The series simultaneous system involves face advance and lining completed in one cycle with each being done one after the other. The lining is erected either downward or upward and temporary lining is eliminated. The parallel simultaneous system involves simultaneous face advance and lining erection.

Shaft buntons, beams, guides, and so on are usually installed following the advance of the permanent lining; however, in some methods of shaft sinking (e.g., shaft boring) they are erected following the completion of the shaft lining.

Shafts can be sunk to the final depth or to depths required for certain stages of the mining process. Shaft extensions to subsequent levels need to be synchronized with reserve depletion in the upper levels to ensure uninterrupted production. Shaft extensions can be undertaken by either sinking or raising.

Before sinking a shaft, preparatory work needs to be done. This includes

- Determination of geological and hydrological conditions,
- Preparation of technical documentation, and
- Construction work associated with site preparation and construction of the shaft head.



The shaft site should be secure from flooding. From a design perspective, this would be based on a 100-year flood level. Numerous activities associated with the preparation of a shaft site include but are not limited to

- Construction of access roads and materials storage areas,
- Grading,
- Provision of a water supply,
- Provision of electrical power and other power sources, and
- Temporary and permanent buildings.

Drilling and Blasting

When undertaken correctly, drilling and blasting will ensure

- Correct size and shape of the excavation,
- An even face surface for simpler mucking and drilling of the next round,

Source: Unrug 1992.

Figure 12.4-6 Typical circular shaft drilling patterns for different rock types

- Uniform sizing of the broken rock for effective mucking, and
- Safe and economic operation.

Shaft blasting uses a variety of high explosives. The correct product has to be used given site-specific conditions such as explosive gas emissions, reactive ground conditions, and the presence of water. Electric detonators with millisecond delays are also employed. The drilling pattern has a strong influence on sinking performance. It should ensure

- Accuracy in the shape of the excavation,
- Clean separation of rock from the bottom of the excavation,
- Even and sufficient comminution of rock,
- Avoiding cutoffs of neighboring active holes, and
- Avoiding damage to nearby shaft installations.

The drilling pattern depends on such factors as

- The shape of the shaft section,
- Rock strength,
- Cleavage,
- Dip of strata,
- Water inflow, and
- Hole-loading structure.

Typical drilling patterns for circular shafts are shown in Figure 12.4-6. With small and moderate strata dip, holes are placed on concentric circles drawn from the center of the shaft. The number of circles is three to five, depending on the shaft diameter. The central hole is vertical and shorter, about two-thirds the length of the other holes. This hole initiates conical excavation by cut holes and is especially recommended in strong rocks. Holes of the first (central) circle ("wedge holes") are inclined toward the shaft center and are fired first to open an additional free surface and to make the work of the remaining external holes easier and more efficient. They are drilled with an opposite (outward) inclination of 65°–75°. Four to ten holes are drilled for the first circle. The ends of four holes are intended to create a square with sides of 180–300 mm. For a larger number of holes, a 400–600-mm circle is used. In general, the harder the rock, the more first-cut holes are required. Holes of the next two, three, and sometimes four circles crush and lift the excavated material.

The inclination of holes varies from 65° to 85°; the farther they are from the center of the shaft, the more vertical they are. The distance between adjacent holes on a circle should not exceed 0.8 to 0.9 m for 32-mm and 36-mm cartridges; for a 45-mm cartridge, it should lie in the range of 1 to 1.2 m. The last circles of perimeter holes are supposed to leave the shaft wall smooth. They are holes drilled toward the shaft wall, 65°–85° (less inclination for weak rocks and more for stronger ones). In very weak rocks, they can be slightly inclined toward the center of the shaft. Perimeter holes are placed in a circle with a diameter of 0.6 m less than the shaft diameter in rocks with a coherence factor of $f = 2–8$ and 0.3 m for rocks with $f = 9–20$. The distance from the shaft wall has to be such that in rocks with $f < 8$, holes should not project from the design shaft section, and in rocks with $f > 8$, they should protrude about 100–200 mm outside the shaft contour. The distance between rib holes in moderate-strength rock is 0.9–1.2 m and in strong rocks 0.7–0.9 m.

Drilling of Shot Holes

Blastholes can be drilled with sinker percussive drills, hand-held or mounted on a special shaft jumbo. Sinkers are

self-rotating, driven by compressed air or hydraulically with air or water flushing.

Two systems exist:

1. *Series*, in which the drilling starts from the shaft center toward its perimeter after completion of mucking
2. *Parallel*, where mucking and drilling are done at the same time. Drilling starts from the perimeter toward the shaft center.

A shaft jumbo can be used only in the series system. A series system is used in smaller shafts when a Cryderman or similar type of mucker is used. This system ensures precision in blasthole drilling.

The parallel system is sometimes chosen in large cross-sectional shafts where cactus-grab cabin muckers start to clean the sides of the shaft moving toward its center. Drilling is done in the cleaned area. Owing to parallel drilling and mucking, some time saving can be achieved; however, it is at the expense of drilling accuracy. Blastholes can be drilled individually or by groups of drillers. In the first case, approximately 25% of the time is lost in changing bits. In the second, one shaft area is divided according to the number of drillers; each group drills in one sector holes of a certain depth only. Bits are changed only when they get dull. Then the drilling rod is changed (lengthened), and work is done in the next sector. Wooden sticks are used to prevent holes from being plugged by muck.

Drilling equipment is delivered in a special bucket (known as a kibble) or basket to the shaft bottom. An elastic hose with quick coupling is connected to the main steel-compressed air tubing. At the end of the elastic hose, there is a distributor with multiple outlets and valves for particular drills. Drilling is a labor-intensive operation that takes about 16% of the cycle time.

Shaft-drill jumbos have been developed to mechanize blasthole drilling. These permit the drilling of larger-diameter holes more precisely, faster, and deeper.

Mucking in Shafts

Mucking in shafts accounts for as much as 50%–60% of cycle time. Table 12.4-1 details the different factors influencing mucking efficiency. Figure 12.5-2 in Chapter 12.5 shows a schematic of the sinking phases with an Eimco 630 loader.

Mucking efficiency is also dependent on the degree of rock fragmentation and the height of the bucket. For mechanical mucking, medium-sized fragmentation, approximately 125 mm, is most efficient. Generally, in a muck pile after a shot, 70%–80% of the material is fine fragmentation, and the rest is composed of larger fragments.

Several types of muckers are in use depending on shaft shape, size, depth, and location:

- Scrapers, used in rectangular shafts and very large-diameter shafts (underground bunkers)
- Overshot loaders on caterpillars (e.g., Eimco 630)
- Cryderman muckers
- Cactus grabs (light)
- Cactus grab (heavy, on central pivot)

A variety of systems are used. Some are driven by an operator (e.g., Eimco), some are hand-guided at the face when hanging from a platform, and some are attached to the shaft wall (Cryderman) and operated from a control cabin. Heavy cactus grab units have a rotating arm on a central pivot below the stage. Muckers can be electric, pneumatic, or hydraulically driven.

To determine the capacity of the mucking unit, the following may be used. The theoretical mucking capacity is

$$P_t = 3{,}600 \times k \times \frac{V_b}{t}$$

where

P_t = mucking capacity (m^3/h)
k = fill factor (0.8–0.9 for sandstones and 1.1–1.2 for shales)
V_b = the bucket volume (m^3)
t = mucking time (seconds)

The mean actual efficiency is found by calculating the actual mucking time and all time losses for unproductive activity such as mucker lowering time to work position, time of temporary support erecting when mucking has to be suspended, and time for final cleaning.

Most shafts intersect one or more water-bearing horizons, so shaft dewatering is an essential part of sinking. The characteristic features of shaft dewatering consist of changing water inflow rates, changing the pump head, filtering water to eliminate rock and mud particles, and periodic changes in positioning dewatering devices.

Dewatering can be considered in two ways, either as limiting water inflow into the shaft or pumping water out of the shaft. Water inflow into the shaft can be diminished by initial drainage of the rock mass, sealing of the water flow routes, or by tapping the water. The following are used to dewater the face:

- Rock kibbles and special water kibbles
- Face pumps
- Combination of face and stationary pumps

- Combination of hanging and stationary pumps
- Submersible pumps
- Airlifts

Shaft Lining Construction

The type of lining is determined by the following factors:

- Hydrogeological conditions
- Shaft function
- Planned lifetime
- Shape of shaft section and its depth
- Availability of construction materials
- Construction cost

In choosing a shaft lining, the geotechnical properties of the rock and hydrologic conditions are decisive in most cases. The chemical activity (corrosiveness) of the water can also be an important consideration.

Since modern new shafts often have automatically operating hoisting gear (moisture sensitive), they should be dry. Main shafts are usually planned for the entire mine life span, so they should be constructed to minimize repairs and maintenance time.

Temporary support is placed to protect the crew and equipment against falling rocks from the exposed shaft wall before a permanent lining is placed. Numerous systems of temporary lining are in use. Forms of temporary lining include rock bolts and mesh and other traditional methods of temporary support used in other mining operations.

Depending on the shaft design and environmental conditions, several different permanent-lining systems can be used:

- Timber
- Brick or concrete blocks
- Monolithic concrete
- Reinforced concrete
- Tubing
- Shotcrete
- Anchor bolts

Shaft-Sinking Stage

Sinking stages are an important element of any shaft-sinking program; they provide a working platform from which to perform the sinking operations. They also ensure the safety of the personnel working at the shaft bottom. An example of a sinking stage can be found on the Andra Web site (2009). This Web site details the construction of test facilities in France for nuclear waste emplacement, with access by shaft. It shows the sinking stage being installed in the shaft following construction of the collar and gives technical details of the shaft-sinking process as well as the development of the test galleries underground. These can vary considerably in design from a simple single-deck working platform to complicated multideck arrangements with facilities for drilling, mucking, shaft concreting or timbering, and storage of hoses, pumps, and all other equipment associated with shaft sinking.

Sinking stages have been used since the earliest shaft sinkings and have developed to maximize efficiency of the operations while minimizing delays. The primary purposes of sinking stages are to enhance safety and maximize efficiency.

Stages are suspended in the shaft by wire ropes and winches that are independent of the main hoisting system. Stages are raised prior to blasting and then lowered to their new position at the end of each sinking cycle. Sinking cycles are usually based on a certain height of concrete pour or timbering.

Specialized Methods of Shaft Sinking

Special methods of shaft sinking are used when the following conditions are encountered:

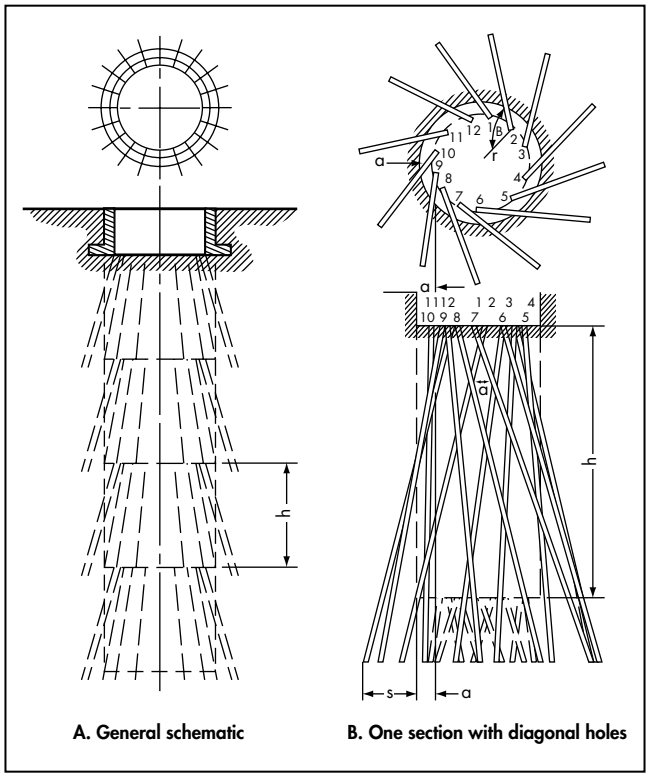
- Incompetent, water-bearing rocks (e.g., quicksand)
- Weak, unstable, soil-type rocks
- Competent fractured rocks with high water inflows above 0.5 m^3/min

Numerous special methods exist that encompass many variations in method and application because of environmental conditions and range of depths. The characteristics of these are given in Table 12.4-2. The following methods will be described in subsequent paragraphs: depression of groundwater level, grouting methods, freezing method, and shaft drilling. An alternative to these methods can be applied in some cases (e.g., moving the shaft to another site).

Depression of groundwater level. Prior to designing a method for depressing the groundwater, the following decisions must be made:

- Choice of the most suitable method for depression of the water table under site conditions
- Determination of the number, spacing, diameter, and depth of the wells
- Calculation of the radius of the depression cone, amount of water to be pumped out, and the height of the remaining wet portion of the water-bearing strata
- Evaluation of equipment, hardware, and pumping facilities
- Choice of the auxiliary method to go through the wet remainder of the water-bearing strata
- Choice of a suitable water discharge plan

To lower the water table in the area of shaft sinking, the following systems can be applied:



- Pumping water from three to six depression wells drilled around the planned shaft perimeter, placed on a circle about 4 m larger than the diameter of the shaft excavation (this system is used most often)
- Draining water through drill holes to existing openings in the mine below
- Draining water through drill holes to water-absorptive strata (e.g., dry sands under water-bearing strata)

Depression wells are drilled with 300–500-mm diameters, without drilling mud. They are spaced uniformly around the future excavation. Within the range of the water-bearing strata, they are equipped with filters perforated by round or elongated holes 5–10 mm in diameter, spaced in a checkered pattern, with an outside screen having eyes 0.4–0.9 mm in diameter, sized against entry of sand particles. Generally, the construction of the filter must be suitable for the character of strata to be drained. Submersible drainage pumps have a wide-capacity range, varying up to 350 m^3/h. Calculations for well efficiency are based on principles of flow through a porous media. The objective of the design is to determine a pumping regime to achieve a dry-out zone surrounding the shaft. This is created by the combined effect of the depression cones around particular wells. The movement of water through a porous media is given by the Darcy formula:

Table 12.4-2 Special methods of shaft sinking and their applicability

Method	Rock Mass	Thickness of Water-Bearing Strata, m	Water Inflow	Range of Depth, m	Approximate Rate of Advance, m/month	Comments
1. Pile wall • Wooden • Sheet pile wall (steel profiles or pipes)	Quicksands, soils (saturated with water without stones and rock fragments)	2–6 6–10	Limited	6–15 Down to 30	2–5 6–10	Required presence of impermeable strata of clay, into which the piles could be driven to lock water in above water-bearing strata.
2. Concrete pile wall drilled or driven piles	Quicksands, soils, loose rocks (sands, gravels), clays saturated with water (also with stones)	10–20	Any	25–30	8–10	Concrete pile wall can be used as a foundation for a shaft headgear.
3. Caisson method • Without pumping water in flow rocks • With steady pumping in weak and loose water-bearing rocks	Uniform flowrocks or loose rocks (sands, gravel), clays, without intrusion of hard rock or boulders	10–15	Not limited Up to 0.3 m^3/min	Down to 30; more in special cases when vibrators or compressed air can be applied	10–20	Flat-lying strata required or with little dip. Presence of the clay strata below water-bearing zone 2–3-m thick is necessary.
4. Caisson with compressed air	Loose or noncoherent water-bearing strata	8–30	Moderate	Down to 40	20–30	Maximum air pressure in the face chamber 3–3.5 atmospheres.
5. Depression of groundwater level	Mid and coarse solids and gravels with coefficient of filtration 10–100 m/d. Fractured competent rocks.	20–30	Great	Around 100–150	15–20	Not supposed to be applied in clay rocks, quicksands, and alternating packages of permeable and nonpermeable rock.
6. Chemical grouting	Sands with clay content not exceeding 10%–15%. Coefficient of filtration 2–80 m/d. Also competent rocks with small tissue.	A few	Moderate	Unlimited		Usually used as an additional interventional method.
7. Grouting (cement)	Competent rocks, with tissues and cracks filled with water (sandstones, shales, mudstones, limestones), and coarse sands and gravels.	Not limited	Mid and large, up to about 10 m^3/min	Any	10–15; 20–30 in good conditions	Not recommended in flow rocks or quicksands, with water flow velocity more than 80 m/d, or in presence of caverns and large voids.
8. Grouting with clay	Water-bearing rocks with large cracks and voids.	Not limited	Not limited	Not limited	10–15	Can be used in presence of aggressive waters. Usually is used combined with grouting (cement).
9. Bitumination	Competent rocks with large cracks and voids; also gravels	20–30	Mid and large	Down to about 40		Used as an auxiliary method for local sealing of the rocks with high flow velocity and aggressive waters.
10. Freezing of the rock mass	All types of water-bearing rocks	10–1,000	Not limited	Down to 1,000	Differs depending on depth, sinking frozen rocks up to 50 m overall less due to length of freezing method	Most reliable method, however, costly and time-consuming because of preparation work (drilling of the freezing holes and the time taken for an ice wall to form after freezing commences.)
11. Shaft drilling	Weak, water-bearing strata	Several hundred	Not limited	To 600		Thickness of competent hard rocks not supposed to exceed 10% of overall thickness of water-bearing strata.

Figure 12.4-7 Grout hole distribution when drilling from the face

$$V = K\frac{dh}{dl} = K_i = K\frac{h}{l}$$

where

V = mean velocity of flow or mean filtration velocity (m/s)
K = permeability or coefficient of filtration (m/s)
d = equivalent diameter of the flow routes (m)
$h = h_2 - h_1$ = difference of water levels in the ground or the depression created by the pumping of water
l = distance in which the head loss appears (m)

$$i = \frac{h}{l} = \frac{h_2 - h_1}{l} = \text{hydraulic gradient (dimensionless)}$$

Application of grouting. Based on geologic data, the following decisions have to be made prior to the start of the project:

- Choice of the grouting system, including the decision as to whether grouting will be done from the surface or from the bottom of the shaft; determination of the grouting depth; and determination of the length of the grouting sections
- Determination of the number of grouting holes and their respective distances, diameters, depth and angle of dip, and applicable drilling method
- Construction and calculation of the grouting plug
- Grout type to be used, its density and admixtures
- Injection system and required equipment
- Determination of working pressure to be applied in particular sections, and approximate calculations of grout consumption
- Number of control holes and their locations
- Set of drawings corresponding to this list of considerations

Necessary hydrogeological information should contain

- Number and characteristics of the water-bearing water horizons,
- Chemical analysis of water flows and determination of their degree of corrosiveness,
- Flow velocity, and
- Coefficient of filtration.

Properly performed grouting seals the rock mass in the area of the shaft, making sinking possible by a conventional method. Grouting is performed from the surface when the water-bearing strata are relatively thick and close to the surface, or from the shaft face when the strata to be grouted are located at such a depth that it is not feasible to drill long holes from the surface. Grouting is most successful in water-bearing, competent but fractured rocks. Grout fills the fractures and cracks, creating a sealed zone around the shaft to be sunk and protecting it against water inflow.

Grouting for sealing is often applied to improve tightness of the lining in existing shafts and to eliminate the voids behind the lining, as well as to seal rocks in the immediate vicinity of the lining (Petterson and Molin 1999).

When grouting from the surface, grouting holes with an initial diameter of 75–150 mm are drilled vertically around the future shaft on a circle with a radius 3–4 m larger than the excavation diameter. Holes should be straight, and with their greater depth, any deviation should be recorded.

Grouting from the shaft face is illustrated in Figure 12.4-7 and is recommended when water-bearing strata occur below 100 m and when their thickness does not exceed 70 m. The length of sections varies between 12 and 25 m.

Holes are drilled along the length of the grouting section, usually by means of heavy drill hammers or small rigs when space allows. Holes are directed at an angle in the vertical plane to get the hole bottoms 1–2 m away from the future excavation. To increase the probability of encountering fractures by the hole, they are also tilted in a tangential direction as shown in Figure 12.4-7. The distances between the hole entries are 0.8–1.5 m. Spacing between the circles of holes is 1.5–3 m. The number of holes drilled depends on the rock character, shaft diameter, and hydrogeological conditions. Practically, it varies from 10 to 30. The initial drill hole size is 50–75 mm; the end size is 30–50 mm. The sequence of drilling and grouting is as follows:

1. The first one-half of the total number of holes is drilled and grouted; during hardening of the cement, the second half is drilled and grouted.
2. All holes are drilled and grouted, one after another, starting with the hole with the largest water inflow.
3. A pair of holes lying on opposite sides is drilled and grouted; then the pair lying in the plane perpendicular to the first one is processed, and so on.

This system is the one most often used, being recognized as the best, because the initial maximum distance between the holes lowers the probability of grout penetration from one hole to another. Grouting plugs are put in the shaft bottom to prevent water and grout inflow into the shaft. Entrance pipes to the holes are secured firmly by grouting them in the plug. The plug can be either natural or artificial.

A natural plug is composed of a protective layer of grouted rock 3–5 m thick, depending on the strength of rock and expected pressure (water and grout).

Artificial plugs are used more often and are constructed of concrete or reinforced concrete. They are constructed on the shaft bottom, 2–4 m from the water-bearing strata. When grouting is completed, the plug is demolished with explosives, and sinking proceeds through the cemented section, but again is suspended 2–4 m above the end of the grouted zone. The shaft lining is constructed and the procedure with the plug is repeated until the shaft passes the whole water-bearing zone. Details of the use of grouting to sink a shaft through water-bearing ground at the Longos gold mine in the Philippines are described by Ayugat et al. (2002).

Freezing method. This is a method commonly applied where a relatively large thickness of water-bearing strata has to be sunk through. Some good examples are presented in Harris (1995). It is commonly applied when shaft sinking to the coal measures in the United Kingdom due to the thickness of the water-bearing Bunter sandstone.

For a freezing process, a suitable design procedure requires solution of the following problems:

- Calculation of the wall thickness of the frozen rock cylinder
- Calculation of the diameter of the circle where freezing holes are located, their number, depth and spacing, and the number and distribution of surveying and control holes
- Selection of the drilling system for freezing holes, specification of equipment, choice of freezing pipes and their diameter, and assessment of time required for drilling
- Design of a temporary shaft head with a freezing basement
- Planning of the freezing procedure in active and passive periods, with specifications of freezing temperature, heat balance, required efficiency of freezing installation, and freezing time
- Determination of the system and time of thawing and liquidation of freezing holes
- Initial planning of freezing technology, shaft sinking and lining, and complementary grouting

An artificially created cylinder of frozen rock or an ice wall around the shaft creates a shaft lining, thus shielding the inner space against water and unstable rock. The thickness of the frozen rock cylinder, e_c, in meters, for shallow and moderate depths is calculated for external pressure, p, in megapascals, from the Lamé formula (in metric units):

$$e_c = r\left(\sqrt{\frac{k_c}{k_c - 2p}} - 1\right)$$

where

r = shaft radius of the excavation (m)
k_c = allowable stress of the frozen rock (mPa)

The allowable stress of the rock is 50% of its compressive strength in the mean range of freezing temperatures. For calculation of the thickness of the cylinder of frozen rock, the mean temperature of the rocks should be taken. The temperature within the wall of frozen rock changes from a minimum value just beside the freezing hole to a maximum around 0°C on the outer wall limit.

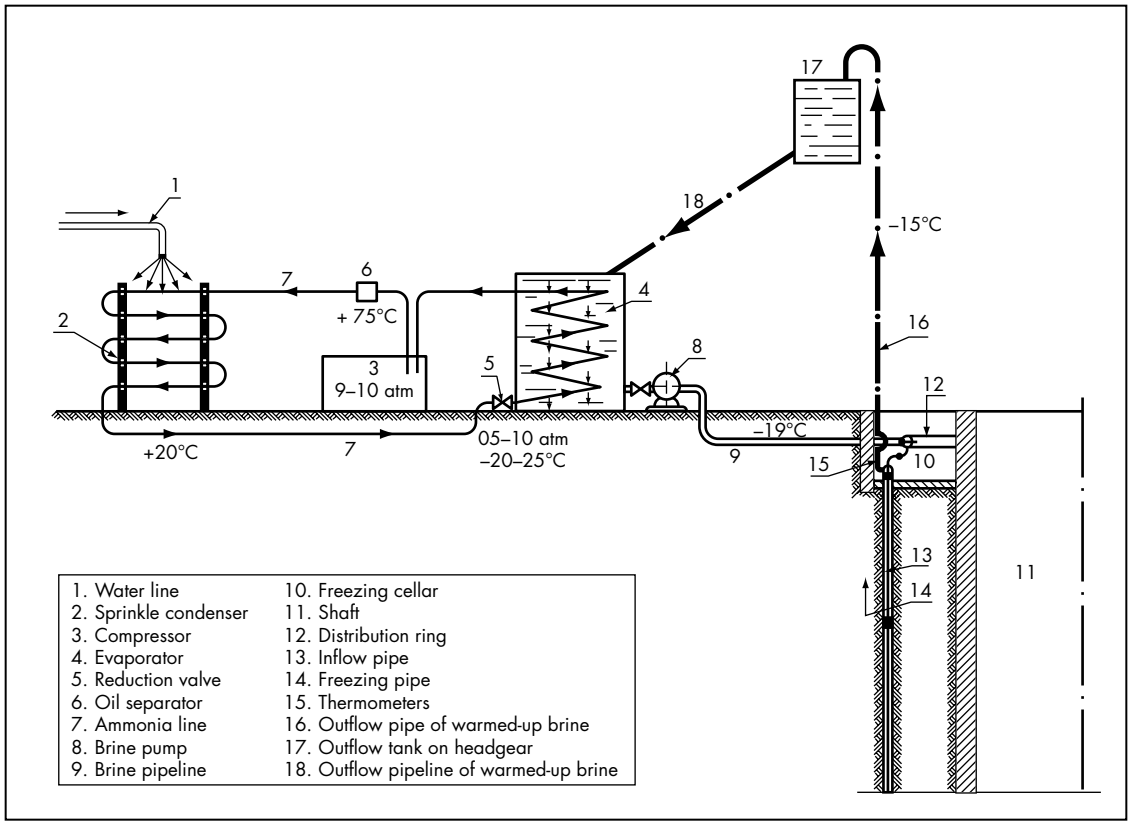
The cylinder of frozen rock, when properly created, allows the sinking of a shaft of moderate depth even in long sections using temporary lining. This is desirable because there are fewer seams between lining sections.

The most important problem during the drilling of freezing holes is to ensure verticality of holes. Every hole is equipped with two columns of tubing as follows:

1. **Outside:** The freezing pipe itself has a diameter of 102–152 mm and is constructed of steel with inside connectors so it is smooth on the outside and has a welded bottom.
2. **Inside:** The inner tubing has a smaller diameter of 32–51 mm, is made of steel or polyethylene pipe, and has inside diameter and wall thickness of 75 × 43 mm, respectively. Polyethylene pipes are used because they have several advantages over steel. They are cheaper and easier to install (by unwinding from a reel), have lower thermal conductivity, and the specific gravity of the pipe is close to the specific gravity of the brine, resulting in less suspended weight. Freezing brine flows at high velocity down the inner pipe. It rises more slowly in the annulus, absorbing heat from the surrounding rocks.

The collars of freezing holes with pipes connecting them with the distributing ring, shut-off valves, and thermometers are installed all together in a so-called freezing cellar. A freezing cellar is designated either as (1) temporary, to speed up construction time (it will be demolished when the permanent shaft headframe is installed); or (2) permanent, considered a part of the permanent shaft headframe, requiring a longer construction time.

Freezing media used as refrigerants are



- Ammonia (NH_3): Ensures a freezing temperature of –20°C with one stage and –40°C with two stages of compression, and is used in most cases.
- Carbon dioxide (CO_2): Provides a freezing temperature of –50°C.

A schematic of an ammonia freezing station is shown in Figure 12.4-8. Two main periods of freezing can be identified: the active period and the passive or maintaining period.

During the active period, a frozen collar of a predetermined thickness is created around the future shaft. To achieve the designed capacity of the freezing station, two or three aggregates are installed together to provide the required heat efficiency. During an active period, all units work at full capacity. The passive period starts after the frozen collar is created and lasts through the sinking, lining, and assembling of the shaft installations. During the passive period, usually only one unit works, while the others are on standby as a reserve.

Methods of excavation in frozen ground are similar to those under normal conditions; however, when explosives are used, special care is required because of the proximity of the freezing holes and the potential danger of their destruction. When the core of a shaft is not frozen, a cactus grab or other mechanical mucker can dig the shaft bottom. When the rock is partly frozen or too hard to be excavated, handheld drill hammers with chisel picks are used; however, these working conditions are very unhealthy. In hard-frozen rock, the drill-and-blast method is used with limitations. The *Hard Rock Miners Handbook* (de la Vergne 2009) provides some good examples of freezing calculations and "rules of thumb" for ground freezing, as shown in Table 12.4-3.

Shaft drilling. Shaft drilling is a commonly applied technique for the development of small-diameter ventilation shafts in the United States. It has also been applied with moderate

Source: Unrug 1992.

Figure 12.4-8 Ammonia freezing station

success in Australia. Shaft boring uses a mechanical borer similar to a large-diameter drill bit to excavate the shaft. A typical 4.25-m cutterhead is illustrated in Figure 12.4-9 and further details of shaft drilling technology including technical details on equipment, methods of shaft drilling, and some case studies are provided on the Shaft Drillers International Web site (n.d.).

Zeni and Maloney (2006) identify the following hazards with a conventional drill-and-blast shaft-sinking operation:

- Falling of persons
- Falling objects
- Methane and other gases
- Hoisting and communications failures
- Equipment operating in a small work area
- Respirable dust
- Water inundation
- Back injuries
- Ignitions in the shaft
- Concrete burns
- Blasting
- Escape in an emergency
- Noise

Zeni and Maloney also state that many of these hazards can be eliminated using blind boring of shafts, because blind boring is probably safer than conventional sinking. Shafts in the range of 4.3–4.9 m in diameter are routinely bored using this technology, with larger diameters achievable. The blind-boring machine is rotated from the surface using a rotary table. In addition, the shaft is also completely filled with a fluid such as water; therefore, the boring element is completely submerged. The cuttings from the boring operation can be lifted from the bottom of the shaft in a number of ways; however, hydraulic and airlift systems are most common.

The most common problem associated with blind drilling is lining the shaft. The most common lining for shafts fewer than 4.6 m in diameter is the use of steel linings placed from the surface with concrete or grout used to bind the lining with the rock by injection in the annulus between the steel and rock. Other techniques do exist and are discussed by Zeni and Maloney (2006). These include remote slipforming concrete, lightweight composite linings made from extruded fiber-reinforced polymer, lightweight concrete combined with steel or polymer, and totally waterproof cast-in-place concrete. The future of shaft drilling depends on technological advances in fabricating and installing linings remotely, which would avoid the need for humans to work in a shaft environment.

Another good example of the method is presented by Bessinger and Palm (2007) for the installation of a ventilation shaft at the San Juan coal mine in New Mexico (United States). The paper particularly discusses the options available for construction of the shaft, the reasons why boring was chosen, and a number of the technical aspects of the project such as collar construction, pilot-hole drilling, shaft reaming, lining installation, and fitting of the ventilation and escape hoist system.

Table 12.4-3 Rules of thumb for shaft sinking using ground freezing

• For a ground-freezing project, the lateral flow of subsurface groundwater in the formation to be frozen should not exceed 1 m/d. (Source: Khakinkov and Sliepcevich)
• To determine the diameter of a proposed circle of freeze pipes around a shaft collar, 60% should be added to the diameter of the proposed excavation. (Source: Sanger and Sayles)
• When ground freezing is employed for a shaft collar, the area of the proposed collar excavation (plan view) should not be greater than the area to remain inside the circle of pipes (area that is not to be excavated). (Source: B. Hornemann)
• The minimum practical thickness for a freeze wall is 1.2 m. (Source: Derek Maishman)
• The maximum practical thickness for a freeze wall with a single freeze circle is 5 m. Concentric circles of freeze pipes should be employed when a thicker freeze wall is required. (Source: Derek Maishman)
• The radiation (heat transfer) capacity of a freeze pipe containing brine may be assumed to be 165 kilocalories/m^2 of pipe surface. However, if the brine velocity is too slow (laminar flow), this capacity will be reduced by 40%. (Source: Jack de la Vergne)
• The capacity of the freeze plant selected for a ground-freezing project should be 2–2.5 times the capacity calculated from the radiation capacity of the total length of freeze pipes installed in the ground. (Source: Berndt Braun)
• Groundwater movements over 3 to 4 ft/d are significant in a ground-freezing operation. (Source: U.S. National Research Council)
• If the drill casing is left in the ground after installing the freeze pipes, it will cost more but the freeze pipes will be protected from blast damage or ground movement and the heat transfer will be increased due to the greater surface area of the steel casing. (Source: Jim Tucker)
• The heat gain from circulating brine is equal to the sum of the friction losses in the pipes plus the heat generated due to the mechanical efficiency of the brine pump. The value calculated for the heat gain should not exceed 10% of the refrigeration plant capacity. (Source: Jack de la Vergne)
• The amount of liquid nitrogen (LN) required to freeze overburden at a shaft collar is 1,000 lb LN/yd^3 of material to be frozen. (Source: Weng Jiaje)
• Due to the heat of hydration, the long-term strength of concrete poured against frozen ground will not be affected if the thickness exceeds 0.45 m. Below this thickness, designers will sometimes allow a skin of about 70 mm. (Source: Derek Maishman)
• Ground freezing with liquid nitrogen should only be considered for temporary or emergency conditions (1–2 weeks). For the longer term, conventional freezing with brine is less expensive. (Source: George Martin)
• The freezing method may be simply applied to a small problem by laying bags of solid carbon dioxide (dry ice) against the problem area and covering it with insulation. In this manner, ground may be frozen to a depth of up to 1.5 m. (Source: C.L. Ritter)
• When making the calculations required for ground freezing, it is necessary to have a value for the natural temperature of the ground. If this temperature is not available, the average or mean annual surface temperature at the project may be used for this value without sacrificing accuracy. (Source: Jack de la Vergne)
• The brine circuit employed for a ground-freezing operation requires a surge chamber. The best one consists of an elevated tank (open to the atmosphere) in a short tower. It provides simple visual observance of the pumping head and, if equipped with a sight gauge, gives precise changes in the volume of brine in the system and early notice if a leak should occur. Slight losses in brine volume will occur as it becomes colder (coefficient of volumetric thermal expansion is 0.00280 per degree Fahrenheit). (Source: Leo Rutten)
• When freezing a shaft collar with a conventional brine system, one can tell when the freeze wall cylinder has built up to the point of closure by noting a sudden rise of the water level in the pressure relief hole drilled in the center. Excavation may normally commence soon afterward, since the ground pressure against the freeze wall is smallest near the surface. (Source: Derek Maishman)
• When freezing a shaft collar with a conventional brine system, the freeze pipe headers must be bled of any air accumulation once a day. (Source: Leo Rutten)
• When freezing a shaft collar with a conventional brine system, thermometer instruments should be recalibrated once a week by inserting a thermocouple into a container filled with water and ice (temperature exactly equal to the freeze point of water). (Source: John Shuster)
• If the freeze wall does not close when calculated, the problem may be due to a flow of groundwater. If the return temperature of the brine from holes on opposite sides of the freeze circle is slightly higher than the average, there is very likely a significant lateral flow of groundwater. The elevation of this flow in the ground strata may be determined by stopping the brine flow to one or more of the "problem" freeze holes, waiting 2 hours, and then measuring the standing brine temperature at vertical intervals (usually 0.6 m). The water is flowing where the brine temperature is slightly higher than the rest of the measurements. If the return temperature of the brine from only one hole is higher than average, it can mean that groundwater is flowing from the bedrock where it is penetrated by the freeze pipe. In either case, the default remedy is to grout from holes drilled to the vicinity of the problem area(s). If the return temperature from one hole is lower than average, it usually means there is a short circuit in that hole. (The inner freeze pipe, usually plastic, was not installed to the bottom of the hole, or it has come apart at a splice.) The proof is to pull the inner freeze pipe from the hole so it can be measured and examined. (Source: Jack de la Vergne)
• When a liability rider is incorporated in the contract documents for a ground-freezing project, the contractor will often extend the ground-freezing cycle. For a shaft collar, this often means that the excavation will be frozen solid inside the freeze circle before releasing it for excavation. Although this procedure provides added safety, it increases the costs and delays the project because excavation is much more difficult in frozen ground than it is in a soft core. (Source: Derek Maishman)
• An acoustic instrument has been developed to measure the thickness of a freeze wall under construction. (The speed of sound is different in frozen and unfrozen ground.) This instrument is not reliable (and its use may lead to great confusion) unless it is employed by a single experienced operator and is properly calibrated before the freezing process begins on a particular project. (Source: Jack de la Vergne)

(continues)

Table 12.4-3 Rules of thumb for shaft sinking using ground freezing (continued)

- If a brine freeze plant does not cool to the expected final temperature [at least –250°C], the most likely causes in order of greatest frequency are as follows:

Cause	Remedy
Low level of refrigerant	Top up
Clogged water spray holes	Remove and clean piping over condenser
Oil buildup in refrigerant	Bleed off at bottom
Air in refrigerant	Bleed off at top
Vacuum feed to compressor	Adjust to positive feed
Faulty valves in brine line	Replace
Faulty expansion valve	Replace
Undersize brine mains	Replace
Oversize brine pump	Replace

(Source: Jack de la Vergne.)

- If the freeze wall ruptures during excavation of a shaft collar, it will occur near the bottom of the excavation. Normal practice is to immediately clear personnel and equipment from the bottom and dump a truckload(s) of fine gravel or coarse sand in the excavation to prevent further inflow of soil through the freeze wall. It is then typical practice to drill from the surface and chemical grout in the vicinity of the breach. Then drill and install another freeze hole in the vicinity of the breach to accelerate and reinforce its closure, after which the excavation may resume. The new freeze hole may be frozen with liquid nitrogen to minimize the delay. (Source: Leo Rutten)

- If a freeze wall rupture occurs in a section of the excavation that is in very compact granular soil, undisturbed glacial till, or in the bedrock, normally only water will flow into the excavation. In this case, it is typical procedure to allow the excavation to flood. When the level of the water in the shaft collar has peaked, ready-mix concrete is tremied or pumped down through the water to form a concrete pad on the bottom. After the concrete has set and sufficiently cured, the shaft collar is pumped dry and grout is injected through the pad. When the grouting is completed and the freeze wall restored, the pad is broken up and the excavation can safely resume. (Source: Jack de la Vergne)

WINZING

Winzing is the term for small-scale shaft sinking. Usually it is a form of internal mine development used, for example, to connect levels. Winzing has the following characteristics:

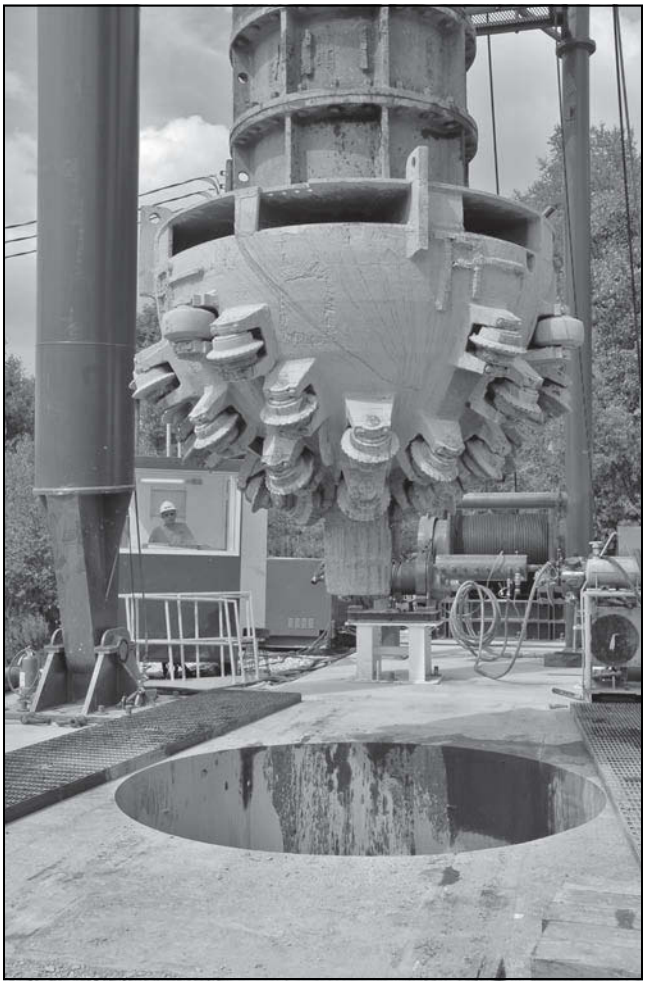
- Usually small diameter
- No room for mechanization, although in modern systems raise-boring machines can be used to develop winzes; however, most are still sunk by hand
- The possible range of sizes and depths are limited due to problems with muck removal
- Muck removal is usually by hand shoveling
- Use of pilot holes makes winzing easier as deviation can be avoided if levels are connected by a pilot hole
- Ventilation is highly important, but usually poorly done
- Secure ladders are essential for access
- Small winches are used for raising and lowering small kibbles
- Typically a bench cut is used
- Water can be a problem, but its impact can easily be overcome by using a pilot hole
- All services need to be removed prior to a blast (ventilation ducting, water pumps and hoses, compressed air lines)
- Hard physical work, especially in hot conditions
- Vacuum-lift devices have been used successfully for muck removal

Winzing is always a slower and more expensive undertaking than anticipated. In modern mining it is avoided wherever possible and raising is used in preference.

RAISING

A raise is a vertical or steeply inclined opening excavated from a lower level to a higher level (i.e., inverse winzing). The inclination is such that a ladder is required for passage. Raises are used to gain access to ore, as traveling and supply routes, and as ventilation routes. Raises are also used as orepasses, waste passes, or as slot raises to provide free faces for initial blasting of certain types of stopes.

Raises can be constructed through conventional raising, cage or gig raising, Alimak raising, longhole raising, and raise boring.



Conventional Raising

This method is restricted to shorter raises of up to 100 m in length and involves drilling and blasting using handheld drills. An important requirement in this type of raising is the provision of a working platform at the face to allow drilling and charging operations to occur. This platform is dismantled prior to blasting. Raising operations can be dangerous if correct procedures are not followed. The advantages of raising include the following:

- Raising is independent of mining production, so its input on current mine performance is minimal.
- Loading of muck into buckets is avoided.
- Blasting effectiveness is greater.
- No water pumping is required.

The disadvantages of raising include the following:

- The height of a raise is limited to between 100 and 120 m.
- Ladder climbing is an inconvenience for personnel and the transport of materials to the face.
- Potential hazards of rock falling from the face exist.
- Potential threats of muck jamming in the chute compartment exist.
- Surveying is difficult (deviation is possible).
- Time and cost implications are involved in preparing the opening for raising purposes.

Figure 12.4-9 Blind boring cutterhead

Cage or Gig Raising

Cage or gig raising is a mechanized raising technique and is illustrated in Figure 12.4-10. A pilot hole is drilled from the upper level to the lower level. A hoist rope is passed down the pilot hole and attached to a cage (or work platform) that can be raised or lowered in the raise to the face, allowing work to proceed as normal by hand methods.

Alimak Raising

Alimak raising is a development of cage raising using a rigid steel guide rail attached to one wall of the raise. No pilot hole is required and all the controls are mounted on the cage or at the base of the raise. The design of the system incorporates provision for air and water hoses, drilling equipment, blasting requirements, and accessories. Alimak raising has the capability of driving longer raises at faster rates than conventional methods.

The machine runs on a guide rail that incorporates a pin rack. The segmented guide rail is fastened to the side of the excavation with rock bolts. The Alimak method has the following advantages over conventional systems:

- It allows the driving of very long raises, vertical or inclined, straight or curved.
- When traveling to the head of the raise, personnel are well protected in a cage under the platform.

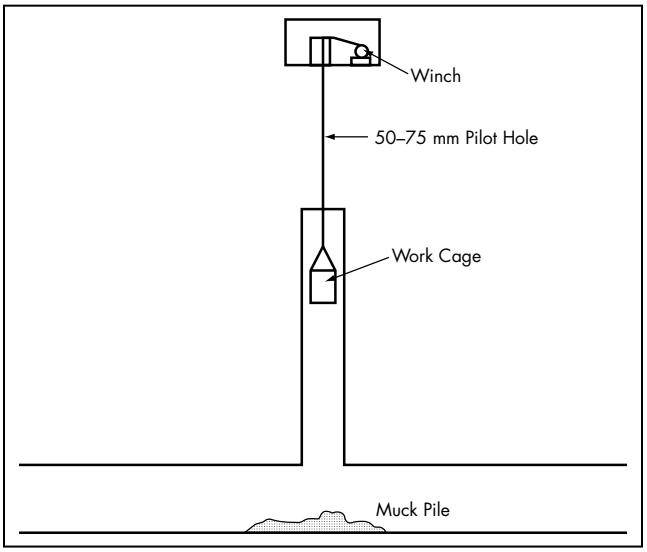

Figure 12.4-10 Cage or gig raising

- The miners work from a platform that is easily adjusted for convenient height and angle.
- Risks involving gases are reduced, as the raise is ventilated after blasting with an air–water mixture supplied in the raise climber.
- All equipment and material required can be taken to the head of the raise in the raise climber.
- Timbering is avoided, and if needed, rock bolts, with or without mesh, are used for support.
- The raise climber can be used for areas up to 8 m^2.

The disadvantage is the cost of the raise-climber system, which cannot be justified for short raises; therefore, the most frequent application is in mines where driving raises in hard rock is part of the mining method. The Australian Contract Mining Web site (2009) provides some excellent examples of the use of the Alimak climber as well as many images of Alimak climbers.

Longhole Raising

In this method all operations are undertaken from the top level. Long holes are drilled from the top level to the level at which the raise is to start. Holes need to be drilled accurately and can be reamed out. Charging is undertaken from the top level and blasting carried out in a similar manner to that used in vertical crater retreat mining. Figure 12.4-11 illustrates the longhole raise method.

Raise Boring

Raise boring is the most common method of raising in modern mining. It is a safe method for the driving of long raises, but it requires a high capital expenditure. Numerous methods of using raise borers are available such as blind-hole raising, pilot-hole methods, and so on.

Raise boring is one of the newest technologies in shafts and raises and has matured through improvements made during the decades since its initial application. Large-diameter holes or shafts can be drilled vertically or inclined. The costs of raise boring have been substantially reduced due to the improvement of cutters.

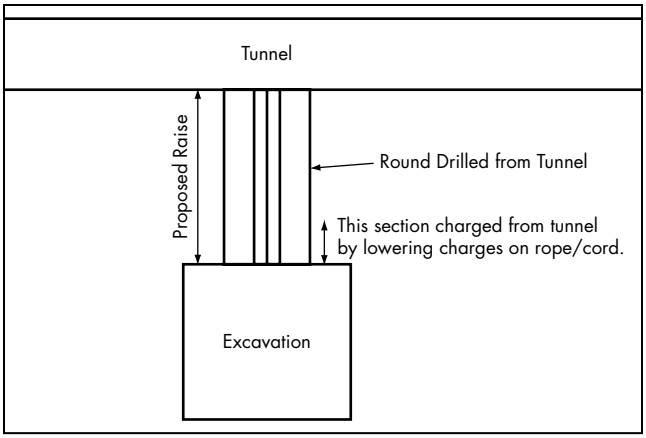

Figure 12.4-11 Longhole raising

Raises are used as a part of multilevel mining systems for orepasses and ventilation, as coal-mine ventilation shafts, and also as full-sized shafts, primarily in coal mining.

Excavating rock by a continuous boring system has several advantages over the conventional drill-and-blast methods, especially in vertical excavations such as shafts and raises, where it eliminates the hazards associated with the presence of workers at the face, similar to shaft boring. The continuous action of raise boring usually ensures faster completion of the project than conventional blast-and-drill methods. Boring does not disturb the surrounding rock, and as such, often there is no need for support or, alternatively, only minimum support is required for the finished excavation. A perfectly round shape makes the hole inherently stable, and its smooth walls reduce resistance for ventilation, as well as for the passage of ore with little prospect of hang-ups. Provided conditions are amenable, the cost advantage over other systems is clearly apparent for long raises and for shafts.

The disadvantages of a continuous boring system include a general requirement that rock conditions be similar along the length of the raise bore. Another disadvantage is that drilling in very hard rock is slow, and costs rapidly increase. Also, access to upper and lower levels is necessary. A raise-bored rock mass is preferably dry. The initial cost of the drilling rig is also high.

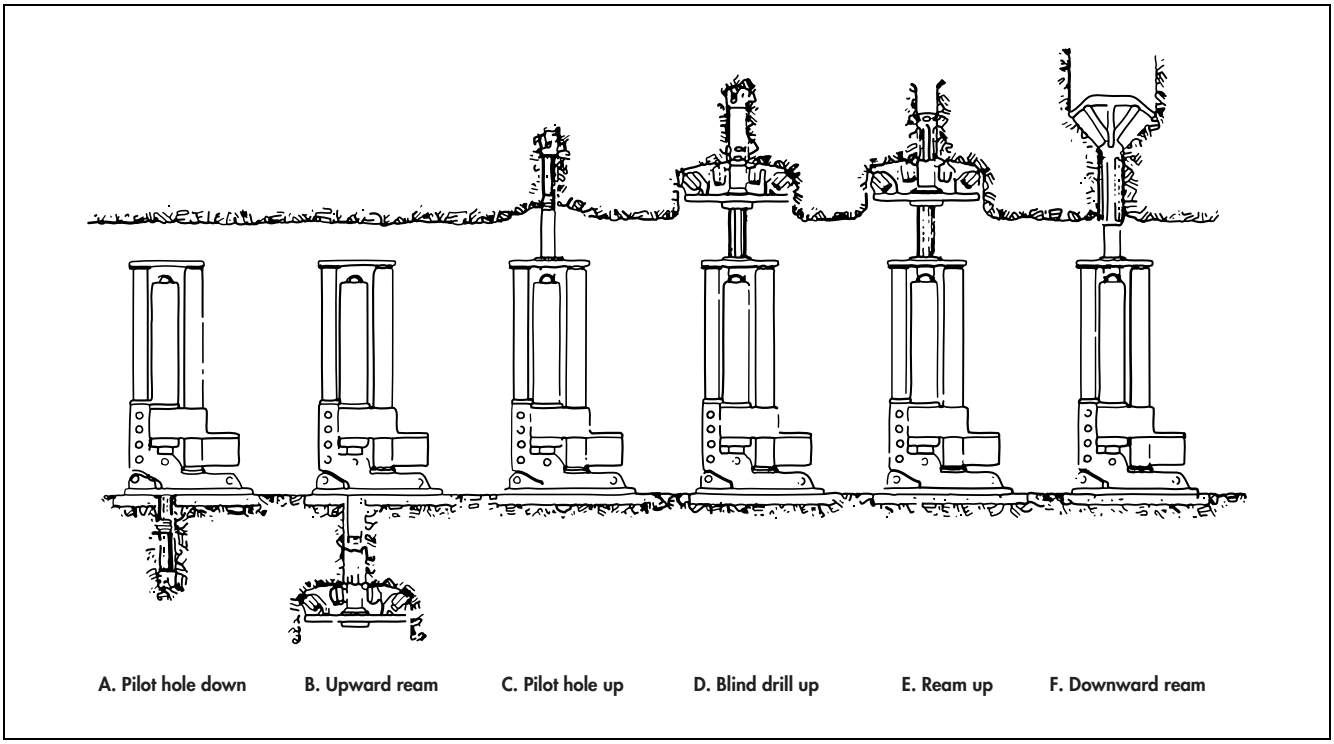
A large variety of machines are available that are designed for certain sets of rock conditions and nominal sizes and lengths of the finished hole. Typical characteristics of the machine specify the pilot-hole diameter, drill-pipe diameter, reaming torque, type of drive (AC, DC, or hydraulic), its rpm and power (hp or kW), and type of gear reducer. Additional specifications are the pilot-hole thrust and feed rates, reaming pull, size of drill pipe, base plate and derrick dimensions with characteristics (especially important for underground application), the type of transporter/erector, if applicable, and the water and air consumption.

Raise-boring machines operate on the principle of first drilling a small pilot hole and then reaming the hole, in one or more stages, to the desired size. The modes of operation are shown in Figure 12.4-12. The most frequently used is a conventional scheme with the pilot hole down and reaming upward. However, in some mining systems, box-hole drilling upward in one stage is chosen.

The raise-boring machine consists of several parts. The rig is composed of a rigid plate and a structure on which are assembled drilling, hydraulic, and electrical equipment. The rig has its own crawler driven by compressed air, or it is mounted on rail wheels for haulage. The rig can also be disassembled and transported. A pilot hole is drilled through the stem with stabilizers and a conventional drilling bit.

Stabilizers are used to ensure directional accuracy of the pilot hole. Several types are in common use. They are of a larger diameter than drill rods, with strips of tungsten carbide welded vertically or spirally on the outside, bringing the outer dimension close to the hole diameter. These stabilizers are used for reaming up. Other types, for pilot holes and reaming down, have more clearance, allowing cuttings to pass.

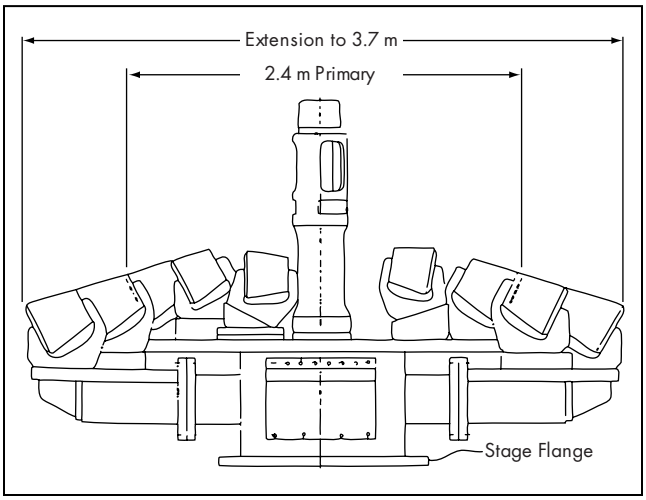
After the pilot hole penetrates to the target opening, the pilot bit and stabilizer are removed. The stabilizer is mounted on the drill stem and the reamer is put in the place of the small pilot-hole bit. Starting the hole (collaring) is a critical operation, and damage to the cutters or bit body can occur because of the uneven surface. The tension on the stem has to be adjusted to allow starting the hole without highly variable, dynamic loads acting on the drilling components. The stem is the longest at this stage of drilling and is, therefore, prone to maximum elongation and twist. The design of the reamer depends on the final size of the hole and the number of reaming stages.



In the past, the primary body of the reamer was often supplemented with stages mounted below, resulting in a "Christmas tree"-shaped tool, as illustrated in Figure 12.4-13. Because of large torque requirements, this system is presently used only for shaft-sized holes, together with large nonrotating stabilizers. In another configuration, extensions are attached to the primary body. By doing this, an increase of the final diameter is achieved by adding more cutters in the same planes as the cutters on the primary body itself.

The accepted measure of drilling performance is the rate of penetration, which depends primarily on bit design. The cutting action has to match the rock properties to optimize the drilling rate. During the reaming operation, in addition to the cutters, the design of the reaming head also influences the raise-boring performance. If no other source of information is available, an analysis of the wear of cutters can help in the design of an improved cutting structure. Independent variables when drilling are rock properties, which are usually characterized by compressive, tensile (indirect), and shear-strength measurements.

One of the most important technological aspects of boring is the removal of cuttings. Standard drilling technology with compressed air, air and foam, or drilling fluid is used for cuttings removal during pilot holing. During the reaming operation, cuttings simply fall down the hole.



The access point usually determines whether to drill raises from the top or bottom. If only one end of the raise has adequate room, the machine must be put there. The extent to which raise boring will interfere with production must also be evaluated. Locating the borer where fewer disturbances will be caused is preferred. Cost is also of major concern. Generally, drilling down and reaming up is cheaper than other configurations. Rock quality and its predicted response to drilling can influence the choice of direction as well.

In strong rocks without fractures, usually no support or lining is needed. If support is required, shotcrete, rock bolts (with or without wire mesh), or steel lining can be applied. Shotcrete can be placed remotely or by workers from a cage.

Source: Unrug 1992.

Figure 12.4-12 Typical modes of operation for raise boring

Source: Unrug 1992.

Figure 12.4-13 Raise head with extensions

Rock bolts must be installed manually. Steel lining, required in unstable formations, is installed remotely, directly behind the reamer.

Table 12.4-4 compares the factors that influence the selection of vertical/subvertical construction methods used in mining.

DECLINES

A decline is an inclined tunnel from a higher level to a lower level, usually but not necessarily from the surface. The purpose of declines is to access ore bodies or coal seams and provide use at a later stage as haulage routes. In coal mining, declines are known as drifts. These either provide access from the surface or from seam to seam; in the latter case they are known as cross-measure drifts. Drifts in coal mining operations can be driven at steep grades, up to 1 in 2.5 (40%), as the predominant mode of haulage of coal is by belt conveyor, which can handle such steep grades. Steep grades shorten the length of the drift, saving costs and giving early access to the coal seam(s).

In metalliferous mining, declines also allow access and may be used for truck haulage. Grades of 1 in 7 (14%) are common; however, steeper grades are possible in modern mining as more powerful underground trucks continue to develop. Various cutoff depths for declines can be found in mining literature as shown in Table 12.4-5. Beyond these depths, shaft systems should be employed. Over the years, the economic cutoff depth for declines has increased; for individual mines, the cutoff depth of declines is a purely economic decision and should be treated as such (McCarthy and Livingstone 2009). Medhurst (2001) shows that other factors also need to be considered in the determination of a cutoff depth including advances in technology such as the development of larger underground haul trucks, production rate, proposed mine life, potential for mine life being increased, and ventilation flow. Tables 12.4-6 and 12.4-7 compare and contrast decline and shaft access.

Declines are excavated and supported in a similar manner to horizontal tunnels, but drainage may require more attention. Details of tunneling techniques applied are described in the following sections.

TUNNELING

After the site of the surface connection(s) has been selected, the sites of tunnels or drives are often limited by the position

Table 12.4-4 Comparison of factors influencing the selection of vertical and subvertical construction methods

Factor Influencing Selection	Blind Shaft Borer	Blind Drilling	Raise Drilling	Vertical V-Mole	Conventional Shaft Sinking
Design Considerations					
Safety	Uses underground operators working under cover and behind shields. No operation of large moving equipment required.	Does not require miners to work underground	Only requires underground labor setup and mucking. No labor required in the shaft prior to shaft lining.	System uses underground operators working in a controlled environment. Considered safer than conventional shaft sinking as operators are located remotely from the working face.	Requires equipment operation in confined environment. Considered to be the most dangerous of the five shaft construction methods.
Shaft size	Depth is limited by skip-hoist rope capacity.	Limited by required depth, available equipment, and cost. Drilled shaft diameters range from well size to 20+ ft.	Nominally limited by available machine torque. Short (300-ft) shafts have been raised at 20-ft diameter.	Limited by available equipment from 16 to 23 ft in diameter.	Required to be larger than 10–12 ft for most applications. Upper limit not controlled by method.
Shaft depth	Depth is limited by skip-hoist rope capacity.	Limited by required diameter, available equipment, and cost.	Raise depths up to 3,200 ft have been reported.	—	—
Shaft verticality	Verticality can be controlled within extremely tight tolerances. Equal to or better than conventional.	Deviation can be estimated from geological data. Difficult to maintain an absolutely vertical shaft in subvertical structure. Suggested tolerance for design purposes = 0.25°–0.5°.	Shaft verticality is controlled by pilot borehole. Pilot-hole accuracy controlled by directional survey and careful drilling practice. Design tolerance should be specified based on use requirements.	Shaft verticality is controlled by pilot hole. However, offset reaming can be controlled by the operator providing additional control when following a deviated pilot borehole.	Verticality can be controlled within extremely tight tolerances. The most accurate shaft construction method with regard to verticality.
Ground disturbance	Minimal mechanical disturbance of shaft wallrock.	Provides minimal mechanical disturbance of shaft wallrock.	Provides minimal mechanical disturbance of shaft wallrock.	Provides minimal mechanical disturbance of shaft wallrock.	Conventional (drill-and-blast) excavation can result in deep-seated blast damage.
Timing/ schedule	Setup time is 1 month or more. Advance rate should be between 20 and 40 fpd. In general, muck haulage and lining limit advance.	Typically much faster than conventional shaft construction methods.	Reaming range from 15 fph (5-ft dia.), 3 fph (10-ft dia.), to 1 fph (15-ft dia.).	Reported rates between 30 fpd (16-ft dia.) and 60 fpd (23-ft dia.).	Generally restricted to one round per shift (e.g., 1 fph).
Operational Considerations					
Groundwater	Same techniques as conventional sinking.	Method provides superior control of groundwater during excavation.	Groundwater controlled by pretreatment where necessary.	Large projected inflows require pretreatment (e.g., using grouting or freezing).	Large projected inflows require pretreatment (e.g., using grouting or freezing).
Support during excavation	Temporary or final support can be installed a short distance behind advancing face.	Support provided by hydraulic pressure and impermeable polymer skin permitting excavation in very poor ground conditions.	Not possible.	Temporary/final support can be installed a short distance behind advancing face.	Temporary/final support can be installed a short distance behind advancing face.
Final lining	Installed during excavation.	Steel/concrete composite lining typically used in weak ground. May incorporate bitumen layer for groundwater control and be designed for full hydrostatic, bituastatic, or lithostatic loading conditions.	None is usually required. Many rapid lining systems available	Final lining may be installed during excavation.	Final lining may be installed during excavation.
Miscellaneous	—	—	Requires existing underground access.	Requires existing underground access.	—
Other Considerations					
Shaft outfitting	—	If a final steel lining is installed, considerable time can be saved through surface installation of guides, brackets, and pipes. All furnishings can be aligned prior to welding to the downhole liner assembly.	Pilot-hole deviation usually prevents raises from being used for worker or materials winding.	Outfitting in line with excavation and final lining if required.	Outfitting in line with excavation and final lining if required.
Initial costs	—	High	Medium	High	Low
Operating costs	—	Medium	Medium	Medium	High

Table 12.4-5 Cutoff depths for declines compared to shafts over time

Maximum Decline Depth, m	Comments	Source
350	Average value	Northgate and Barnes (1973)
500	Based on a maximum haul length of 3,500 with a 1 in 7 (14%) gradient	Thomas (1978)
1,000	Average value	Medhurst (2001)
1,400	Stawell gold mine, Victoria, Australia	Atlas Copco (2008)

Table 12.4-6 Shaft/decline impact on mining operations

Operation	Decline Truck Haulage	Shaft Hoisting
Truck haulage	• Direct to surface • Long haulage cycles from depth • Expanding fleet size • Rising insurance for fleet • Increasing fleet maintenance	• Underground haulage to shaft • Additional trucking or conveying at surface • Shorter underground haulage cycles
Ore fragmentation	• Popping of oversize at surface	• Stope firing to suit hoisting systems • Underground crusher and/or grizzlies required to limit ore size at shaft loading station
Decline	• Increasing decline congestion for haulage access • Increasing road maintenance in decline	• No decline haulage between the shaft production level and the surface
Production shaft and underground crusher	• Continued surface crusher operation	• Hoisting system operation and maintenance • Underground crushing station operation and maintenance (if applicable) • Fixed plant insurances required
Workshops	• All truck servicing at surface workshops • Surface refueling for trucks generally	• Routine truck servicing underground • Truck refueling underground • Major truck service/overhaul on the surface
Site crew	• Increasing crew size for drivers, service staff, grader operation, support staff, and management • Expanding fly in/fly out routine	• Crushing and hoisting system maintenance staff required • Overall smaller site crew
Change of shift	• Inefficient shift change with large truck fleet and long haulage cycle times (approximately 1-hour cycle from 800-m depth)	• Organized crew transport for shift change of underground truck and maintenance staff
Energy source and greenhouse effect	• Diesel fuel required for haulage (generally) • Increasing fuel usage with depth (30%–50% higher than fixed plant)	• Hoisting system may be supplied from the grid (if available) • Remote power plant may use diesel fuel or natural gas • Overall lower energy use
Operating costs	• Haulage costs increase steadily as depth increases • Higher cutoff grades required for economic mining	• Reduced total haulage/hoisting costs at depth • Lower grades may be mined economically, extending reserves and mine life • Deferral of costs associated with mine closure
Health and safety	• Increased risk of truck fires in decline	• Safety systems and procedures required to ensure safe operations and maintenance in production shaft

of the ore body in relation to the surface connection(s). If choice is available, the most competent ground should be chosen. As with surface connections, the drive size is determined by duties such as ventilation, access, haulage, and so on. Another prime consideration is the mining method, as this controls the size of mining equipment required.

In modern mining, drives smaller than 2×2 m are not common. A 2×2 m drive will accommodate a small loader and allows easy passage for people. Medium-sized drives have a cross-sectional area in the range 10–25 m^2 and represent the most common size range of mining drives. Such drives can accommodate locomotives, conveyors, and rope haulage systems as well as allowing ventilation flow and access.

From a mining viewpoint, large drives lie in the range 25–40 m^2. This drive size is becoming increasingly popular, especially in mines employing trackless equipment and mines employing decline access. This drive-size range allows for the use of off-highway trucks and other larger items of trackless equipment.

Drives have a limited range of sizes due to the need to maintain a level floor for haulage and access reasons. Common shapes are square, rectangular, and arched. Arched roofs have better strength characteristics than square or rectangular cross sections; they are used for drives where long-term stability is required. Square and rectangular section drives are very popular in mining, especially in areas of competent ground or in production areas where the drives have a limited life span.

Two methods of excavation exist: traditional drill-and-blast and mechanized methods (which are described in subsequent sections). Drill-and-blasting is a cyclical operation, whereas mechanical methods offer a more continuous system of excavation.

Table 12.4-7 Shaft/decline impact on mine infrastructure

Infrastructure	Decline Truck Haulage	Shaft Hoisting
Truck fleet	• Larger truck fleet for decline haulage at depth • Upgraded truck capacity (subject to decline limitation) • Surface haulage fleet (optional)	• Modest truck fleet for underground haulage to shaft • Surface fleet for haulage from shaft to plant (if required)
Mechanized ore handling	• Continued use of surface crushing and conveying facilities	• Introduction of hoisting system, underground crushing, ore bins, and associated plant • Local mine development to integrate with shaft
Mine ventilation	• Expansion of mine ventilation for decline haulage from depth	• Hoisting shaft acts as main airway from surface • Reduced ventilation demand
Decline	• Additional passing bays and/or duplication of the decline to address decline congestion • Upgrade to traffic control system in the decline • Upgrade decline fire protection and associated refuge bays	• No significant impact
Workshop	• Upgrade/expansion of surface workshops to suit larger truck fleet • Increasing inventory of truck spares	• Expansion of underground workshops • Upgrade electrical maintenance facilities
Power supply	• Upgrade for ventilation fans and surface facilities	• Upgrade for demand of winder drive, underground crusher, and associated conveyor drives
Fuel	• Upgrade diesel storage for truck fleet • Expand fleet refueling bays for larger truck fleet	• Upgrade fuel storage for power station demand (if applicable) • Provide underground fuel storage and refueling bays
Water supply	• Upgrade for larger crew and truck fleet, and reticulation for decline fire protection	• Upgrade underground water reticulation for maintenance, sprays, and deluge systems
Second means of egress	• Extend/upgrade emergency egress facilities at depth	• Hoisting shaft provides emergency egress above loading station
Surface facilities	• Upgrade/extend due to larger crew	• Minimal upgrade
Underground services: rising mains, raw water, potable water, power cable(s), fiber-optic cable, leaky feeder, blasting control cable	• Route mechanical and electrical services via the decline and/or boreholes • Establish rising mains in boreholes	• Most services can be routed directly via the hoisting shaft
Mine control	• Mine operations generally controlled from surface	• Main control center usually located at winder house with unstaffed satellite stations underground

Drilling and Blasting

The majority of mining drives are excavated by traditional drill-and-blast; however, mechanical mining is becoming much more popular outside its traditional area of coal and other soft-rock mining. Drilling can be done by hand using air legs. The number of air legs in use will depend on the drive size (e.g., in a 2×2 m drive, only one drilling machine can be accommodated). In larger drives, drilling is mostly undertaken using mechanized drill jumbos with twin or three booms common. The most common form of drill jumbo is electrohydraulic, but other forms of power are used. In dry holes, ANFO (ammonium nitrate and fuel oil) is the most commonly applied explosive, whereas in wet holes, explosive emulsions or slurries are increasingly being used. Figure 12.4-14 shows the basic cycle of operations for a typical drill-and-blast tunnel.

A good example of a typical cycle of operations is provided by Argyle Diamonds (2007). Argyle is developing a new block cave operation to mine diamonds in Australia. The cycle of operations during the mine development prior to establishing caving uses typical drill-and-blast tunneling, with one of the key design elements being that at no time does the work force work under an unsupported roof, a common element in Australian mining. For each heading under development, the cycle takes about 18 hours to complete for a nominal face advance of 4 m/cycle and an average heading advance rate of 32 m/week.

In small drives, mucking may be carried out by hand, shoveling into mine cars. This is really only a viable method when cheap labor is available. In the past, rail-mounted shovel loaders were used extensively. These were almost universally powered by compressed air and operated as a front-end loader, "slinging" the muck over the body of the loader into mine cars located behind. Generally, bucket capacity was limited to 0.5 m^3.

The real revolution in mucking operations came with the development of rubber-tired loaders, which lead to the development of load-haul-dump units (LHDs). The advantage of these units is their mobility and flexibility. Bucket sizes vary from 1 to 10 m^3; the size selected depends on drive dimensions and production rate required. Motive power is either by diesel engine or in some cases electrical power (either battery or trailing cable). LHDs have a limited economic hauling distance range; if haul distances become too large, a more economic intervening haulage system such as trucks needs to be added between the LHD and the transfer point to the main mine haulage system. Numerous other methods of mucking also exist such as front-end loaders and gathering-arm loaders.

Numerous methods of haulage exist. In small drives, hand tramming of mine cars may be used. Other commonly applied methods include the following:

- Locomotive (rail) haulage: Motive power can be provided in numerous ways such as diesel engine, battery locomotive, electric trolley wire systems, or rope haulage.
- LHD with or without truck.
- Shuttle cars with or without trucks/conveyor.
- Belt conveyor.

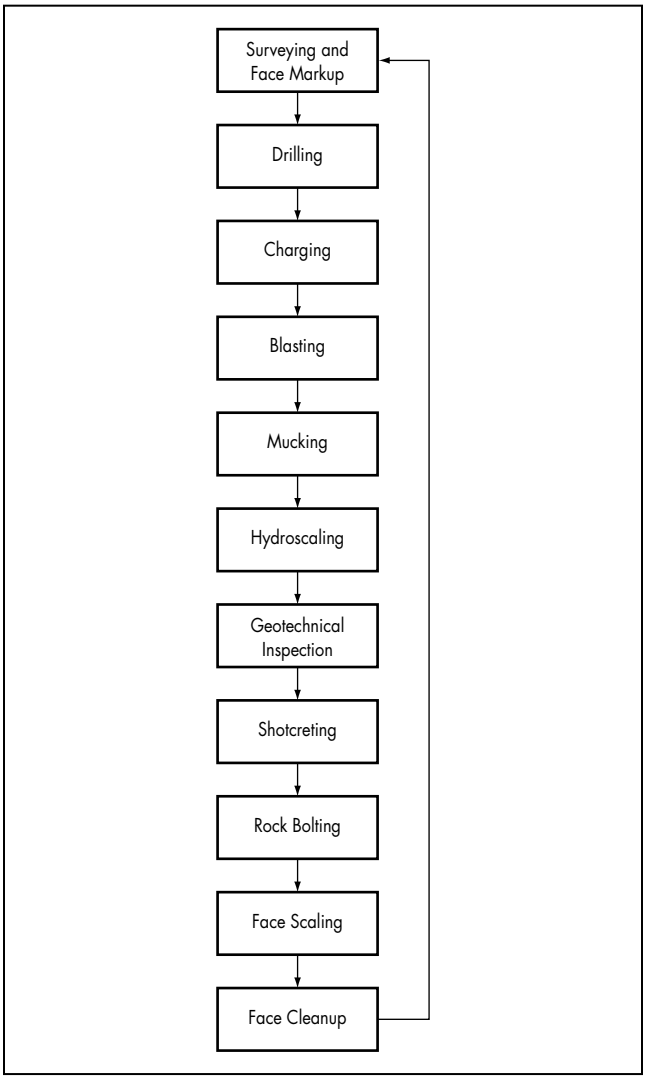

Figure 12.4-14 Basic tasks in drill-and-blast tunneling

Several methods of support are possible; the support required depends on local conditions. The main methods of support include

- Rock bolts,
- Cable bolts,
- Steel sets,
- Timber sets,
- Shotcrete,
- Concrete,
- Combinations of methods,
- Mechanical shields, and
- Natural support.

To design a drive blast, the method outlined by Persson et al. (1994) can be employed. The method can be broadly summarized as follows:

- Determination of the burden and spacing for the cut holes, to provide the relief space required such that the main blast does not freeze, for both angled and parallel hole cuts
- Determination of the burden and spacing for the main blastholes or production holes, also called easers, for the holes that blast downward and sideways into the cut area
- Determination of the burden and spacing for the main blastholes or production holes, also called easers, for the holes that blast upward into the cut area
- Spacing of the trimming or perimeter holes in the backs and sides of the tunnel for both conventional and/or perimeter blasting
- Spacing of the lifter or floor holes

Mechanized Tunneling

Three basic rapid mechanical tunneling systems exist: full-face tunnel boring, mobile miners, and roadheaders or boom-type machines.

Full-Face Tunnel Boring Systems

Full-face boring systems, or tunnel boring machines (TBMs), have been in common use in civil tunneling for many years but are used less frequently in mining projects. Nevertheless, TBMs are viable for mine development. Some good examples of TBM application and other mechanized tunneling techniques are shown in the video *The Burrowers* (Harris 1994).

Constant development and improved tooling have resulted in machines that are capable of advancing large-diameter openings in strong igneous and metamorphic formations at rates that compete favorably, and in many cases exceed, conventional drill-and-blast methods. In addition to high advance rates, TBMs leave a smooth profile, and usually minimal ground support is required. A disadvantage of TBMs is their wide turning circle, although a range of mini-full-face machines are available that have smaller turning radii. The high initial cost of these machines is balanced by low running costs compared to drill-and-blast excavation systems.

Full-face boring machines consist of a rotating cutting head fitted with disk cutters, drag bits, button bits, or various combinations of these. Advanced machines are available on which the tool type can be changed and tool spacing varied. The cutting head may be an open structure with spoke-like cutting arms, or it may completely conceal the face except for muck-removal openings and accessways for tool maintenance. The open-type head gives better access to the face and tools, and can be used with a forepoling arrangement. Cutting forces are provided by the head rotation, whereas normal forces are provided by the thrust of the machine against the tunnel face. Reaction to this thrust is provided by grippers mounted on the TBM body, which in turn react against the tunnel sidewalls. Mucking is performed by buckets mounted on the periphery of the cutterhead, and muck is removed via a central conveyor system.

Preparations for TBM excavation typically involve construction of a portal, placement of a concrete pad on which the TBM is assembled, and installation of support services and equipment as shown in Figure 12.4-15. Careful excavation, including the use of controlled blasting techniques, is usually required to mine the setup area to the tight tolerances required. Placement of a thin concrete layer against the start-up face is recommended to reduce out-of-balance loads.

TBM excavation is a continuous process, with cutting, mucking, and support installation proceeding concurrently. As the cutting head rotates, it moves forward, reacting against the grippers. The grippers are repositioned periodically when they reach the limit of their travel. The grippers are also used to steer the machine in some cases; in others, a floating main

Courtesy of The Robbins Company.
Figure 12.4-15 Tunnel boring machine

beam is used to steer while boring. Mucking in the immediate vicinity of the face is done by buckets located on the head periphery, and a central conveyor system moves the muck through the body of the machine to a bridge conveyor. When the rock is wet or where water inflow is a problem, earth pressure balance systems are used and the muck is removed in a coagulated form in a batch process. The bridge conveyor allows access for track laying and service installation without disrupting the mucking operation. A variety of mucking systems can be used to haul muck to the surface, but usually conveyors or shuttle trains are used. Adequate muck removal rates are critical to optimum face advance rates.

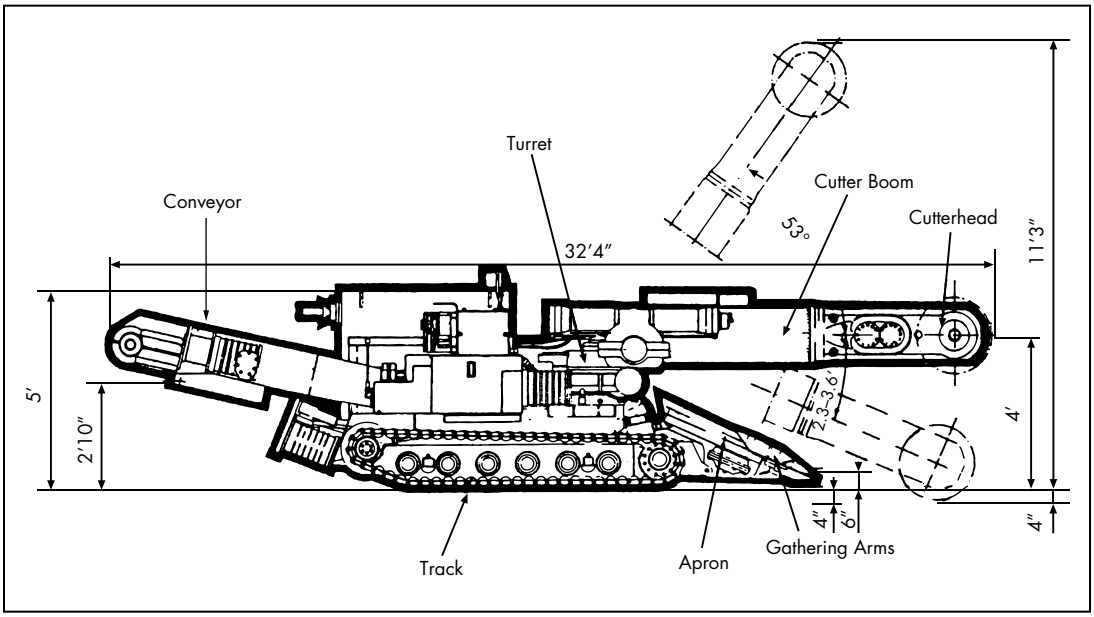
Rock support requirements for hard-rock TBM drives are generally minimal, and estimates have suggested that the savings in rock support costs (compared to drill-and-blast) can offset the cost of the machine in as little as 7 km of tunnel. Hard-rock TBMs are commonly equipped with a partial or slotted shield, and when support is required, conventional rock-support methods are used. Both soft-rock and hard-rock TBMs can be equipped with a full shield and segmental linings installed. This equipment enables hard-rock TBMs to cope with localized occurrences of soft ground.

Mobile Miners

Mobile miners are continuous hard-rock mining machines. A prototype Robbins mobile miner was used in 1984 for the development of a 1,150-m decline at Mt. Isa in Australia. Advance rates of 3.66 m/shift were attained mining a decline 3.66-m-high × 6.4-m-wide section through high-strength quartzite (Boyd 1987).

Roadheaders

Roadheaders have been used in mining and tunneling for a number of years. They are known by a number of names including boom headers, boom-type tunneling machines, and selective tunneling machines. Figure 12.4-16 shows commonly used terminology for the various machine components.



Originally developed as a means of advancing roadways in underground coal mines, early roadheaders were limited to cutting relatively low-strength strata. Development of these machines has greatly extended the range of applications, and they are now used in a wide variety of mining and civil tunneling work. Improvements in cutterhead design and the increasing use of water-jet-assisted cutting will result in a further extension of the range of roadheader applications in the coming years.

Roadheaders offer a number of advantages over TBMs, chiefly related to flexibility. They can cut a variety of cross sections, limited only by the basic dimensions of the machine, and are able to cut tight curves or corners.

These machines also offer advantages over conventional drill-and-blast methods. One of the most important advantages of roadheaders is the avoidance of blast damage to the rock and the consequent savings in ground-support costs. In addition, because mechanical excavation is a continuous process, shift time is more effectively used.

Roadheader cutting assemblies consist of a cutterhead on a movable, hydraulically powered boom, mounted on a rotatable turret attached to a track-driven chassis. In addition to the cutterhead, the machine also incorporates either a gathering arm or chain conveyor mucking system to remove broken rock from the face. The machine may be controlled by an operator seated on the machine or located some distance away, inside a shield, or beneath a supported roof section. To improve machine stability during cutting, many machines are equipped with hydraulically powered steering rams that are used to brace the machine off the excavation sidewall.

Two types of cutterheads are available from several manufacturers and are interchangeable on specific machines. These heads are termed *transverse* (or "ripping") heads and *in-line* (or

Source: Breeds and Conway 1992.

Figure 12.4-16 Main components of a roadheader

"milling") heads. In-line heads rotate coaxially with the boom. These heads are best suited to cutting rock with an unconfined compressive strength of 80 MPa or less. In-line heads require less thrust when sumping, and the head shape allows greater selectivity in cutting specific beds or bands. Transverse heads rotate at right angles to the boom axis. Advances in cutter booms have resulted in machines equipped with telescopic booms, or booms with extended length for cutting high backs or crowns. Telescopic booms are useful for cutting on steep gradients or on weak floor materials where the thrust from the machine's travel system would not be adequate.

Roadheader face-mucking systems generally consist of an apron with either a scraper chain or gathering arm system. Without adequate mucking capacity, the face will become muck bound and excavation will be delayed. In low-strength formations in which high cutting rates are possible, the mucking system may become the limiting factor in controlling advance rates. Roadheader cutting booms are generally mounted on a custom chassis with track propulsion. Track dimensions control ground pressures and should be carefully assessed in conditions in which the invert rocks are weak or prone to slurrying.

In the local area around working roadheaders, high concentrations of airborne dust, generated during both cutting and transport of the muck, and high ambient temperatures commonly occur. In addition to exceeding statutory respirable dust limits, excessive dust may completely obscure the face, resulting in inefficient excavation and increased overbreak. High temperatures and humidity result in labor inefficiency and overheating of electrical motors. The use of water-jet-assisted cutting leads to a reduction in dust levels, but does not entirely eliminate the problem, and may actually increase humidity at the face.

One of the primary advantages of using a roadheader excavation system over drill-and-blast methods is the elimination of blast damage and the consequent savings in rock-support costs. All types of rock support can be adopted for use in conjunction with roadheaders. Because it can be relatively difficult to reverse a roadheader away from the face, the machine must be covered prior to shotcrete application.

CHAPTER 12.5

Subsurface Mine Development

Richard L. Bullock

INTRODUCTION

To prepare a deeply buried ore body for extraction by underground mining methods, the mine must be developed. This means driving all of the underground openings for entry into the mine as well as all of the openings needed for exploration, exploitation, and services for the mine. Many openings must be driven before the mine can begin production and many more ongoing openings must be progressed as the ore body is extracted. For some block caving mines, this means driving an average of as much as 25 km/yr (14 mpy). This chapter discusses the types of openings that must be developed, the purposes for developing them, what they are called, and how they relate to various mining methods.

A development in a hard-rock mine is any initial opening driven to provide an accessway anywhere in the mine. It may not necessarily be in the ore. Such accessways usually are driven as single openings and provide space for roads, ventilation, power, air and water lines, drainage, storage areas, shops, dump stations, offices, and so on. They also expose the ore so that stope exploitation can begin at the points of exposure. The term *development* implies only that there is an opening for some mine service or where production might begin.

In contrast, in coal mining the term *development* refers to that phase of the mining cycle during which multiple entries are advanced through a virgin seam, forming pillars by breaking crosscuts or breakthroughs between the entries. When the development has reached the extent of the advance, the coal-extraction process removes all or part of the pillar on the retreat, or a longwall panel is set up for the extraction. The only area of obvious similarity between the two meanings is where the development opens more extractable ore or coal.

All underground mining development openings can be classified into four categories:

1. To open production accessways
2. To obtain information
3. To construct service facilities
4. Combinations of the first three categories

For each development, decisions must be made pertaining to each of the five physical variables:

1. Length
2. Direction
3. Inclination
4. Size
5. Method of ground control

Each development must serve the purpose for which it is intended and usually named. Predevelopment studies should include a discounted cash-flow analysis and ensure that all elements of each alternative are included and are indeed comparable.

Spacing and Alignment of Development Excavations

There are other general rules for recommended or preferred location and direction of mine developments. The following is taken from the works of Spearing (1995) and has been distilled from many years working in South African deep mines. While it may be true that all of this information applies to rock under considerable stress, it applies equally to weaker ground under low to moderate stress.

These rules are based on the theory of stress concentrations around underground openings and the interaction of those stress concentrations. The usefulness of these guidelines has been proven by experience obtained underground. Stress interaction between excavations can obviously be controlled by an increase in the installed support, but costs will also increase significantly. If there is adequate available space, it is generally more cost-effective to limit stress interaction between excavations.

Flat and Vertical Development

In flat development, the spacing between two square cross-sectional openings is

- Spaced horizontally at three times the combined width of the excavations; and

Richard L. Bullock, Professor Emeritus, Mining & Nuclear Engineering, Missouri University of Science & Technology, Rolla, Missouri, USA

- Spaced vertically at three times the width of the smaller excavation, provided the area of the larger excavation is less than four times the area of the smaller.

The spacing between a rectangular cross section is

- Spaced horizontally at three times the combined maximum dimensions of the excavations; and
- Spaced vertically at three times the maximum dimension of the smaller excavation, provided the height-to-width ratio of either excavation does not exceed either 2:1 or 1:2.

The spacing between two circular cross-sectional openings is

- Spaced horizontally at three times the diameter of the larger excavation; and
- Spaced vertically at three times the diameter of the smaller excavation, provided the area of the excavation is less than four times the area of the smaller.

In vertical development (e.g., shafts and raises), the spacing of

- A square cross section is three times the combined widths of the excavation,
- A rectangular cross section is three times the combined diagonal dimensions of the excavations, and
- A circular cross section is three times the diameter of the larger excavation.

Successive Turnouts (Breakaways)

Multiple turnouts from a given intersection should be avoided to reduce dangerously large roof spans at intersections. The rule is that turnouts should be spaced at six times the width of the excavation between successive tangent points. (This rule does not apply to room-and-pillar stoping. In this case the roof spans are safely designed.) Acute turnouts (less than 45°) should be avoided because these result in pointed "bullnoses," which are unstable. Fracture and failure of a bullnose result in large, unsupported hanging wall spans. The breakaways for inclines are often brought too close to the connecting crosscut. The length of the connection between an incline and the flat drifts should be three times the diagonal dimension of the flat end.

Orientation of Adjacent Excavation Developments

The most highly stressed part of an excavation is the corner. Therefore, positioning a development such as a decline in an unfavorable orientation, too close to the corner of an adjacent opening, should be avoided.

Development Influenced by Geology

In all cases, the geology of the area should be taken into consideration in planning the development. Known weak geological horizons should be avoided even at the expense of longer developments. In permanent excavations (sumps, settlers, hoist chambers, etc.), the position of faults and the orientation of joint sets are critical to the stability of the development. Layouts must therefore cater to such geological features. All excavations should be kept away from high stress dikes where possible. When a dike is traversed, the most direct route should be used. Breakaways should not be sited in dikes, even at the expense of extra development. Haulages (drift opening) should not be positioned in fault zones, and development should not occur alongside a fault. A fault should always be intersected at an angle as near to 90° as possible.

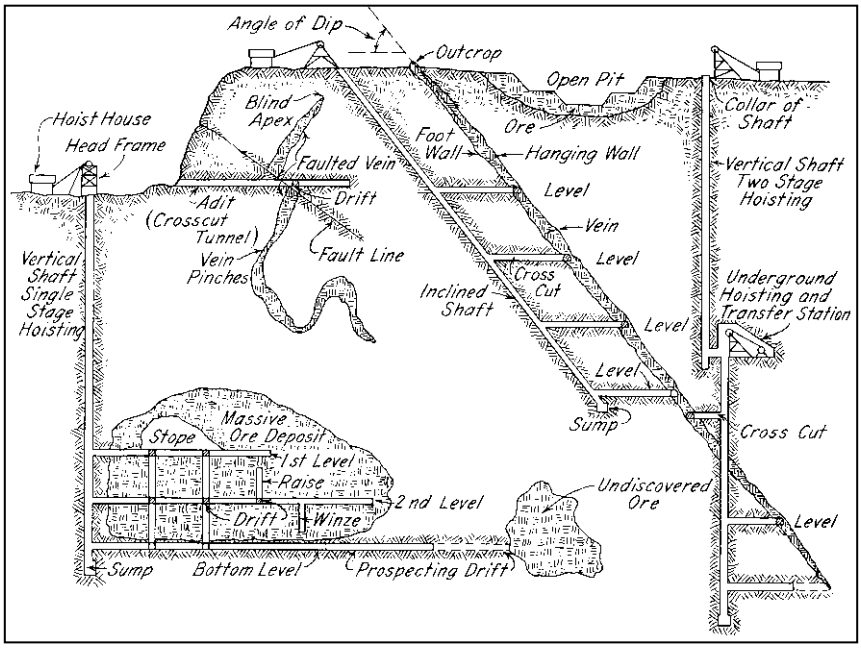
Development Influenced by Stress Condition

When haulages are positioned beneath mined-out areas, consideration should be given to the 45° destressing guideline. An overstoping angle of 45° is generally required to destress a haulage. At an angle greater than 45°, stress concentrations are higher. This rule applies to reefs of 0° to 20°. Dips greater than this often call for computer modeling to show the extent of overstoping needed. Haulages should not be laid out too close to remnant pillars, which are very highly stressed. Another case of this application is where the production level for block caving is developed beneath and well ahead of the extraction level to avoid the high-stress conditions that will come once the extraction level is opened.

OPENING PRODUCTION ACCESSWAYS

Initial Entry into the Underground Mine

Figure 12.5-1 shows various types of entries into an underground mine. The initial entry may be for further exploration, a test mine, production openings, or eventual service openings. The opening may be a drift entry (adit) into the side of a hill, a decline (slope), a vertical shaft, an incline shaft, or a multiple-stage hoisting shaft. The type of opening will depend on many factors: the purpose of the opening; the elevation of the terrain at the surface of the mine in relation to the elevation of the ore body; the type of ore body or shape of the ore body; how material, workers, and ore/waste will be moved in and out of the mine; the depth needed to eventually develop openings; and the mining method that will be used to exploit the ore. Each of the types of initial openings is discussed in the following subsections.



Drift Entry (Adit)

An adit, or drift entry, is the most economical approach when the extractable material is above the floor elevation of a nearby valley. Literally thousands of Appalachian room-and-pillar coal mines have been opened this way to mine coal seams exposed on the hillsides; these are known as "punch mines." Most of the early western-U.S. hard-rock mines used this type of development, as did most of the limestone and dolomite mines throughout the Missouri–Mississippi river basin. The exposed rock could be opened through horizontal adits into the sides of the mountain bluffs.

A few of the advantages of the drift entry are

- Mine drainage by gravity,
- Level or downhill haulage for mined material,
- Easy access for equipment in and out of the mine, and
- Rail haulage can be used if desired.

Adits are usually driven by drill-and-blast methods using trackless jumbos, rail-mounted jumbos, jackleg handheld drills, or with a mechanical excavation machine such as a tunnel boring machine (TBM) or roadheaders. The grade of the adit should be driven at a +2% to 3% grade for good drainage, but probably limited to +1% to 2% if rail haulage is to be used. Almost never should a drift be driven by drill-and-blast methods on a flat grade if the adit goes any significant length, because there is no way to drain it unless the water rises enough to top the roadbed. For nearly flat grades, laser-guided equipment should be used, and if there is a lot of water, it will likely be necessary to overexcavate the bottom, build a flume-type ditch (U-shaped) on the side, and build a roadbed up to the grade that is needed.

Source: Lewis and Clark 1964.

Figure 12.5-1 Underground mine showing names of mine openings

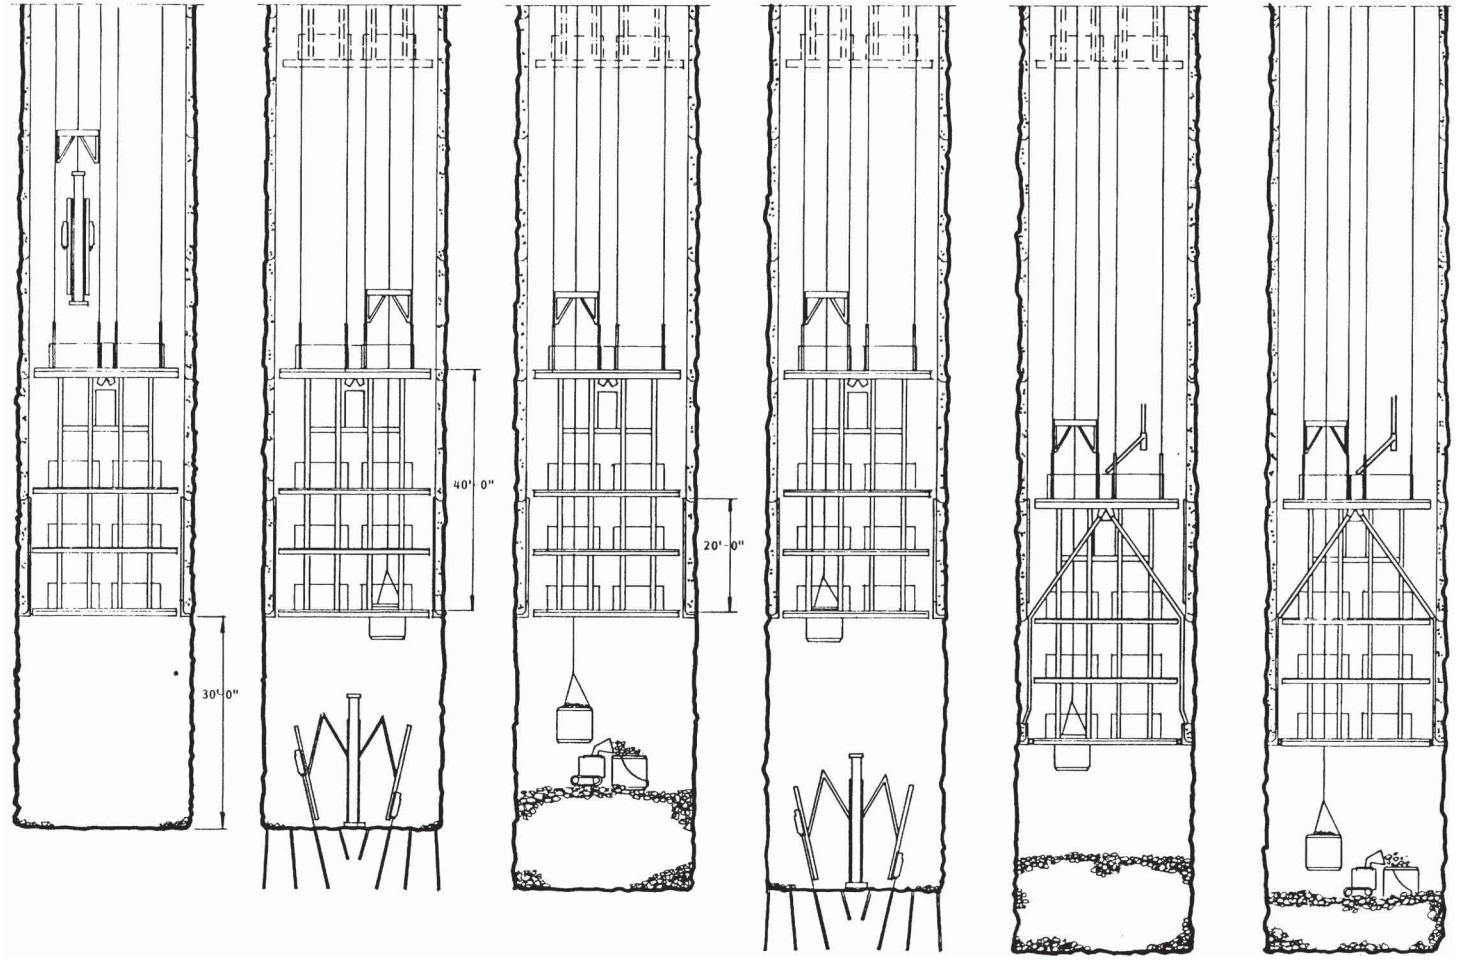
When the mineable material goes to a depth lower than the surrounding terrain, either a slope (decline) or a shaft must be developed. Many mines start out as adit mines and then a shaft is sunk or a decline is driven to exploit the lower portions of the ore body. The ore is then brought to the level of the adit, where it is hauled out of the mine. The same is true for ore lying above the adit. The shaft or ramp will be excavated above the adit and the material will be dropped down to adit level for haulage to the surface. Some refer to these as "upside down" mines. A few examples can be found at the Pine Creek tungsten mine (Bishop, California, United States), the El Soldado copper mine (Chile), and the Stillwater and East Boulder platinum mines (Montana, United States).

Decline (Slope) Entry

Again, there is a difference between what this development is called in hard-rock mining and coal mining: coal mines term such development as *slopes*, and these slopes usually contain a production conveyor belt; hard-rock miners call them *declines*, and unless it is a very high production mine, more than about 4,540 t/d (5,000 tpd), they probably will not contain a conveyor belt. Slopes/declines are usually limited to relatively shallow mines because for a given vertical depth, declines require approximately five to six times the linear distance compared to a shaft. Thus, to reach a depth of only 460 m (1,500 ft), an 18% slope would be approximately 2,540 m (8,333 ft) long.

The declines will normally be driven by using drill jumbos and trackless loaders and trucks. Roof bolting and shotcrete will normally be used for support. It is common practice to drive "muck bays" at regular intervals as the decline is being driven so the blasted round can be moved very quickly from the face to the muck bays, leaving the face available for another drill round sooner. The development muck can then be transferred to the surface while the next round is being drilled and charged. The usual distance between muck bays is about 120–180 m (400–600 ft). Declines can, in theory, be excavated by TBMs but rarely are.

There is an ongoing debate regarding what the proper decline grade for truck haulage should be. However, it depends on the length of the haul, power of the truck's engine, and drivetrain versus the size of the load and the surface condition of the decline. Normally, for good, efficient haulage, the truck should be able to maintain a speed of 12–13 km/h (7–8 mph) hauling a full load up the ramp. As an example, hauling a 48-t (53-ton) load up a straight, well-maintained road surface at 15% grade, a truck with a 485-W (650-hp) engine should be able to maintain 12 km/h (7 mph) for the full length of a 4-km (2.4-mi) decline. Many operators try to drive haulage declines at 18%–20% to save initial cost with a shorter decline, but this usually increases the operating cost by increasing the cycle time of the haul. This can be remedied by employing engines and drivetrains that are much more robust than those used for normal mine haulage. Many suppliers of haulage equipment today can supply the needed drivetrain for very steep grades, even for large-haul trucks.



Gradients steeper than 15% are not practical for main production areas due to difficulties maintaining the road surface to an adequate standard. The road surface tends to undulate and creep, particularly when wet. There are also issues with accelerated transmission wear on trucks.

The slope driven for conveyor-belt haulage for most crushed ore and coal can be up to 30°; however, if rubber-tired mobile equipment must also operate on the decline, this may limit the grade to less than 20% for safe operation.

The advantages and disadvantages of declines are discussed later in this chapter (see the "Slopes Versus Shafts" section).

Vertical Shaft Entry

In North America, for most deep hard-rock mines over 450 m (1,500 ft) deep, vertical shafts are still the preferred method of opening the mine for production. The purposes of vertical shafts

① Begin cycle.
Lower drill jumbo.

② Drill out and load round.
Raise stage 200 ft.
Clear shaft and blast.

③ Blow smoke.
Lower stage, EIMCO 630, and buckets.
Muck out.

④ Lower drill jumbo.
Drill out and load round.
Raise stage 200 ft.
Clear shaft and blast.

are distributed as: production, 22%; exploration and test mine development, 18%; service (including ventilation), 27%; and production and service combination, 33% (Dravo Corporation 1974). These proportions have probably not changed since the 1980s for North America. However, in Australia, where declines are used more than shafts for production, the primary use for vertical shafts is ventilation.

Basic design considerations. Like all underground openings, vertical shafts demand considerable study, planning, and design; indeed, this becomes even more important with shafts. The detailed engineering includes seven specific areas that must be considered:

1. **Size:** In the United States, shaft size varies from only 1.2 m (4 ft) to 8.5 m (28 ft), depending primarily on the purpose of the shaft.
2. **Configuration:** While most new shafts that are sunk from the surface today are circular, many older shafts and those sunk from underground are rectangular.
3. **Ground support:** For deepening old shafts, timber supports are still used. However, semimonolithic concrete lining is the most important shaft lining used today. Concrete linings have many advantages:
   - Good bond between the lining and the rock
   - Decreased labor intensity for permanent linings
   - High strength-resisting rock movement
   - In some cases, complete mechanization of lining placement

   The disadvantages of concrete linings are
   - The inability to take load immediately after placement,
   - Lower resistance to some corrosive waters, and
   - Higher sensitivity to mass rock movement and more difficult to repair.
4. **Internal arrangement of services:** Various compartments for hoisting ore and waste—which may or may not include timber or steel conveyance guides, workers, materials, and utility services—all have to be designed. Sometimes the utilities are incased within pipes embedded in the concrete lining.
5. **Depth (length of shaft):** For hoisting ore and waste rock, the shaft needs to be sunk to a depth where there is adequate room below the haulage level for
   - A large storage bin (orepass) between the rock dump and the feeder system that feeds the crusher,
   - The crusher system,
   - Feeding the crushed material into the skip loading system,
   - Accommodating the length of the skips, and
   - Accommodating some sort of shaft-spill rock cleanout equipment.

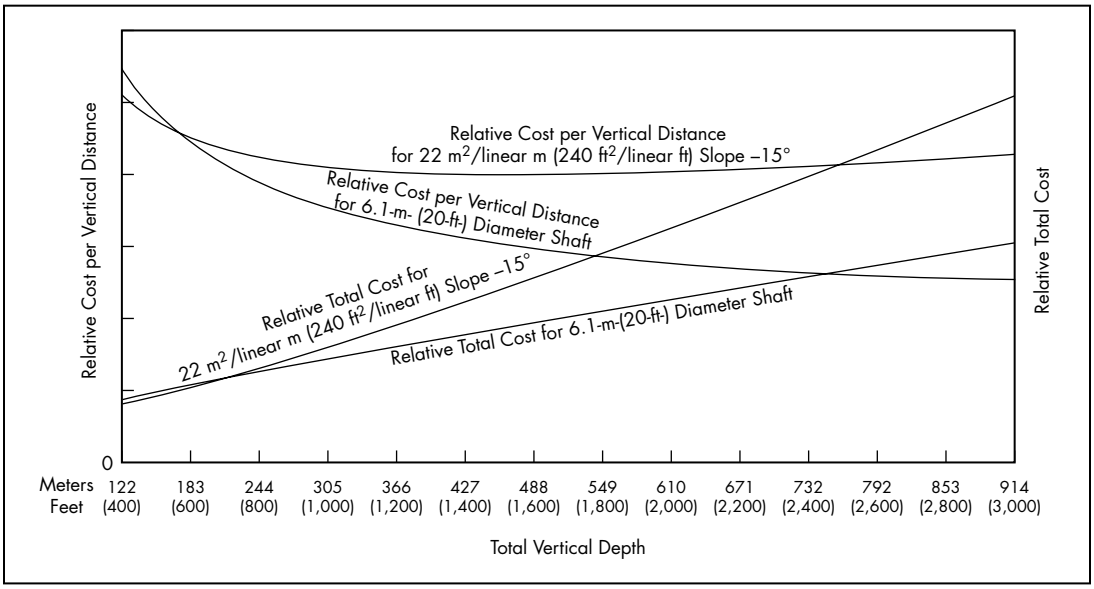
   The practical depth for shafts sunk for hoisting in one pass is about 1,220–1,500 m (4,000–5,000 ft); beyond that depth, an underground hoisting and ore transfer system should be considered (see Figure 12.5-1). The notable exception to this is what is being done in South Africa. The constraints on the unique deep gold mines in South Africa have led to improvements in the development of deep-shaft hoisting. These followed an industry research and development program undertaken in the last decade. Changes in legislation, winder control, and operating practice has allowed the depth limits of single-lift hoisting to be extended beyond a previous practical limit of about 2,400 m (7,900 ft). Several shafts have been commissioned where the winding depth is beyond 3,000 m (9,850 ft).
6. **Shaft linings:** Concrete lining strength is usually between 19 and 33 MPa (2,800 and 4,200 psi) but may be as high as 50 MPa (7,200 psi). Type III cement is usually used where the concrete is mixed on the surface and can be placed either by dropping batches down the shaft in a container and then distributing to the forms (shutterings), or by using slick lines and pots that distribute the concrete to the forms. In either case, the concrete must be compacted in place with pneumatic vibrators. Usually, the shutterings are collapsible steel forms that can be quickly erected and torn loose. Curb ring forms are placed and poured first, then the shuttering forms are placed on top of them.

   Shotcrete linings can be placed in a few variations depending on the shaft wall stability. The shotcrete may be applied directly on the wall by itself; it can be sprayed over woven wire fabric or the walls can be rock-bolted before or after the shotcrete is placed. Some operators prefer using steel fibers in the wet shotcrete for the added yield strength rather than shotcreting over woven wire fabric. Shotcreting of very small shafts is particularly desirable where steel forms are difficult to work with. Using shotcrete over wire mesh is also fairly common in European coal mines for internal shafts where the permanent lining is only roof bolts, wire mesh, and shotcrete.
7. **Shaft collars:** All hoisting shafts require a massive block of reinforced concrete designed to anchor the headframe and secure the top portion of the shaft in the unconsolidated material through which the shaft collar was excavated. They must be designed to allow all of the mine utilities to pass through the collar into the shaft.

Basic shaft-sinking equipment. Most deep shafts are sunk using a multistage platform that is installed in the shaft and stays in the shaft until it is completed. Some call this platform a Galloway stage. The drill jumbos can pass through the opening in the stage, the concrete forms can be stored and assembled on the stage, and mucking-out the bottom of the shaft can take place with the stage in place while buckets (kibbles) can pass through the opening.

Most shafts use one of the following mucking (lashing) systems:

- Cactus-type air-operated grab
- Pneumatic or hydraulic Cryderman mucker
- Backhoe-type machine
- Riddle clamshell-type machine
- Crawler-type, overshot loader



Also, the first portion of any shaft (the "presink") may be excavated with a clamshell or cactus grab bucket operated from a surface crane, before the Galloway stage is placed in the shaft.

The shaft-sinking schedule using a multistage platform is shown in Figure 12.5-2. Shaft sinking is normally performed by specialized contractors.

Another concept is blind boring or upreaming the shafts. Literally hundreds of blind-bored shafts have been completed in the United States and elsewhere around the world.

Slopes Versus Shafts

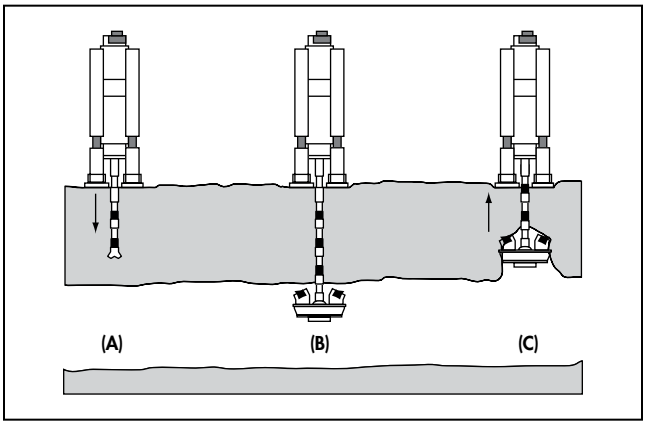
No general rule governs whether a shaft or a slope is the proper type of entry to be developed; each has advantages

Source: Adapted from Dravo Corporation 1974.

Figure 12.5-3 Relative comparison between shafts and slopes of cost in vertical distance versus total depth

and disadvantages. Every major development decision should include a complete trade-off study combined with an accurate discounted cash-flow analysis that considers net present value (NPV) and internal rate of return (ROR) on capital investment alternatives.

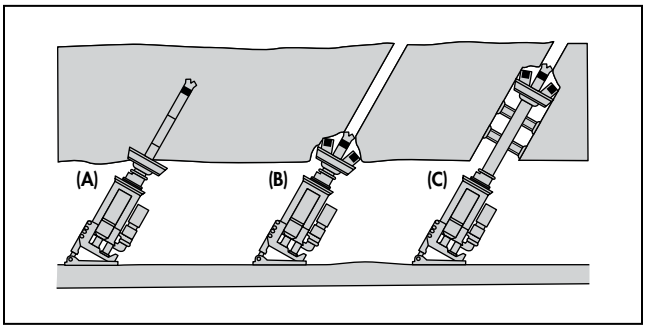
Although the cost per unit distance for a decline may be somewhat lower than for a vertical shaft, the overall cost usually is higher and the development time is usually longer as a result of the greater length required. Thus the cost per vertical meter (foot) for the development, except for very shallow depths (e.g., 150 m [500 ft]), is considerably higher for slopes than shafts. Figure 12.5-3 compares relative costs per vertical unit of distance with total depth for declines and shafts. This chart was taken from work done many years ago on U.S. mines that produced between 1.6 Mt/a and 6.6 Mt/a (1.8 million tpy and 7.3 million tpy), and while the actual cost is no longer accurate, the relative costs are still approximately comparable.



Declines (slopes) have specific advantages over shafts:

- The technique of driving a decline does not require as much specialized technique as sinking a shaft.
- Declines can be used for trackless, track, or conveyor-belt haulage. When used for conveyor-belt haulage, the tonnage can be very large.
- The ground support cost for roof bolts and shotcrete is usually less expensive than the concrete liner normally required in a shaft.
- Large equipment can be moved in and out of the mine without disassembly.
- Maintenance is easier and less costly.
- If the production is from a fairly shallow depth and greater than about 5,000 t/d (5,500 tpd), the decline with a conveyor is likely to be lower cost.
- No visible head gear is required (i.e., no visual pollution).
- No winding gear is required, which in a remote location may need to be transported considerable distances along an unsuitable road network.
- No surface winding facilities need to be constructed, maintained, or manned.
- For major wrecks within the opening (shaft or decline), there are fewer production delays in declines. For an inclined ore body, and if only the top portion is initially developed, declines incur a much-lower initial cost than a shaft that would go to the depth to mine the entire ore body.

The disadvantages of declines over shafts are



- For an equivalent depth, the slope will be four to six times longer. The total cost and the time to construct for very deep declines will be greater (but for inclined ore bodies, production may be able to start early in the upper ore body).
- If there is a thick, very weak zone of rock to penetrate, the shorter distance of the shaft to penetrate through this zone will probably be much easier and less costly than for a decline where substantial ground support may be required.
- If the development opening is to be used for ventilation, the length of the opening will be increased four to six times, and the wall rock will be rougher than the concrete-lined shaft. Both of these issues will require more power to overcome the increased resistance for the same size development opening.

From depths of about 250 to 350 m (800 to 1,100 ft), mines producing from 3.3 to 6.6 Mt/a (3.6 to 7.3 million tpy) have been developed with declines. At these tonnages, at depths of more than about 350 to 500 m (1,100 to 1,600 ft), a shaft is probably more economical than a decline, except for very high tonnage mines using conveyor belts. However, many factors must be taken into consideration before making this decision. For example, if developing from the bottom of a mined-out open pit at a depth of 300 to 400 m (980 to 1,300 ft), the decline down another 800 m (2,600 ft) would probably make more sense than a shaft from the surface down to 1,200 m (3,900 ft). Likewise, if there is only proven ore down to a depth of 400 to 500 m (1,300 to 1,650 ft), and the annual tonnage was to be between 1 and 2 Mt/a (1.1 and

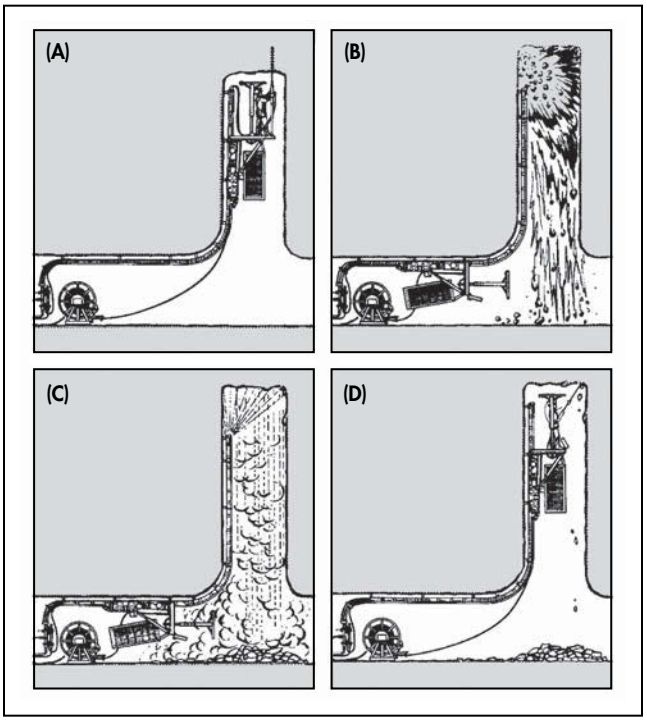
2.2 million tpy), then in all probability the decline would have the advantage. However, there is a strong caveat even to this general statement: if the surface material is very much unconsolidated and/or is below the water table, the cost of developing through this material is much higher for a decline rather than a shaft. For example, if the ground must be frozen in order to penetrate safely, a shaft would be the obvious choice. This is one of the reasons that shafts in North America are sometime favored over declines, particularly in the plains area where large regional aquifers occur.

Incline Shaft Development

An incline shaft is an opening driven steeper than a decline but not vertical. They were often used in the past for maintaining a somewhat constant haul distance between the dipping ore body and the shaft. However, with today's trackless haulage equipment this advantage is minimized. Hoisting with incline shafts is less efficient and requires more maintenance than vertical shafts. Thus they are used very little today.

Multiple-Stage Hoisting

When the hoisting depth reaches approximately 2,400 m (8,000 ft) in depth, a second hoist may be placed underground and continued with multiple-stage hoisting. Usually these facilities are not placed one beneath the other as shown in Figure 12.5-1, but rather the lower shaft is placed wherever it makes more engineering sense to optimize both hauling to the shaft and hauling from the lower shaft to the loading facility of the upper shaft. Also, ground conditions could play a role in where to locate the lower shaft. Many times with today's powerful diesel or electric trucks, the choice may be to haul up an incline rather than sink a second deeper shaft.



Types of Raise Developments

Raises are needed for many reasons, mainly for the transfer of ore, workers, and materials. They also provide for a void space for stope blasting, ventilation, escapeways, and combinations of these. There are many ways to excavate a raise:

- **Conventional raise drilling and blasting:** Here the miner enters a bald raise and drills and blasts the drill round. A work floor is created by drilling pin holes in the sides of the raise.
- **Raise boring by upreaming:** This system requires two levels, between which the raise is bored (Figure 12.5-4). First, a pilot hole is drilled from the top down, then a large reaming bit is put on the drill string and the hole is reamed upward.
- **Blind-hole raise drilling with a "box hole" drill:** In this case there is only one level, and the blind-hole boring machine usually drills a small pilot hole and then reams out the blind raise (Figure 12.5-5). This is sometimes called a "box hole."
- **Drop raise by predrilling and blasting the raise in stages from the bottom up:** The drillers use long-hole drill machines and very accurately drill small blastholes and larger, parallel-cut open holes. The holes are charged and blasted in sequence from the bottom up, making sure that each sequence blasts clear before the next round is blasted.
- **Raise climber:** The raise climber is a mechanical machine that climbs on a cog-wheel track installed in the raise (Figure 12.5-6). The miner drills out the raise round, charges the round, then moves the raise climber back out of the raise before he shoots the round. The miner then runs the machine back up the raise, scales the loose rock under the protection of a canopy, installs another section of track, and repeats the cycle.
- **Boliden raise cage:** As raise-boring technology has become increasingly efficient, the Boliden raise cage is not used as much as in the past. Still, it is a viable method. Where there are two levels, a pilot hole is first drilled between them, and a small hoist is set at the top of the hole. A hoist cable is dropped down to the lower level and a two-deck drill cage is hoisted to the top of the raise. The upper deck has a canopy, to protect the miners while scaling and drilling. After drilling and charging, the cage is lowered and moved from the bottom of the raise for blasting. The cycle is then repeated.

Other Types of Mine Developments

Many other types of developments shown on Figure 12.5-1 need some explanation. The terms *drift* and *crosscut* have unique meanings in a vein type of ore body. Drift usually means the opening is driven parallel to the strike of the vein, whereas a crosscut typically is an opening driven perpendicular to the

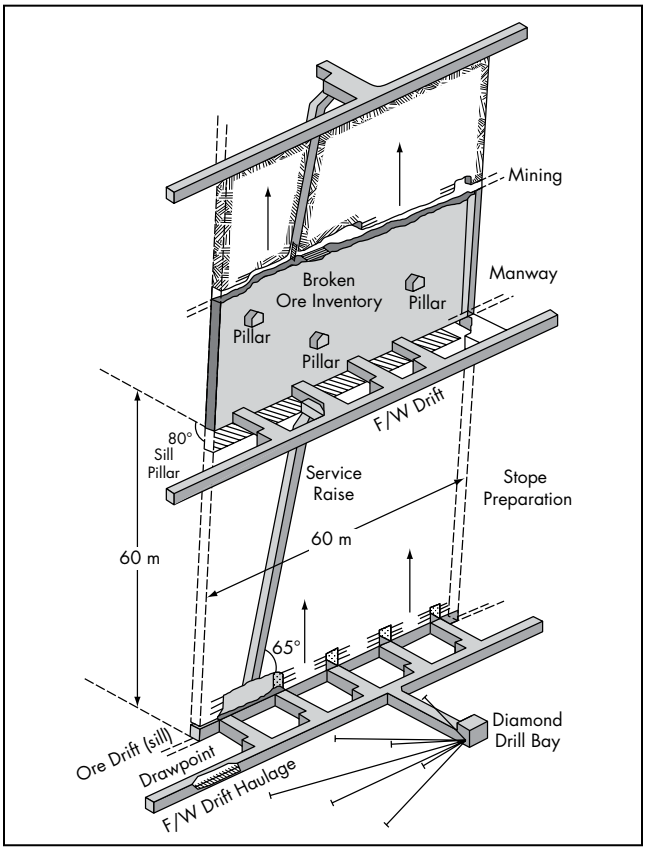
Figure 12.5-6 Raise boring using a raise climber. (A) The raise climber track is installed; the climber goes up and drills and charges a raise round. (B) The raise climber travels back down the track and the raise round is blasted. (C) The raise is ventilated. (D) The raise climber goes back up the raise with the miner under the protection of the steel cage. The miner, from the top of the raise climber, scales the loose material in the raise and extends the new track up the raise. Drilling can again commence.

strike of the ore body. However, crosscuts can also mean any opening driven between two other openings.

The term *raise* is commonly used for an opening driven at a high angle upward from the existing opening, and a *winze* is aan opening driven at a high angle downward from an existing opening. However, with today's technology, it is very common to drill and blast a drop raise from the opening in the downward direction and then blast it from the bottom up; this would still be called a raise.

Ramps are similar to declines in that they are driven at a steep grade that can still be navigated by trackless equipment. However, they are usually driven between mine levels, more for the purpose of traveling between production stopes and dumping points or to develop a new stoping entry. Ramps are better developed in an oval or figure-eight shape than in a true circular configuration. Ramps are more efficient when they are limited to a 15% –18% grade.

Stope Developments for the Various Mining Methods



For those who are not familiar with the various underground mining methods, the following discussion should be studied along with the chapters on mining methods in Part 13 of this handbook. It is not the intent of this chapter to explain or describe how the mining methods work, but rather to describe the differences in the developments that set up the various mining methods.

Hard-Rock Room-and-Pillar Mine Development

The configuration of a room-and-pillar mine generally follows the shape of the mineralized ore body to be mined. Therefore, the basic shape of the mine should start by determining the path of the main haulageways (entries), branching from these to reach the lateral extent of the reserve. Wherever possible, a few basic principles should be followed in planning the production developments:

- The central gathering point for hoisting should be as near to the center of the extractable mass as practical. That keeps the haulage, personnel, and material movement distances to a minimum. Although this may mean a large shaft pillar is left in the center of the mineral reserve of a flat-lying deposit, it does make the mining operation more efficient. At the end of the mining project, most of the pillars can probably be extracted, providing that proper mine planning has been used in the design and proper pillar removal systems have been established.
- Normally, room-and-pillar mines without ground stability problems should be developed as symmetrically as possible to allow the maximum number of working areas to be opened with a minimum of development time. In trackless mines, it is advisable to cut the main haulage opening as much as 50% larger than the minimum size needed to operate the existing equipment. Large main haulageways improve productivity, ventilation, and road conditions, and they are much more efficient to drive. They also allow productivity to be maintained by permitting efficient operation of larger equipment. The haulage drifts in several Mississippi Valley–type room-and-pillar mines are driven 5.5 × 9.8 m (18 × 32 ft), and the mines use very large equipment such as 36-t (40-st) or larger trucks.
- Haulage roads and railroads should be kept as straight as possible, with steep grades other than conveyor slopes being kept as short as possible. The grade limits depend on the type of haulage equipment being used. For main haulageways, railroad grades should be less than 2%, and for rubber-tired diesel equipment it is advisable to keep the grade less than 8%. However, for very short distances where the equipment is allowed to gain mass momentum, 15%–18% grades can be negotiated quite efficiently. If a 20% decline is to be driven for a conveyor system or service slope, rubber-tired, diesel-powered loaders are the best equipment for loading and hauling the material from the development. As mentioned previously, for such steep declines, very high horsepower engines are required for efficient haulage.
- The radius of a curve that can be negotiated by trackless equipment is somewhat dependent on the size of the equipment in relation to the size of the drift and the turning radius of the equipment. Normally, a radius of 15 m (50 ft) is handled easily by any trackless mining equipment. A road grader usually requires the greatest turning radius. For rail-mounted haulage, a radius of 24 m (80 ft) is adequate for stope development, but a limited-service main line requires a minimum radius of 38 m (125 ft). However, a radius of 60 to 150 m (200 to 500 ft) would be appropriate for main-line haulage, depending on the speed of the train.

The preceding discussion has outlined the need for operating flexibility in relation to the size, shape, and thickness of the mineral reserve in the room-and-pillar mine plan. For

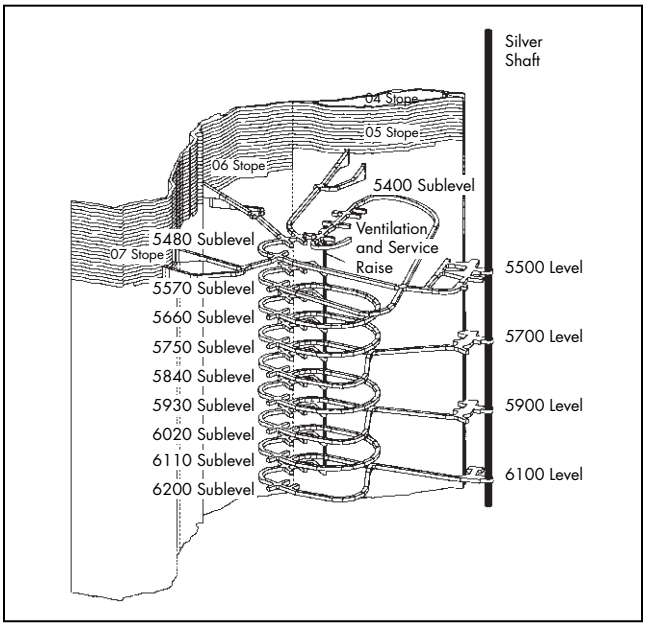
Figure 12.5-7 Typical shrinkage stope mine development

example, it is often advantageous to incorporate a lower level of uniform grade below the main ore horizon to create a ventilation circuit, providing mine drainage that removes water from the operating headings and roadways to make ore movement more efficient. The Fletcher, Brushy Creek, Buick, and Sweetwater mines—all located in the United States—of Doe Run Company incorporated multiple-level planning in the early years of operations, with all of the planning features described. These mines have been extremely efficient over their 45 years of operation.



Shrinkage Stoping Development for Production

Shrinkage stopes for extraction can be developed in many ways. Several years ago, William Lyman (1998) wrote on the subject, describing thirteen ways to develop the shrinkage stope and variations of the ventilation and service facilities. In Chapter 13.3 Haptonstall describes several of these methods. What is described here is a very common method that can be adapted to developing a trackless or a rail haulage shrinkage stope as depicted in Figure 12.5-7 (Marchand et al. 2001). The mine described here is Cambior's Mouska mine in Quebec, Canada.

An ore drift (sill) is driven and kept in the ore at about 30 m (100 ft) ahead of a footwall haulage drift. It is important that the sill drift width stays as near the same width of the ore vein as possible. The sill drift and the haulage drift are kept about 10 m (30 ft) apart. In this case the vertical distance between levels is 60 m (200 ft) with a stope width of 60 m (200 ft). At 10-m (30-ft) intervals, crosscuts are driven between the haulage drift and the ore drift to serve as drawpoints to shrink the broken ore from the stopes. (*Shrink* refers to the process of shrinkage stoping where the amount of broken ore out of the stope is decreased; most of it is left temporarily as a working platform and ground support.) The crosscut size will depend on what type of equipment is used to remove the ore. In this case small overshot pneumatic muckers were used and trammed back to the railcars for dumping, and the crosscuts were only 2.7 × 2.9 m (8.9 × 9.5 ft). For load-haul-dump (LHD) haulage from a drawpoint to an orepass or dump pocket, the crosscuts would have to be sized at least 1.2 m (4 ft) larger than the dimensions of the LHD. From the lower sill drift, a service raise is driven to the haulage drift of the level above. This service raise is equipped with a ladderway, service pipes, and a slide (with air tugger) all connecting to the level above. The upper level also provides the ventilation circuit. Shown also is a service manway from the bottom of the stope, which is, in this case, timbered as the stope advances upward, thus completing the ventilation circuit and maintaining two access points to the stope at all times. Other mines sometimes leave pillars between the stopes and place the second access in these pillars, which would require small doghole drifts between the raises and the stope. (A *doghole* is a very small drift driven to serve as an access between a vertical manway and the stope. In some cases it may be only 1.2-m (4-ft) high, where one must crawl on all fours to access the stope.) These pillars can later be removed and capture the ore in the drawpoint below when the stope is completed.

Sublevel Open-Stope Development

Most sublevel open-stope mines are applicable to dipping-type deposits, but the thickness of the deposit between the hanging wall and footwall normally varies from a few meters to tens of meters wide. The development access from the main decline or hoisting shaft is gained by level developments, usually in the footwall, that vary from 46 to 122 m (150 to 400 ft) depending on the vertical extent of the ore body, the eventual stope heights, and the number of production stopes that may be excavated per level. These levels usually become the haulage drifts and approach the bottom of each stoping block running parallel to the block with connecting access crosscuts running over and into the ore. Between the main levels, ramps are usually driven for trackless haulage transport between levels. These ramps also give access to the sublevels, which are developed at intervals to remove blocks of ore. The sublevel drifts are located in the footwall for haulage, with crosscuts into the ore for connecting to the drifts in the ore, which first become undercut access drifts and later draw drives. These sublevel drifts in the footwall can also be used for accurate delineation of the vein (reef) by drilling prospect holes from the sublevel drifts. Up above at the next sublevel, these drifts driven in ore are used for drilling the long holes that blast the ore. For wide ore bodies, there will probably be a hanging wall drift and a footwall drift. Usually at the widest part of the ore for that block there will be a slot crosscut drive and a slot raise drive between the sublevels, which opens to the undercut of the lower level. This slot raise is then slabbed (slashed) out to the full width of the ore body, and when the broken slot ore falls to the undercut opening, the slot allows room for the vertical slabs of ore to be drilled and blasted from the upper sublevel drill drifts. The ore then falls down to the draw drifts, which are accessed by drawpoint crosscuts for loading out the ore. When the ore is completely drilled and blasted from the first sublevel block,

Source: Peppin et al. 2001.

Figure 12.5-8 Lucky Friday undercut-and-fill mine development infrastructure

the drilling and blasting moves up to the next sublevel and the cycle is repeated until the next main level is reached. An ore sill pillar is usually remaining at each main level.

Sometimes the ore body is narrow enough that a horizontal room can be opened and, instead of drilling fan holes from drill drives, vertical holes can be drilled for the long-hole blasting. This also applies when vertical crater retreat stoping is used. In the sublevel extraction method, termed "longitudinal mining" in Chapter 13.4 (Figure 13.4-21), the sublevel sill drifts serve as both the top cut for the downhole drilling and as a bottom cut for remote mucking. Ventilation raises can be placed in the ore or close to the stope accessway from the ramp. Raises are usually opened with raise boring machines, raise climbers, or drop raises. Rarely in today's modern mechanized mines are raises drilled and blasted by conventional methods.

Cut-and-Fill Stoping

Because cut-and-fill mining is so versatile and can be used to mine any shape of an ore body, it is impossible to generalize a specific development approach that fits all types of cut-and-fill systems. Normally the essential criteria for using cut-and-fill stoping is that the excavated stope needs support; the remaining rock is not competent enough to stand open to allow further mining of the area. However, where the ore is so high-grade that it is planned to extract nearly 100% of the ore and leave no pillars, there is a need for immediate backfill, even in competent rock. Consideration must be given to the general types of deposits that are to be mined by one of the many forms of cut-and-fill mining.

Steeply dipping, narrow ore bodies. Steeply dipping ore bodies are most commonly mined by cut-and-fill systems. Such mining occurs throughout the Silver Valley (in Idaho's Coeur d'Alene district), the Stillwater mines and the Cannon mine in Washington (all in the United States), to name but a few. The major infrastructure developments are normally developed in the footwall, but not necessarily, since nothing will be allowed to cave—even the hanging wall should remain structurally competent for developments. A classic example of infrastructure development is seen in Figure 12.5-8 of Idaho's Lucky Friday mine, illustrating the main shaft, the haulage levels coming off the shaft, the oval-shaped ramp contacting all of the sublevels, and the service and ventilation raise. Because this is an undercut-and-fill mine, there are 15% stope attack ramps to the top of each sublevel stope block and working down, slice by slice, to the bottom of the sublevel stope block. In an overhand cut-and-fill mine, the sublevel attack ramps would start at the bottom of the stope block and work up the ore block in slices, establishing a new attack ramp for each slice. Not shown on this sketch are orepasses from the sublevel ramp down to the next haulage level.

Flat, thick, and wide ore bodies. A few years ago only steep vein deposits were worked by cut-and-fill mining, but with today's technology wide and thick ore bodies are also mined in this manner. Almost all of the underground mines of the Nevada (United States) gold district use cut-and-fill mining, and more specifically, undercut, drift-and-fill, or ramp-and-fill. In this type of mining, the upper-level drifts should be driven and filled at a different direction azimuth than the drifts immediately below. This can be seen in Chapter 6.5, Figure 6.5-6.

Sublevel Caving

Sublevel caving is an underhand method where all of the blastholes are drilled upward. Gravity moves the ore down to the extraction and drilling drift. The main haulage drifts on the major levels will probably be longer from the hoisting facility to the production stoping than in noncaving mining systems, since this mining system allows for the overburden to cave. When the angle of the caving surface is taken into consideration, the hoisting facilities must be well removed from the zone of potential caving.

For transverse sublevel development, the haulage drift for a particular level is driven down the strike of the ore body, probably in the footwall waste, with production crosscuts turned off at regular intervals crossing the ore body. This divides the ore body into geometric blocks that will correspond to the geometric spacing of the sublevels. These drifts are driven to the hanging wall, and a slot raise up to the cave above is developed at the end. These slot raises must be slabbed out to the full dimension of block and will provide the opening for the initial blasting at the end of the stope. There are many development schemes to connect the sublevels, but all of them involve ramps that connect to the various sublevel haulage drifts. Also connecting to the sublevel haulage drifts are major orepasses that transfer the ore to a main haulage level.

Development for a sublevel cave stoping method is extensive. This is because so much of the ore must be mined by development to set up the drilling and blasting of the ore so that the surrounding waste rock will cave uniformly. In 1990, about 25% of the ore was extracted by drifting in the sublevels; now this can be as little as 6% (Bullock and Hustrulid 2001). The reason for the drastic decrease in development is because the better drills and drilling systems today are more efficient, drilling larger, longer, and much more accurate holes for blasting; thus the spacing between sublevels has more than doubled.

As indicated, ore is recovered both through drifting and through stoping. Because the cost per ton for drifting is several times that for stoping, it is desirable to maximize stoping and minimize drifting. This has meant that through the years, the

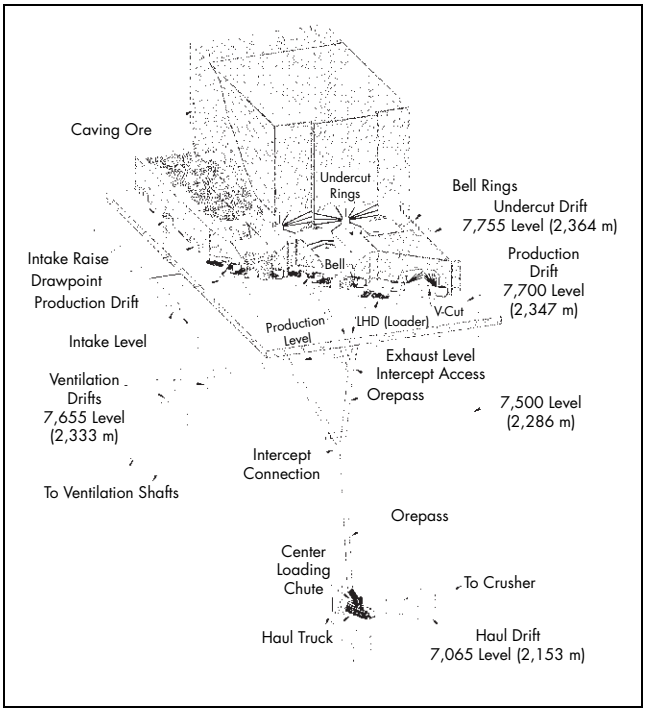
height of the sublevels has steadily increased until today they are up to 30 m (98 ft). The sublevel intervals have changed from 9 m up to nearly 30 m (30 to 98 ft). A number of factors determine the design. The sublevel drifts typically have dimensions (width × height) of 5 × 4 m, 6 × 5 m, or 7 × 5 m (16 × 13 ft, 20 × 16 ft, or 23 × 16 ft) to accommodate LHDs.

After the sublevel vertical interval has been decided, it is necessary to position horizontal dimensions of the sublevel drifts. As an example, the drifts might be placed so that the angle drawn from the upper corner of the extraction drift to the bottom center of drifts on the overlying sublevel is 70°. This is approximately the minimum angle at which the material in the ring would move to the drawpoint. The resulting center-to-center spacing is 22 m (72 ft).

Longitudinal sublevel development is commonly used in ore widths of 18 m (60 ft) or less but may also be used to advantage in wider ore bodies. For longitudinal sublevel caving developments, almost all of the stope development is in ore, but for irregular ore bodies, there is a greater chance of leaving ore undrilled and blasted.

Mine Development for Block Caving (Panel Caving)

In this section, the term *block caving* will be used to represent both block and panel caving, suggesting the mining of individual blocks, and panel caving, indicating a laterally expanding extraction. The time and cost of developing a block caving mine is very significant compared to other types of mining.



Since block caving methods are associated with extremely high production rates, the main haulage developments are likewise designed for large high-volume/high-speed haulage. These initial developments must also accommodate very large ventilation capacities to handle all of the equipment needs of a modern massive caving mine. At the same time, the major permanent development facilities, including shafts and permanent ventilation raises, must be located far enough from the caving material so as not to be engulfed within a zone of high stress or rock-mass deterioration. An example of this infrastructure development in relation to the caving ore body is shown in Chapter 6.1 (Figure 6.1-2).

The most important development elements of a caving system are the undercut level, which removes the support for the overlying ore column; the funnel, trough, or bell through which the ore is transported downward to the extraction level; and the extraction or production level. In some cases, the undercutting can take place on two levels rather than one (see Chapter 6.5, Figure 6.5-24C). There are three types of systems for drawing the ore from the caving ore body: the LHD system, the slusher system, and the gravity system (in order of importance). Much of the main development infrastructure is similar for the three methods, but the stope developments are somewhat different.

Stope development for LHD caving systems. In Figure 12.5-9 the undercut level is the upper level where the long drill holes of the undercut ring are shown. The production level is the level below where the LHD is loading ore from the bell draw holes. Note the intake and exhaust drifts and raises that carry the ventilation and the orepasses and load-out chutes on the mail haulage level drift.

For more extensive discussion and illustrations on LHD caving systems development, see Chapter 13.10.

Stope development for slusher caving systems. In the top level shown in Figure 12.5-10—the undercut level—longhole drilling will open the troughs that the ore will collapse into and then flow down into the multitude of finger raises, where it flows by gravity to the grizzly (haulage) level where it is slushed to the main haulage level. In some cases, instead of slushing directly into the ore trains, the ore may be slushed into another orepass leading to an even lower main haulage level. The ventilation drifts and raises are not shown in the diagram. This mining system is labor intensive and would only be used where labor costs are extremely low.

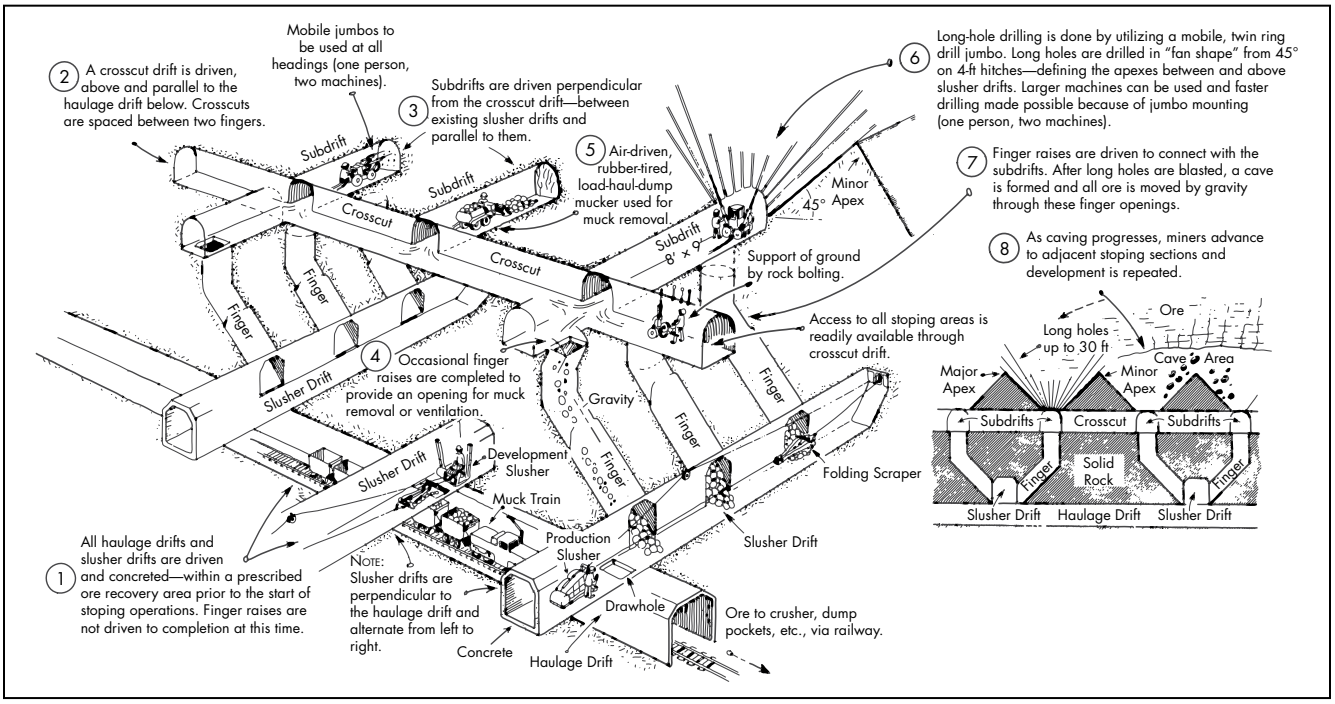

Figure 12.5-9 Underground development needed for LHD block caving

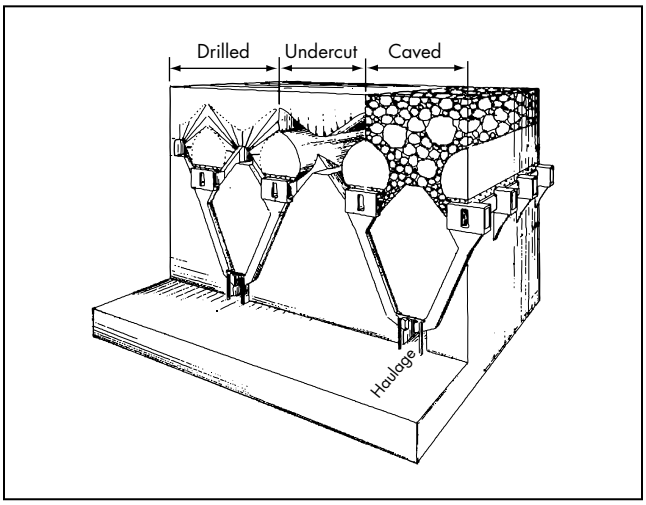
Stope development for gravity caving systems. Figure 12.5-11 illustrates how the development has much less horizontal development, but many more raises for orepasses and draw extraction bells, in a 14 × 7.6 m (76 × 25 ft) grid pattern. When the ore is being drawn from a specific area, a miner must stand and assist the ore flow with a mining bar or explosive bombs in each of those grizzly chambers, as the ore flow becomes blocked with boulders. Because this method of block caving is so labor intensive, it is seldom used in new mines being developed in countries where labor costs are high.

PLANNING FOR EXCAVATION



Rapid-Development Incentives

Very large initial capital expenditure is required to construct a block cave mine and bring it into production. The eventual NPV of the investment is dominated by the time taken to start production, typically 5–8 years. The rate of advance is a key factor, and cost per meter, although important, tends to be secondary. One very large, multinational mining company that is currently operating or developing four large block caving mines, plans to develop 1,000 km (600 mi) of development and 12,000 drawpoints over the next 11 years (Moss 2009). Over many years and projects, this mining company's advance rate has stayed at around 4 m/d (13 ft/d), and the company states this has been a critical factor for bringing any block cave projects in on schedule.

Figure 12.5-11 Stope development required for gravity draw block caving

While rock-drilling efficiency has increased by fivefold over the years between 1960 and 2000, the advance rate in meters per day of development has decreased by threefold; thus, the cost per meter has gone up by tenfold. The primary reason for this is the new emphasis on safety at the development face. These protocols have now evolved in the mines to a point where most development requires that all ground is at least fully bolted and in most cases has skin support in the form of shotcrete or wire mesh. This means that currently most of the ground control functions must be carried out within the development cycle. Yet a few mines and many tunneling operations get much higher advance rates, some more than 10–15 m/d (31–49 ft/d). How is this accomplished? It must be planned, equipped, and executed as if it were a civil tunnel contract.

What Must Be in Place?

From the very beginning, there cannot be any compromise of worker safety; management must develop procedures whereby no worker is exposed to ground that has been inadequately secured. By reviewing many studies of rapid excavation, it is apparent that the following steps must be set in place to achieve these advance rates:

- The mining operation must know the best drill round to achieve 95% of the drilled distance for the type of ground at the mine location.
  - A thorough geotechnical study must be ongoing to define rock types related to blast design and ground control problems, and detailed planning must precede each step of the mine development.
  - Drill rounds must be designed by qualified engineers, and the execution of drilling and blasting must be followed according to the design. In a recent survey by the National Institute for Occupational Safety and Health (NIOSH), 60% of mines allow drillers to decide what type of a drill pattern and how much explosive to use in the round.
  - Miners think in terms of blasting or bombarding the rock with as much force as possible, and every hole is the same; blast designers tend to think of cutting the rock, particularly in the cut area and the periphery of the drift.
  - Oxygen-balanced emulsions should be used to minimize ventilation time, and electronic blasting should probably be used to ensure perfect hole timing and minimize vibration and peak particle velocity where it may be required.

- Since 50% of the cost and about 25%–40% of the face time are now spent in ground control, controlled smooth wall blasting should be used. Damage to the remaining rock must be limited and overbreak minimized. NIOSH recently conducted a research study showing that the total cost of drifting using controlled blasting is about 4%, or $59/m ($18/ft) less than conventional drilling and blasting. No credit was given for less ground-control cost (Camm and Miller 2009). The ground-control savings could easily be $150/m ($45/ft).
- Driving the largest faces consistently with geotechnical issues of ground control and ground stress conditions allows for the most drifting efficiency, since larger equipment can be used and, in some cases, there is room for multitasking at the face. In one case the development advance went from 1.7 m/shift (6 ft/shift) to 3.4 m/shift (11.1 ft/shift), even though the size of the drift tripled (Bullock 1961).
- The most efficient and reliable equipment should be acquired for driving the developments, particularly the critical path developments, including computerized drilling controls and the use of improved explosives systems designed for controlled blasting. The initial, up-front cost may be millions of dollars, but many millions more will be saved in the NPV of the operation.
- The entire mine development operation must focus on getting the men and supply logistics and maintenance planned, so there will be little or no time lost at the face between cycles. In one Rio Tinto study (Moss 2009), 39% of the time was spent "waiting" for the next step in the 15-hour cycle.
- Procedures and metrics must be put into place where all parameters of the drilling, blasting, ground control, and loading portions of the drifting cycle can be defined in quantitative forms and are measured for development projects. If quality is not measured, it cannot be managed.
- To achieve the desired results, every project needs to establish a quality control group that has the responsibility and authority to enforce the drilling, blasting, and ground control procedures that have been put in place. This group should report to the mine manager. In one project observed by the author, where quality control was completely ignored during the "controlled" blasting of poor ground, the result was that the tunnel had a slab of more than 1.5 m (5 ft) of overbreak for at least 15 m (50 ft) of tunnel, which the contractor (on a cost-plus contract) was allowed to simply fill with layers of shotcrete until the correct tunnel dimension was achieved.

The following are a few recent examples of high-speed development.

Norwegian tunneling technology opened a new haulageway for a coal mine, which averaged 103 m/week (338 ft/week) driving a 38.5-m^2 (414-ft^2) tunnel 5,630-m (18,471-ft) long (Nilsen 2009). Much of the tunnel was in permafrost, making the advance more difficult. The key is to use the face to advance development. To achieve this, some Norwegian tunneling operations use

- Side-tipping loaders;
- Trucks sized to the tunnel, enabling drivers to perform a three-point turn in the tunnel;
- Drilling equipment with navigation that is fully instrumented to implement a plan of the drill layout, including the survey of the hole collar and hole toe;
- Use of 5.8-m- (19-ft-) long drill steels (where ground is appropriate), logging of the drilling performance, blasting using emulsion, and rapid-setting shotcrete (one-half hour in freezing conditions); and
- Most importantly, a dedicated, highly skilled work force regularly achieving more than 100 m (328 ft) per week of development in openings up to 38.5 m^2 (414.4 ft^2). The best week achieved 150.1 m (492.5 ft) of advance.

The world's best decline advance rate is that currently achieved at the Cadia East project in New South Wales, for Newcrest Mining Limited, which was 260 m/month (853 ft/month) for 9 months ending in May 2008 and included a single best month of 311 m (1,020 ft). This project also shows a cost of A$4,500/m (US$3,894/ft), which is 31% lower than the industry average for Australia (Lehany 2008).

In general, tunnel contractors do a better job of rapid advance rate excavations than mining companies do.

What Is the Payoff for Rapid Excavation?

Assume one is developing a 2% copper, block caving mine to produce 100,000 t/d (91,000 tpd). One can also assume a typical cost per ton of copper production, a copper sales price of about $0.90/kg ($2.00/lb), a $360 million capital cost ($45 million for 8 years versus $72 million for 5 years), a 10% discount rate, and a regular development rate of 4 m/d (13.1 ft/d) compared to 8 m/d (26.2 ft/d). Based on this data, the mine would come into full production in the sixth year rather than the ninth year. This would result in a difference in NPV in the eighth year of $260 million for the regular development compared to $86 million for the accelerated development, or a difference in NPV of $154 million, favoring the accelerated case. However, by the 13th year, the accelerated development case shows a positive discounted cash flow and NPV compared to the regular development case, which does not show a positive discounted cash flow until approximately the 35th year. This theoretical example illustrates that with a difference of $154 million, considerably more capital dollars might be spent to put the proper equipment and practices in place, resulting in the doubling of development advance per shift.

Developments Driven for Obtaining Information

Exploration

Often developments must be driven out ahead of the rest of the mine infrastructure to identify both the specific location and grade of the ore to be mined. There are no set rules as to how these developments must be driven, since so much depends on the type of deposit. In some cases, the development needs to be driven directly into the ore to assess its character, and in other geologic settings the developments need to be driven a specific distance from the deposit so a series of diamond drill holes can be used to sample those deposit characteristics. The primary objective should be to get these developments completed well ahead of the need to mine the area. This means getting the developments done many months before the information will be needed for mining operations.

Information for Mine Planning Obtained by Development

During the very early stages of evaluation and planning, a lot of information is needed to make the correct decisions concerning the property. Therefore, the initial opening might be driven to test a particular aspect of the mineral reserve that

is considered critical for successful exploitation. More often, this is termed a *test mine*. This could be from an adit, ramp, or shaft (see Chapter 4.6). In any case, permitting is usually required that may delay the project.

A large amount of the technical information required can be obtained from diamond-drill holes, particularly where the mineralized zone is fairly shallow, continuous, and flat. Unfortunately, the true economic potential of many mineral resources cannot be determined until after an exploration development or test mine is driven. From the development opening, underground prospecting can further delineate the materials present, a bulk sample can be taken for metallurgical testing, and/or true mining conditions can be revealed. This procedure involves considerable financial exposure and, unfortunately, the delineated resource may turn out not to be economically viable. Nevertheless, there may be little choice about driving a test development opening if the potential of the resource is to be proven and the risk to larger downstream capital expenditures is to be minimized. This is another case where the decision must be made between a decline or a shaft as well as the size of the opening.

Regardless of the reason for driving a preliminary development, three basic principles should be observed:

1. The development should be planned to obtain as much of the critical information as possible without driving the opening in a location that will interfere with later production. For most mining methods, it is usually possible to locate at least a portion of the exploration development where it can be used in the developed mine that may come later, even if it becomes necessary to enlarge openings to accommodate production equipment at a later date.
2. The preliminary development should be restricted to the minimum needed to obtain the necessary information.
3. The development should be completed as quickly as possible. Most exploration drifts for metal mines are only large enough to accommodate small loading and hauling units (from 2.4 × 3 m to 3 × 4.3 m [8 × 10 ft to 10 × 14 ft]). If geologic information is needed, it is often possible to locate the developments in proximity to several of the questionable structures without actually drifting to each one. With modern high-speed diamond drills having a range of 213 to 305 m (700 to 1,000 ft), these structures can usually be cored, assayed, and mapped at minimum cost.

After the preliminary development has been completed to satisfy a specific need, the development should be used to maximize all other physical and structural information to the extent that will not delay the project. As much geotechnical information on the rock mass quality should be obtained as possible, and should be just as important to the company as resource information.

No rules regulate the size of the shaft or the entry for exploration development. The size depends on many factors, including the probability of the mine being later developed to the production stage. If the probability favors follow-up with full mine development immediately after exploration development, and if the shaft depth is not excessive (e.g., 244–366 m [800–1,200 ft]), it would be logical to sink a shaft sized for later use in production development. This is particularly true of operations normally using small shafts for production. Using a small shaft of 3.7 to 4.0 m (12 to 13 ft) in diameter is not uncommon in hard-rock mining in the United States. For example, most of the Doe Run Company's shafts in the Viburnum Trend area of Missouri are of this size, as well as many of the shafts in the Tennessee zinc district—the Elmwood mine, originally opened by New Jersey Zinc, is a good example of this practice. Initially a 3.7-m- (12-ft-) diameter conventional shaft was sunk for exploration. After the continuity and quality of the ore were proven by drifting and underground prospecting, the shaft was used for further development of the mine and was eventually used as the production shaft.

The Savage Zinc Company's mine at Carthage,Tennessee (United States) is another example of a 3.8-m shaft originally sunk as a test mine and then later opened as an operating shaft. In contrast, some companies choose smaller-drilled shafts to speed shaft sinking and minimize early expenses. Such shafts are usually completed considerably faster than conventional shafts, but not as fast as a raise-bored shaft (i.e., where an opening already exists, and the hole is reamed upward, and the cuttings fall back into the mine). Because this section is directed toward initial mine openings, removal of cuttings must be upward through the hole and out from the shaft collar. Various methods involve the use of air or mud, with either direct or reverse circulation. A large number of blind-bored shafts exist in the industry. Although bored shafts may stand up very well without support, most of these shafts contain either a steel or concrete lining.

Developing Service Facilities

Shop and Storehouse Developments

The efficiency of a modern mining system depends heavily on the productivity and availability of the equipment used to extract the material. Most of the energy to move the material horizontally must be provided. Since the material may be very heavy and/or abrasive, and because the environment of an underground mine imposes adverse operating conditions, underground mining equipment requires a great deal of preventive maintenance and repair. One of the most serious and most prevalent errors made in designing a mine is the failure to provide adequate space and equipment for necessary maintenance and repair work. The amount of service, if any, provided underground depends on several factors:

- The degree of difficulty in moving equipment into or out of the mine is a major consideration. If the property is a limestone mine with adit entrances and a good shop on the surface, it would probably not be advantageous to duplicate the facilities and personnel underground. As a generalization, most decline mines do not need an underground workshop; they require only service and refueling bays. Maintenance is done on the surface.
- Underground shops should provide a safe and clean working environment. In mines that are gassy or carry a gassy classification, building underground shop facilities may not be practical.
- If the active working area will be totally abandoned after a fairly short life, it would not pay to invest in an extensive underground shop area. Mines such as the punch mines in Appalachia (United States) are typical examples of this situation.

Most underground mines with shaft entries should develop good underground shop facilities. In the Viburnum Trend mines, which are developed with shafts 152–396 m (500–1,300 ft) deep, all of the mines rely on large mining

equipment and have well-developed underground shop areas. The total area usually used as a shop area can range from 465 to 1,394 m^2 (5,000 to 15,000 ft^2). The important criteria for shop design are to provide

- One or two large bridge cranes over the motor pits;
- Easy access from several different directions for access to and around the cranes when they are in service for extended periods of time;
- A motor pit and service area for scheduled lubrications performed as part of the preventive maintenance program;
- A separate area for welding operations;
- A separate area and equipment for tire mounting and repair;
- An enclosed separate area for recharging batteries;
- Various work areas equipped with steel worktables or benches;
- Close proximity to the main supply house;
- An area for washing and steam-cleaning the equipment;
- An office for the shop foreman, records, manuals, catalogs, drawings, and possibly a drafting table. The main pit areas should be visible from the office windows; and
- If rail haulage is used, a separate locomotive and car repair shop must be developed, with provisions for at least one motor pit.

The size of the underground supply room also depends on several factors. Some mines have no supply room, whereas others have very large rooms providing as much as 1,115 m^2 (12,000 ft^2). Factors influencing the inventory policy include the frequency and ease with which the mine receives supplies, whether a supply system is installed at the collar or portal of the mine, whether there is a separate access to obtaining repair parts without disrupting the mine production, and the dependability of the parts suppliers for the equipment being used.

Sump Area and Pump Station

In mines below surface drainage, areas must be provided to store the water before it is pumped to the surface and discharged. No general rule exists to determine the capacity for water storage. The water flow into mines in the United States has varied from 0 to 2,208 L/s (0 to 35,000 gpm). Adequate pumping capacity is the only permanent solution to removing water from a mine. However, fluctuations in the water inflow and/or the time periods when some or all of the pumps are inoperable must be handled by having an adequate sump capacity.

Many mines use "dirty water" positive displacement pumps. The challenge is to keep the mud suspended until it enters the pumps, screening out the big lumps. This is economical up to about 80 L/s (1,320 gpm). Beyond that, settlers with centrifugal pumps will be necessary. Sumps are also needed in wet trackless room-and-pillar mines; the rubber-tired vehicles traveling on the roadways create fine material that eventually collects in the water ditches if the roadways have drips or continuous streams of water on them. Although this situation should be corrected to keep water off the roadways, it invariably occurs or recurs. A place must be provided for the fines to settle out of the water so they do not damage the clear-water high-head pump impellers. This can sometimes be done effectively in a small catch basin that is frequently cleaned out. However, if the water flows are substantial, the main sump receives the bulk of this fine material. As a result, provisions must be made to clean the sump with conventional or special equipment, divert the water into another sump while one sump is being cleaned, provide a place to put the fines ("soup") removed from the sump, and transport the fines to the surface.

One of the most common methods of cleaning a sump is to use conventional front-end loaders to remove the material. However, a ramp must be provided down to the sump-level floor. If deep-well impeller sections are suspended from a pump station down into the sump, considerable care must be taken to avoid bumping the impellers with the loader. Other systems using slurry pumps, scrapers, or diverting the material into skips have been tried, but there still is no single, efficient, low-cost way to clean a sump.

When cleaning a sump, diverting the water flow into another sump can also be a problem unless at least twice the normally required pumping capacity is provided. Half of the pumps must handle all of the inflowing water while one sump is being pumped down and cleaned. Mines that make large amounts of water also produce large amounts of fine material that fills the sumps much faster than anticipated. The sump of a new mine in the development stage cannot be cleaned too soon; if the mine is not producing much water at a particular stage of development, the sump should still be kept clean. The next shift may bring in more water than can be handled with half the pumps, and when that point is reached, there will be no way to reach the muck in the bottom of the sump for cleaning.

Two methods are often used to divide the sumps for cleaning. One is to locate a concrete wall between the two areas and provide a means of closing off one side and making the water flow to the other side. With this method, the wall should be anchored properly on the top and bottom with reinforcing steel into the rock. This provides a safety factor in preventing the wall from collapsing into the side being cleaned. The other system is to develop two physically separate sumps. Both sumps must be provided with pumps, a method of stopping the water inflow and diverting it to the other sump, and a means of access for cleaning.

Many mines locate the pump station below the sump chambers, using horizontal centrifugal pumps instead of deep-well turbine pumps. These mines avoid the installation of a vacuum priming system because the overflow feeds the main pump. Although this system provides easier access to the sumps and makes cleaning easier, the risk of losing the pump station by flooding is increased because of its lower elevation.

If the power for the pumps originates from a source not maintained by the mine (i.e., public power with or without "tie lines"), the mine may be without power for extended periods of time. Therefore, every protective measure should be provided. Using deep-well pumps on one of the upper or middle levels helps protect the facility for the maximum length of time. If the pumps are in a room or chamber with the power lines coming in and the water pipes going out, it may be impossible to access the pumps for replacement without a small overhead crane on a rail above the pumps. If deep-well pumps are used, sufficient headroom is needed to remove the multistage impellers.

Storage Pocket (Skip Pocket) Size

For mines that extend over a large vertical distance, there is usually enough storage capacity in the orepasses to accommodate any mismatch between production schedule and hoisting schedule. But for mines that are on a single level, there is often

a need to build a large storage capacity between the production of the mine and the hoisting system.

The correct size of the skip pocket depends on what it is intended to accomplish. For example, if management decided to try to hoist for 20 shifts per week but stoped two shifts per day in a mine producing 4,536 t/d (5,000 tpd) between midnight Friday and 7:00 AM Monday, the minimum pocket size would be found from

$$C = [S_m/S_h] \times S_{md} \times T_{ms} \quad (12.5\text{-}1)$$

where C is the capacity needed in metric tons or short tons, S_m is the number of shifts per week the mine operates, S_h is the number of shifts per week the hoist operates, S_{md} is the number of shifts the mine is down, and T_{ms} is the number of metric tons produced per mine shift.

For this example, the capacity would be calculated as

$$C = [10/20] \times 6 \times 2{,}268 \text{ t/shift} = 6{,}804 \text{ t} \quad (12.5\text{-}2)$$

or in English units

$$C = [10/20] \times 6 \times 2{,}500 \text{ st/shift} = 7{,}500 \text{ st} \quad (12.5\text{-}3)$$

It is invariably found that a much larger pocket or alternative surge capacity will improve the performance of the mine. The loading station and shaft hoist are often a bottleneck on production.

Other Service Facility Developments

A variety of other rooms or drifts must also be developed. A lunch area (or room) is essential around an underground shop. In many underground mines the lunchroom doubles as a mine rescue chamber. Office space should be provided for the privacy of the underground supervisor and the security of records and equipment.

Another underground facility that must be developed is a fuel storage area. For supplying all of the diesel-powered equipment used in the mines, it is usually advisable that a system be developed for centralized fuel storage. Where the mines are shallow, it is common to put the fuel oil underground through boreholes. However, where the mines are deep and have multiple levels, palletized storage containers are common. In either case, a retaining wall must be maintained that will contain the fluids in case a tank ruptures.

A new consideration is that of storing biodiesel fuel underground. Such fuel has the same requirements as diesel fuel in that it is constantly needed in the refueling of the trackless equipment, but there is also the added advantage that biodiesel is low-temperature sensitive and storing it underground will keep it fluid.

There must also be a space for explosive storage. Of course this should be located in a safe location, away from main haulageways and high-voltage electrical lines. Equally important is to construct the explosive magazine with complete security and management control. In addition, a separate storage and secure location must be built for the detonator systems.

MAKING MINE DEVELOPMENT DECISIONS

Many ways exist to develop a mine. However, there is only one "least-cost" method for any specific mine, and it is up to the mine engineering staff to develop trade-off studies to determine the optimum method to develop the mine. A classic example was recently completed for Stillwater Mining Company (SMC) for the development of mining of ore below the 3,200 Level down to the 2,000 Level. The mine production is at a nominal capacity of 4,200 t/d (4,600 tpd) of combined ore and waste, and is projected to increase to 4,900 t/d (5,400 tpd) over the next 10 years.

The 3200 Haulage System Trade-Off Study (C. Jacobs and B. LaMoure, personal communication) at the Stillwater mine was initiated to evaluate several life-of-mine muck-handling systems, each having the potential to provide for long-term muck-handling requirements for the operation while meeting common operating criteria and long-range goals. Each system evaluated was unique with respect to mine development, timing, required infrastructure, and expenditure profile.

The objective of the study was to evaluate alternate long-term production from the deeper levels of the mine for ore and waste handling systems of various hauling options in lieu of the proposed belt conveyor system, and to make a recommendation for the best haulage option. The proposed conveyor system was listed as an option to provide a "base case" comparison with other options. The primary options in this study included

- A decline with a conveyor option, with diesel trucks (base case);
- Deepening of the existing shaft with rail haulage;
- An internal shaft or winze with rail haulage and secondary hoisting;
- A decline with trucks using only diesel fuel; and
- A decline using electric trucks.

All options consider a common 20-year mining plan, with a maximum total throughput of 4,900 t/d (5,400 tpd).

Economic evaluation of the trade-off study options considered incremental differences in capital and operating expenditures within SMC's gross mining model (GMM). This precluded a pure incremental analysis of the different options but allowed SMC Technical Services to construct 20-year cash flows for each different haulage option, which consider all gross mining costs with respect to each plan, the revenue stream generated for each plan based on metals price assumptions, and downstream processing and commercial cost combined with applicable credits.

It is important to evaluate both annual cash flow and cumulative cash flow. The option with the highest cumulative cash would logically be the best option but may not be the desired option if annual cash flow is negative for 1 or more years.

Net cash flow (NCF) from each option was taken directly from option-specific cash-flow models and compared to perform an economic analysis considering mutually exclusive projects. The NPV for each cash flow is considered. Incremental analysis is then applied to derive incremental NPV values and ROR. Based on the analysis, the following results are relevant:

- NCF in all options are positive values; there are no negative years. This is due to full consideration of revenues and costs via the GMM, applied to what are relatively small capital costs and incremental capital costs of the haulage options.
- Using a discount rate of 10%, the electric trucks option is the best economic choice based on NPV. The incremental NPV for the cash-flow comparison confirms this with a

cash-positive incremental NPV, and a positive incremental ROR. Present value ratio is also favorable.
- In the absence of the electric trucks option, the shaft-deepening option becomes economically favorable. Increasing the discount rate in the analysis to 20% indicates that the base-case option is the economic choice based on NPV, where the shaft-deepening option has more cost in forward years. The diesel truck option was eliminated because of ventilation constraints and the logistics of operating eight trucks in the ramp system.

MECHANICAL EXCAVATION METHODS OF DEVELOPMENT

Because of the many advantages of mechanical mining when the physical properties of the rock and the tools are right for cost-competitive excavation, hard-rock mining companies keep trying to push the edge of technology so they, too, can benefit from mechanical mining. While it has been a very slow process of change, there have been a few notable successes. The principal advantages to mechanical excavation are

- Improved personal safety;
- Minimal ground disturbance;
- Reduced ground support needed;
- Minimum overbreak, thus less material to move;
- Minimal ground vibration or air blast;
- Uniform muck size;
- Reduced ventilation requirements;
- Continuous operations;
- Conducive to automation of system;
- Where the system is applicable, higher production rates; and
- Where the system is applicable, reduced tunneling costs.

The disadvantages to mechanical excavation are

- In hard rock, the system may have a poor penetration rate;
- In hard or abrasive rock, the system may have a high cutter cost;
- Some mechanical systems are not easily adaptable to changing ground conditions;
- It may lack flexibility of operations (TBMs can't cut sharp curves); and
- It often has a very high initial cost for the mechanical excavating equipment.

For designing a TBM for mine developments as compared to civil applications, Friant (2001) makes the following design recommendations:

- Multiple-speed cutterhead—An infinitely variable drive with high/low-speed torque is needed for broken ground changing to solid ground. A variable frequency drive is available.
- Closed or shielded-face cutterhead—Recessed cutters combine with radial bucket openings that extend toward the center of the head. Cuttings should not have to drop all the way to the invert through the slot between the rock face and cutterhead shield to be picked up. Back-loading cutters should be mandatory. There is no excuse for a fatality due to rock falls while changing cutters.
- Adequate shielding for rock support—Shielding, sometimes covering a 360° area, should extend up nearly to the gauge cutters. Adequate space must be provided near the cutterhead to install bolts and ring beams. Shields should not have wide gaps that allow small rocks to rain in. Shields should be active (i.e., with hydraulic adjustments) so if the machine gets squeezed, it can release itself.
- Soft-touch grippers—Grippers, if applied with too much pressure, can break up the tunnel wall and cause massive cleanup jobs after each push. Putting pressure on the crown should be avoided.
- A small length/diameter ratio—Either the whole machine length or its segment lengths dictate the radius curve through which it can bore. Often a 30-m (100-ft) radius is desirable on a midsize machine. A short stroke is an acceptable way to achieve the short turn radius desired. Continuous boring systems are desirable (i.e., with two sets of grippers), but only if they do not compromise other requirements of shielding and grippers.
- Mobility—A machine needs the ability to back out of its own tunnel, break down into manageable size subassemblies, and come apart and go together quickly. This may be achieved by the machine itself or through accessories for the machine. It must be kept in mind that in a mine there will often be many short tunnels as opposed to one continuous drive.
- Access for drills—In addition to rock-bolt drilling, the machine must supply access for drilling for grout curtains, spiling, soil stabilization, probe holes, and drain holes.
- Design simplicity—The simplest methods of thrust, steering, and control must be used, not those that are the most clever. Human-engineered controls and safety systems should be incorporated.

In soft material, such as coal, borax, potash, and trona, the applications of mechanical excavation are too numerous to mention. However, the successful hard-rock applications in mining are covered by a few examples:

- Stillwater Mining Company—Three different TBMs have been used to drive very long lateral drifts that are used first for ore-body delineation drilling, and then for main-line haulage. The rock has an unconfined compressive strength (UCS) ranging from 87 to 165 MPa (12,500 to 24,000 psi). The first machine used had trouble following the curvature of the ore strike, but the latter two machines were built for underground mine applications and were more adaptable. The biggest benefit for using the TBMs was time saved in the development schedule (Bullock 1994).
- Magma Copper Company—To expand the mining from the San Manuel (Arizona, United States) mine, a 4.5-m- (15-ft-) diameter TBM was used to drive 3,156 m (10,353 ft) of development during preparation for panel caving of the Kalamazoo ore body. The UCS of the rock ranged from 150 to 180 MPa (21,755 to 26,105 psi). The tunneling involved some 150-m- (500-ft-) radius curves and a decline of 5.5% (Bullock 1994).
- Heinrich Robert mine—At this coal mine in Herringen, Germany, a Voest-Alpine AM 105 roadheader was used to drive a drift 38.5 m^2 × 3.9 km (421 ft^2 × 2.3 mi). The rock is a massive quartzite sandstone with a UCS of 119 to 167 MPa (17,259 to 24,235 psi). During a period of 1 year, the machine averaged 5.6 m/d (18.5 ft/d), which included arch support on 1-m (3.3-ft) centers (Bullock 1994).

Table 12.5-1 Typical underground development estimated costs in 2009 U.S. dollars*

Development Item	Dimensions in Metric Units	$/m (Accuracy ±25%)	Dimensions in English Units	$/ft (Accuracy ±25%)
Drifts and crosscuts	3.7-m w × 4.0-m h, bolted	2,790–3,100	12-ft w × 13-ft h, bolted	850–950
Stope crosscuts	3.4-m w × 4.0-m h, bolted	2,550–2,900	11-ft w × 13-ft h, bolted	780–880
Stope attack ramps	3.0-m w × 3.0-m h, bolted	1,950–2,050	10-ft w × 10-ft h, bolted	600–630
Decline (contracted)	4.9-m w × 5.5-m h, bolted, and 152-mm shotcrete	6,900	16-ft w × 18-ft h, bolted, and 6-inch shotcrete	2,100
Ventilation drift	4-m w × 4.6-m h, bolted, and 76-mm shotcrete	3,850–4,050	13-ft w × 15-ft h, bolted, and 3-inch shotcrete	1,175–1,230
Ventilation raise	2.4-m diameter, raisebored and lined	6,250	8-ft diameter, raisebored and lined	1,900
Pump station, shops, stores, etc.	10.7-m w × 6.1-m h × length needed for m^3, bolted, and shotcrete	19.0–20.70/m^3	35-ft w × 20-ft h × length needed for ft^3, bolted, and shotcrete	5.80–6.30/ft^3

*Fairly fractured and weathered ground located in central Nevada requiring regular bolting with split sets on 1.2-m (4-ft) centers.

Other Types of Mechanical Excavation

Several other types of tools have been tried in mechanical excavation (Bullock 1994):

- Impact breakers (tunnels in Italy)
- Machines with disks on rotating drums (mobile miners)
- Machines with disks on rotating, programmable arms (continuous mobile miner)
- Various microboring machines

DEVELOPMENT COST ESTIMATES BY DRILL-AND-BLAST

It is not extremely useful to present cost estimates for developments, because the many variables of the rock types, rock-mass conditions and strengths, water condition, size, inclination, and use will affect cost. However, a few examples are presented in Table 12.5-1.

In another example, the Stillwater mine contracted two Alimak 3.35-m- (11-ft-) diameter raises, driven an average of 521 m (1,705 ft) for a cost of $5,612/m ($1,700/ft) in 2005 and 2006. When escalated to 2009 costs, this approximates to $6,600/m ($2,000/ft). There were two reasons why the raise climber was used for these ventilation raises, rather than using upreaming with a raise-boring machine: (1) there was no access to the top of the mountain in this isolated area and everything would have had to have been transported by helicopter; and (2) permitting to build a heliport and raise-boring site would have been difficult to obtain in this pristine area.

In the end, designers and consultants must remember that in planning a mine project, unlike a civil project, the product is not the hole: the hole is only a means to get at what you came for, the ore. Versatility, capability, flexibility, and at times raw power are the features that count.

ACKNOWLEDGMENTS

The author acknowledges the assistance of Curt Jacobs, Brent LaMoure, and the Stillwater Mining Company for their assistance in furnishing both development trade-off study information and the Alimak raise mining costs used in this chapter. The assistance of Dave Linebarger, a mining consultant from Elko, Nevada, is also acknowledged for furnishing typical underground development estimated costs.

CHAPTER 12.6

Construction of Underground Openings and Related Infrastructure

Joe Cline

INTRODUCTION

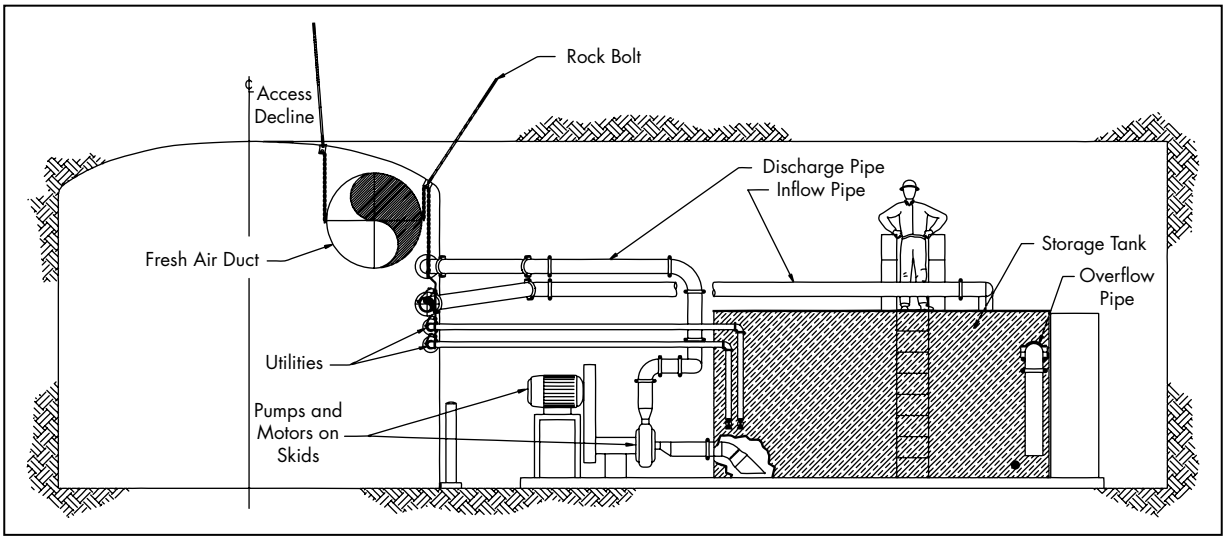
The extraction of deep mineral deposits usually requires the development of significant underground infrastructure in the host rock. Construction of these openings constitutes a major aspect in the development of an underground mine. Depending on their use, development openings will assume various sizes, shapes, and orientations. The openings must be large enough to provide ample space and perform the intended functions to support the underground mining process with allowances for the geologic and geotechnical characteristics of the rock mass.

Mine excavations are categorized into two distinct groups: excavations that are used primarily for rock handling and excavations that are used for service. Development openings that fall in the latter category are considered permanent or semipermanent, usually with an operating life equal to or exceeding that of the operating mine. Thus the locations of these excavations are particularly critical in the overall mine infrastructure plan; they must be designed and constructed to meet rigorous performance standards while maintaining their operating role.

In the development of underground mine openings, the design and construction aspects of the excavations must be considered concurrently. The design aspect will address the size, location, and ground support requirements of the openings with respect to the geotechnical characterization of the host rock to ensure the associated equipment can be installed and any unfavorable geologic/geotechnical conditions will be accommodated. The construction aspect will address the excavation methods and equipment, excavation sequencing, and integration of the development with the associated construction activities.

A significant portion of the underground development schedule is normally dedicated to the construction of major mine service facilities such as pump rooms, crusher rooms, underground maintenance shops, ore bins, orepasses, loading pockets, ventilation and haulage drifts, and so on. In hard-rock mines, the openings for most of these facilities are normally excavated using drill-blast-muck cycles. Vertical and inclined openings, including raises and orepasses, can be excavated using either drill-and-blast or semicontinuous methods (such as raise boring). Accessibility requirements are critical as well in order for mobile equipment and workers to gain access and construct the associated facilities.

Each underground facility has a significant role in the continuous operation of the underground mine. The decisions that are made from the development of the design (such as operational redundancy) to the operation and maintenance phase (such as implementation of control systems and periodic maintenance) are critical in ensuring constant, uninterrupted mine operations. For instance, the pumping system for an underground mine facility with high water inflows would be designed and implemented with enough redundancy to ensure that in the event of a system failure, auxiliary equipment is present that can be commissioned immediately to augment the primary system until such time that repairs are completed and the primary pumping system can be put back into operation. The ultimate reasoning behind designing and implementing redundancy in most underground mine service facilities is to ensure (with economic considerations for capital expenditure) a safe working environment and eliminate or significantly reduce the potential for catastrophes that could result in the eventual loss of revenue.



UNDERGROUND OPENINGS AND RELATED INFRASTRUCTURE

A number of underground openings and related infrastructure are common to most underground mine operations. They include developments such as access drifts, ventilation drifts, sumps, refuge stations, battery rooms, and so on. Major infrastructure such as conveyor galleries, underground crusher chambers, pump rooms, sumps, and underground maintenance shops normally involve significant capital expenditure but are necessary facilities in underground mining operations.

Sumps and Pump Rooms

Sumps and pump rooms are used in underground operations primarily to collect and manage water in and around the mine

Figure 12.6-1 Unitized storage tank and pump arrangement

workings. Water inflow in a mine can occur from the following primary sources:

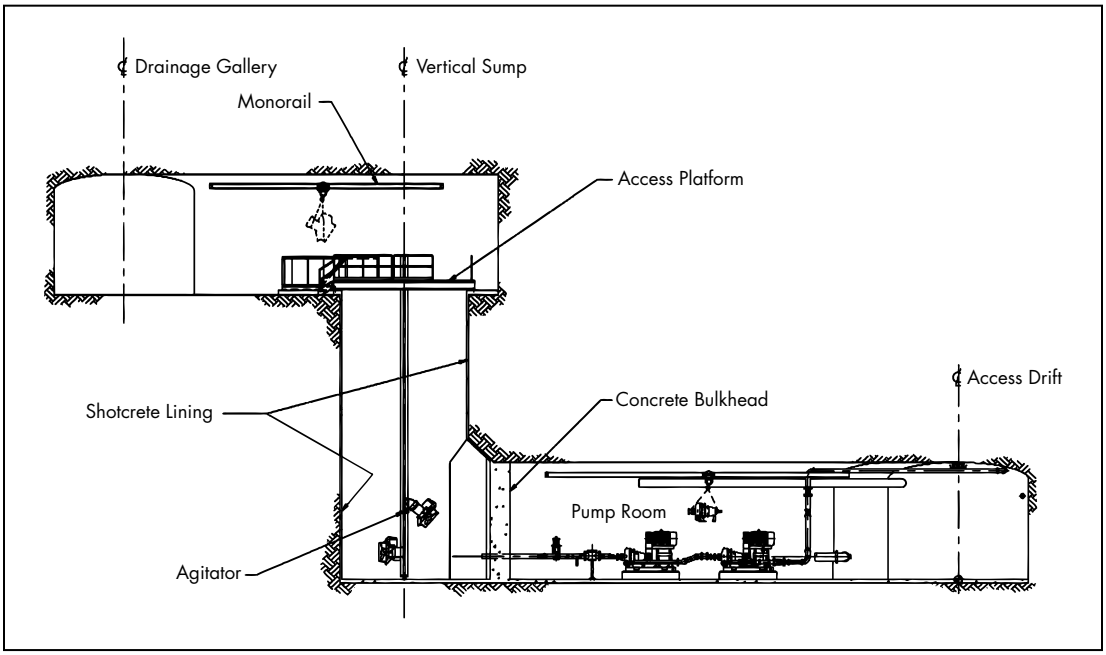
- Drilling and other associated activities during underground development and production (service water)
- Groundwater inflows

In either case, the water must be effectively handled by locating, designing, selecting, constructing, and maintaining a dependable storage and pumping system. The size and configuration of the pumping system depends largely on the predicted amount of water inflow to the mine. Depending on the predicted water inflows, the water handling system arrangement may consist of

- A series of drainage ditches, channels, and pipes at different working levels that direct water to sumps; the water is then stored and ultimately pumped to the surface either with a single high-efficiency pump or by a series of pumps; or
- Drainage galleries or drifts used to transfer water to a central sump or storage facility and then pump it to the surface.

The first arrangement is best suited for small to medium water inflows (up to several hundred cubic meters per hour) where large inflows not anticipated in the hydrologic study could overwhelm the pumping system. The second arrangement is suited for underground operations with large water inflows (several thousand cubic meters per hour) where hydrologic studies indicate there is a potential for flows to peak beyond those predicted.

Common characteristics of underground sumps and pump rooms include the following:



- Excavation and concrete structures for the sump capacity and pump room size
- Concrete bulkhead(s) for the sump containment, equipment foundations, and pipe support structures
- Access platforms and walkways to provide for equipment inspection and maintenance
- Mechanical equipment (pumps, motors, piping, and associated appurtenances)
- Power, electrical, instrumentation, and control equipment (switchgear, mine load center, drives, etc.)
- Lifting devices (monorails, cranes) for removing major equipment and reassembling after service

Figures 12.6-1 through 12.6-3 illustrate three varieties of underground pumping system arrangements that are common in underground mine operations.

In the majority of cases, underground mine pumping systems are designed to handle suspended solids that can be abrasive (depending on the size and distribution of the particles in suspension) on the pump components that are in direct contact with the carrier liquid. Loss of pump operating efficiency due to wear of pump components is a major concern in underground mine operations. The pumps specifically designed for this type of application are referred to as slurry pumps.

Centrifugal pumps and positive displacement pumps are the two most common types of pumps used in underground mine applications. Other pumping arrangements, such as those employing multiple-stage vertical or horizontal pumps, have been employed in underground mining for pumping clear water. These do not handle suspended solids well and thus require the excavation of settling sumps. Vertical deep-well pumps are unpopular in conventional mine dewatering because the entire pump column needs to be removed to access the pump for repair or maintenance; however, they are typically used when dewatering a flooded mine.

The pumping unit illustrated in Figure 12.6-1 is one of several skid-mounted packaged units that comprise the entire pumping system. This type of pumping system is commonly used during the early development of a mine. The pumping arrangement can consist of multiple units of similar design connected in series and located at specific elevations within the mine to collect and transfer water upstream from the lowest extremities of the mine workings. Each unit can incorporate single or multiple centrifugal pumps with motors driving the pumps integrally or via V-belt drive systems. Typically, each unit discharges water upstream into the storage tank of the successive unit in the pumping circuit. The setup in Figure 12.6-1 can potentially handle flows up to several

Courtesy of Barrick Gold and Stantec – Mining.

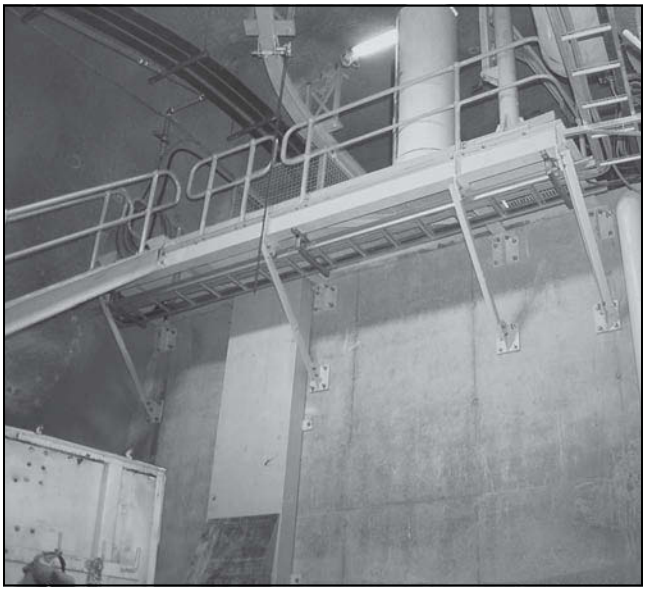
Figure 12.6-2 Combined vertical sump and pump-room arrangement

hundred cubic meters per hour; the actual performance is contingent on the total head to overcome, the number and size of pumps per unit, and the total number of units within the pumping circuit.

Figure 12.6-2 (also shown in plan view later in Figure 12.6-21) incorporates a vertical sump that is located directly upstream of a pump room. A concrete bulkhead separates the sump compartment from the pump room. In this type of arrangement, particular attention is required to locate, design, and construct the bulkhead to ensure stability and provide a watertight seal around the rock–concrete interface and at penetrations through the concrete bulkhead. The sump walls are typically lined with shotcrete or concrete to limit and/or eliminate any seepage into the surrounding rock and to maintain the integrity of the rock wall.

Pumps are usually erected on a concrete pump base that is raised several centimeters above the pump room floor. This arrangement prevents equipment from coming into contact with water in the event of a pipe leak or other malfunction. An overhead crane or monorail is usually provided to aid initial installation and for removing and replacing pump components. The pumping arrangement shown in Figures 12.6-2 and later in 12.6-21 consists of multiple banks of pumps, each having multiple centrifugal pumps connected in series. The number of pump stations that are required to make up the complete pumping system depends on the pressure rating of the pumps.

Contingent on the quantity and specific gravity of suspended solids in the carrier liquid, agitators may be installed inside the sump to keep solid particles in suspension at all times. This type of layout provides the following advantages:



- Can be used to provide redundancy in a mine's pumping system where only one bank of pumps operates at any time while the other is on standby
- Allows for the possibility of installing additional banks of pumps should there be a future demand for more pumping capacity
- Supports the ability to perform equipment maintenance or repair without a complete system shutdown

Courtesy of Northparkes Mines.

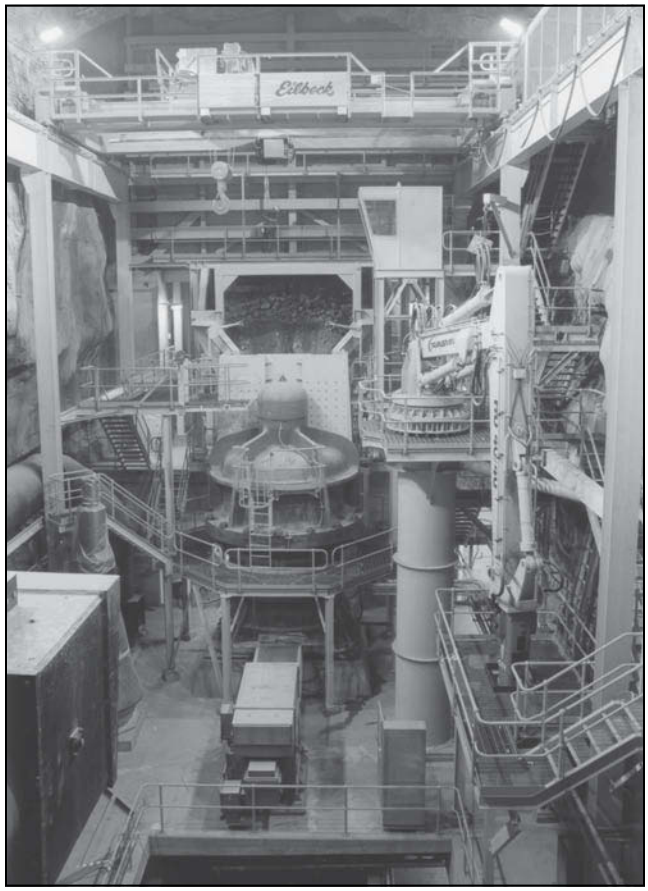
Figure 12.6-3 Remote sump and pump-room arrangement

The primary pumping equipment shown in Figure 12.6-3 comprises multiple piston diaphragm positive displacement pumps, complete with electronics and other accessory features. Each unit is capable of operating at up to 1,000 m of head at low flow rates, and up to about 90 m^3/h at lower heads. They are efficient in handling high concentrations of solids. The figure also illustrates an arrangement where the pump room is located

Courtesy of Northparkes Mines.
Figure 12.6-4 Remote sump at an underground pump station

in a separate excavation that is completely independent of the storage reservoir/sump cutout (see Figure 12.6-4 for sump illustration). Water is fed to the pumps by pipes running from the sump to the main pump-room intake. Unlike Figure 12.6-2, allowance is made immediately above the concrete bulkhead to access the agitator (the agitator keeps solids in suspension) and other equipment in the sump. Pumping arrangements of this type offer several operating advantages, including

- Pumping of dirty water,
- Operating under high static heads,
- Pumping in a single lift without the need for multiple intermediate pump stations,
- Operating at a high efficiency, and
- Eliminating the need for large settling sump cutouts.



Crusher Rooms

Underground crushers are used to reduce run-of-mine ore or waste to a size that is suitable for the materials-handling system to transport to the surface. Crusher chambers can be the largest single excavation and infrastructure development in an underground mine. Substantial capital expenditure normally goes toward the planning, design, procurement, and construction of these underground facilities. An underground gyratory crushing station is illustrated in Figure 12.6-5.

Critical information necessary for making a decision regarding plant suitability and final underground crushing arrangement includes

- Location,
- Access,
- Mining method,
- Ground conditions,
- Ore properties, and
- Required support facilities.

The underground ore transport network must be integrated with the crushing plant location and design, as the mined ore must be transported and fed into the plant for crushing before being transported to the surface.

Courtesy of Northparkes Mines.
Figure 12.6-5 Gyratory crusher

Underground crushing operations can be classified as single-stage or multistage (i.e., primary crushing or primary–secondary crushing). The size and complexity of the facility depend on the number of crushing stages. Because of advancements in belt conveyor equipment and other associated materials-handling systems (to handle larger and more abrasive materials), most modern underground mines only need to install a primary crushing system. There is also an added capital and operating cost–savings benefit that can be realized through elimination of a stage in the overall crushing circuit. Some underground mines in the past have implemented multistaged crushing operations. In the 1970s, ore produced from underground operations at the Climax mine in Colorado, United States (currently abandoned) was crushed by primary and secondary crushing at their No. 4 crusher station.

In hard-rock mines, gyratory and jaw crushers are most commonly used because of their proven capability in breaking hard rock. Sizer technology is advancing to the point where they are now suitable for size reduction of hard rock. Feeder breakers are more successful in softer ores. In coal mines where rock fragmentation activities are not as aggressive, other crushing plant alternatives (such as roll and impact crushers) are more predominant. When developing underground crusher rooms, the following must be considered:

- Location (remote or central) with respect to ore delivery and conveyance after crushing

Courtesy of Northparkes Mines.

Figure 12.6-6 Underground shop service bay with overhead crane

- Crusher chamber access (primarily for maintenance and supply of spare parts)
- Excavation size, stability, ground control, geotechnical instrumentation, and monitoring of the rock mass around the chamber
- Overhead cranes of suitable capacity and other localized lifting devices within the chamber
- Dump pocket (truck or rail dump) and coarse ore surge bin
- Oversize handling arrangement at truck and rail dumps (grizzly, rock breaker, etc.)
- Crusher, drives, mountings, control room
- Concrete structures supporting the crusher, drives, and motors
- Crushed ore loading pocket beneath the crusher or remote surge bin
- Pan feeders, impact feeder belts, screens, and belt conveyors
- Access platforms and walkways
- Dust collectors, scrubbers, and crusher room ventilation
- Power, electrical, instrumentation, and control equipment (substation, switchgear, drives, etc.)

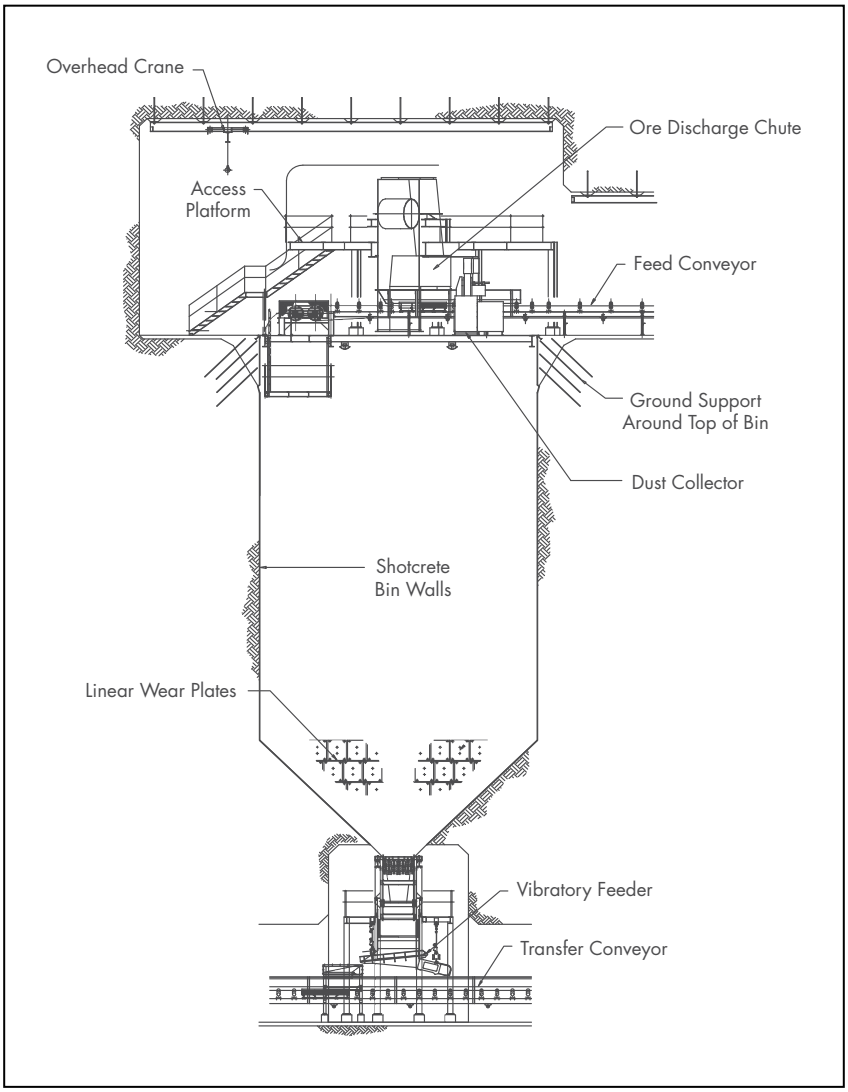
Underground Maintenance Shops

When no direct ramp access exists between the underground operation and the surface, or when the access decline is too long to tram equipment to the surface in a reasonable time frame, a shop and maintenance facility may be constructed underground to service and repair mobile and stationary equipment. In mines with only shaft access, major equipment is normally transported, assembled, and maintained underground.

After commissioning and operating, major equipment often only leaves the underground mine for replacement or major rebuilding in a surface or off-site shop. An underground shop is a major lifeline for the mobile fleets in an underground mine. The main advantage of locating a shop facility underground is for close proximity to the operations so scheduled maintenance and emergency repairs can be completed promptly with less equipment downtime.

Whether fleet maintenance is contracted out to a separate entity or performed by the mine's own personnel, it is essential to establish an ergonomic layout for the shop plan that is safe and maximizes service to equipment with easy access to supplies, spares, and consumables so that equipment times in the shop are limited. For this reason, multiple entry and exit points in the shop must be created to ensure that immobilized equipment undergoing repairs will not hinder the exit or entry of other equipment. When an underground mobile fleet is comprised of both rubber-tired and track equipment, underground maintenance of both types of equipment must be available. The maintenance requirements for track equipment (such as work on engines, braking systems, and other critical locomotive components) are fundamentally different from those of rubber-tired equipment. For these reasons, it is essential to have a dedicated repair shop for track equipment that is independent of the primary maintenance shop. Underground shops are often equipped to replace components such as engines, transmissions, axles, buckets, and so forth.

An essential component of any underground shop is the overhead crane and other associated lifting devices (see Figure 12.6-6) used to move heavy components around the shop floor. Other items of prime importance in an underground shop include



- Ventilation inside the shop;
- Fire protection;
- Access in and around the shop;
- Number of bays and their function;
- Types and level of services to be performed;
- Supply and management of consumables;
- Management of spent hydrocarbons, lube, and gray water;
- Shop lighting and illumination;
- Compressed air supply;
- Storage of tires, spare parts, and tools; and
- Equipment cleaning.

Ore Bins

Ore bins are used primarily for temporary storage of ore underground before final transport to the surface. Depending on the location in the ore circuit and the materials handling methodology, ore bins are generally referred to as run-of-mine or coarse-ore bins when used to store ore that has been sized with a grizzly or sizer, or that discharges from the primary crusher.

Because of the cyclical nature of ore extraction from the mining face, an underground ore bin provides the surge capacity necessary to maintain a constant flow of the ore stream. The material to be stored is normally fed into the bin via trucks, rail, belt conveyor system (typical for remote bins), directly from a system of orepasses, or directly from the crushing plant (if located directly beneath the crusher). The content of the bin is later discharged from the bin bottom through a hopper-chute arrangement for further ore transport by a belt conveyor, rail, or truck system.

Ore bin design and construction depend on a variety of conditions, but, most importantly, on the type and condition of the host rock. In massive hard rock, ore bins are normally excavated in and integrated with the host rock (Figure 12.6-7). In other rock environments (such as medium, soft, or sedimentary rocks), ore bins are predominantly constructed as independent structures in order to limit the effect of any

Courtesy of Stantec – Mining.

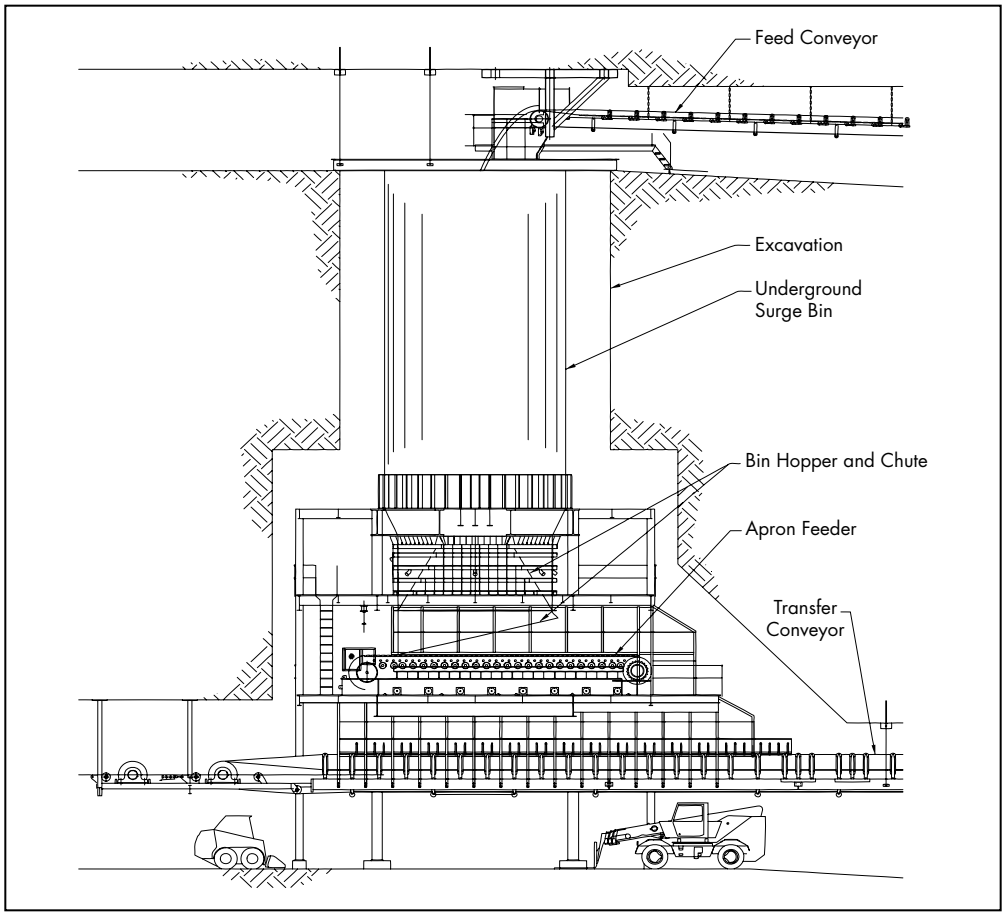


Figure 12.6-7 Ore bin and associated infrastructure in a hard-rock environment

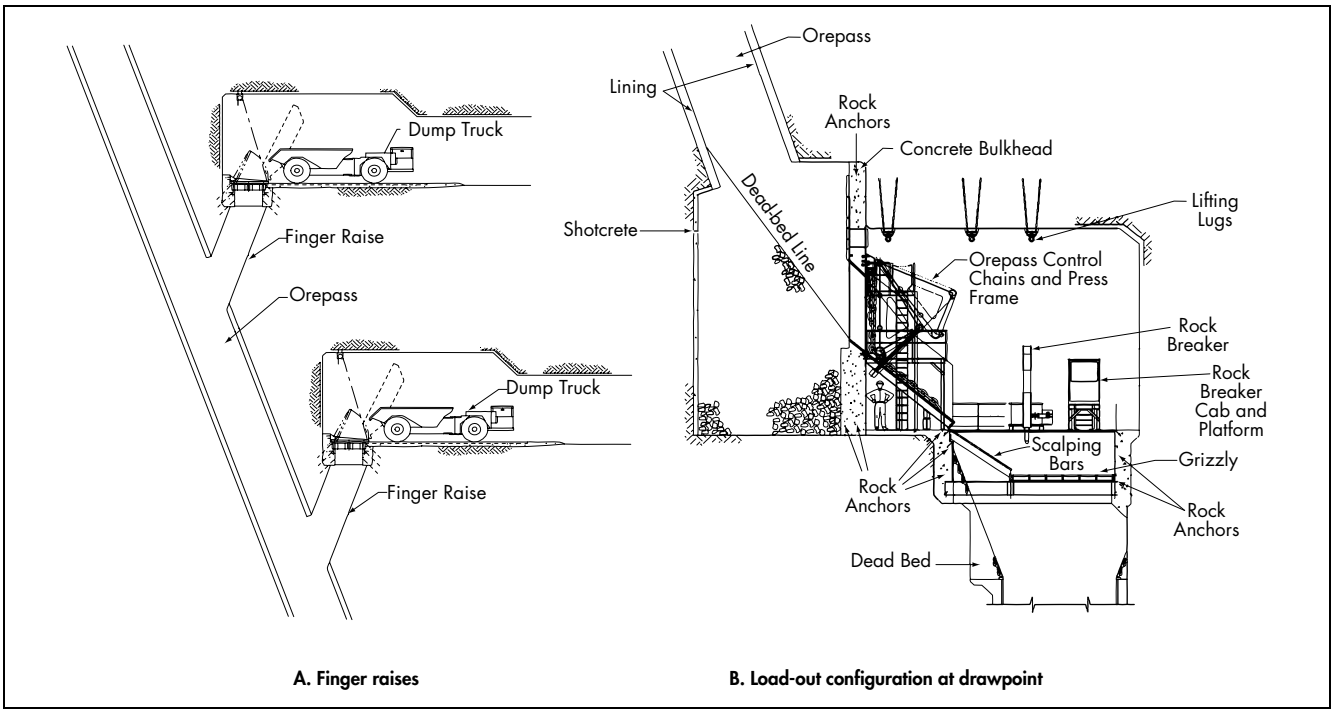
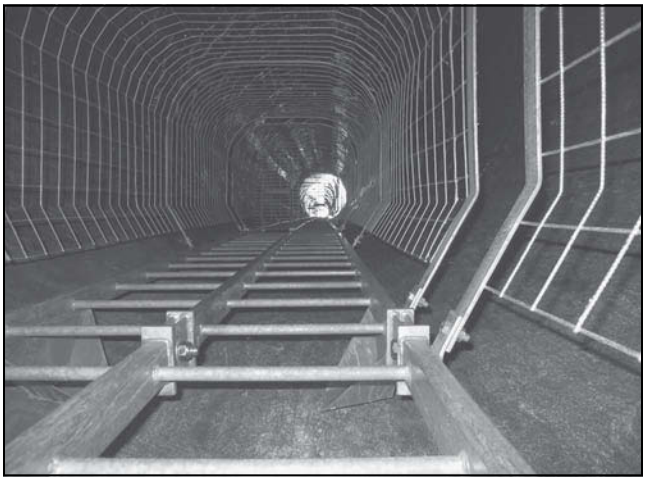
potential ground movement on their ongoing performance (see Figure 12.6-8). Following are other important decision factors to consider with underground ore bins:

- Permanent access
- Access during bin development and construction
- Surrounding rock type and ground support requirements
- Location (above or beneath crusher, remote, close to hoisting plant, etc.)
- Size and capacity (based on production rate, scheduled, and/or nonscheduled shutdowns). Refer to the "Storage Pocket (Skip Pocket) Size" section in Chapter 12.5.
- Shape (circular shape most common, can also be rectangular)
- Associated materials handling infrastructure (feeders, chutes, conveyors, other materials handling equipment) to aid in transporting the material effectively
- Bin wall lining and other materials of construction (depending on abrasiveness of the stored material and characteristics of the host rock)



Ore- and Waste Passes

Passes are vertical or subvertical raises that are excavated in the host rock for transporting ore or waste by gravity flow from the upper levels in a mine to a predetermined lower level. Orepasses can be used to improve underground equipment productivity because they minimize overall travel distances from the ore loading point to the final ore dump point. The location and design of the orepasses are therefore critical in mines that primarily haul waste and ore with trackless equipment. Orepasses commonly run subvertically and may connect production levels by means of finger raises, as shown in Figure 12.6-9A. The top of the pass and finger raises, are usually equipped with a rock-sizing mechanism (such as a grizzly) to ensure that oversize materials which can potentially cause hang-ups in the pass are reduced in size. A load-out control mechanism (such as a discharge chute, chain controls, and press frame) is usually installed at the lowest point of a drawpoint, as illustrated in Figure 12.6-9B. Following are some major items to consider in underground orepasses:



Courtesy of Potash Corporation of Saskatchewan–Allan Division.

Figure 12.6-8 Ore bin and associated infrastructure in an underground potash mine

Figure 12.6-10 Access ladderway looking from top to bottom

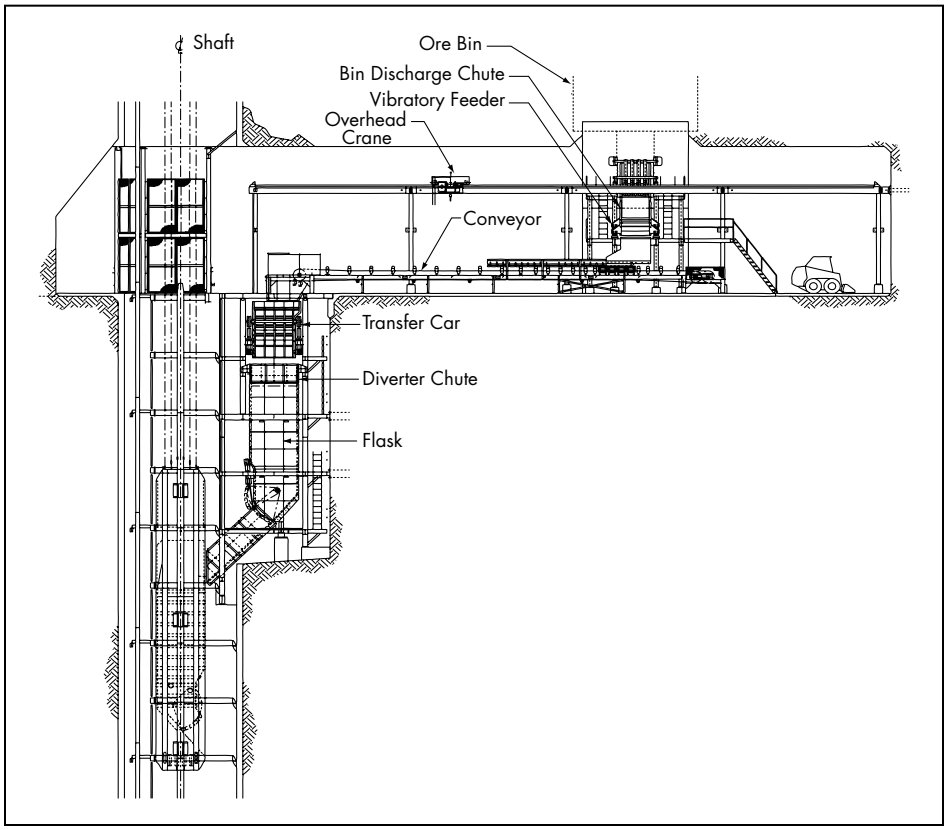
Courtesy of Stantec – Mining.
Figure 12.6-11 Emergency hoist and escape pod

- Shape and size of the orepass, enough to prevent material hang-ups
- Stability of the orepass
- Maximum interval spacing between successive passes
- Orepass inclination
- Daily and total tonnages anticipated
- Type and orientation of ore body
- Material characteristics (fines, moisture content, particle size, etc.)
- Load-out configuration at bottom
- Static pressures on load-out mechanism
- Effect of impact on load-out mechanism (from release of material hang-up or material falling down an empty pass)

Emergency Access

A secondary means of egress is required in all underground mine operations and normally governed by local mining regulations. An emergency access (worker access) is a secondary means of egress that is provided primarily for miner exit from the underground workings in the event of a fire, temporary loss of electric power, or any other occurrence warranting worker evacuation. It is important that emergency exits are located in an area where the ground is stable and the serviceability of the facility can be guaranteed and will not be hampered if the primary means of egress is blocked. A worker access is a vertical or subvertical shaft that is constructed by drill-and-blast or raise bore and is normally located within the mine's fresh-air intake network to ensure the presence of fresh air in the shaft at all times when in use. During the development phase of the mine, rather than install a separate worker access shaft, one of the compartments of a hoisting or ventilation shaft could be dedicated to emergency access. (After a U.S. mine is in the operating phase, the Mine Safety and Health Administration [MSHA]requires a separate entry as an escapeway.) A worker access is usually equipped with one of two evacuation systems, illustrated in Figures 12.6-10 and 12.6-11: an access ladderway, or an emergency hoist and escape pod.

If an emergency hoist and escape pod system is implemented, provision must be made for standby electric power (provided the emergency hoist is not powered by an internal combustion engine) to operate the hoist in the event of an electric power failure. Following are some major items to consider in designing and constructing a worker access (emergency exit):



- Depth of mine operations from the surface
- Type of primary access (shaft or decline)
- Type of evacuation system
- Mine environment (corrosive, may require galvanized steel components)
- Cost

Loading Pockets

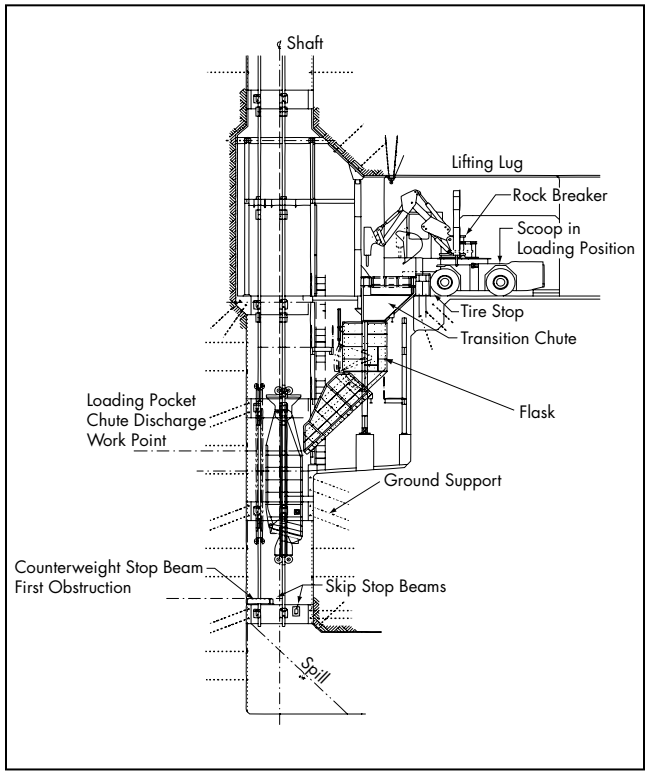
Loading pockets are used to feed ore or waste into skips in a production shaft system. Crushed rock or run-of-mine ore is conveyed and discharged into flasks at the loading pocket by rail, belt conveyors, or mobile equipment. The flasks at the loading pocket serve as a temporary underground repository for rock waiting to be fed into production skips. Several factors, including the following, govern the design and construction of loading pockets:

- Shaft production rate
- Shaft layout and design
- Type and capacity of the skips
- Method of ore (or waste) delivery to the loading pocket
- Construction methodology
- Ground support requirements

Loading pockets consist primarily of steel structures and usually must be integrated with the shaft steelwork at the skip's loading level. It is important that the whole infrastructure around the loading pocket be designed to effectively sustain impact loads from falling rock without inducing undue stresses and movement that could hinder its performance. The design of the loading pocket excavation is therefore important to ensure the structure's long-term stability and must incorporate adequate ground support. Ore delivery to the loading pocket can be semiautomated (with a belt conveyor system feeding from an ore bin or crushing facility) or by means

Courtesy of Stantec – Mining.

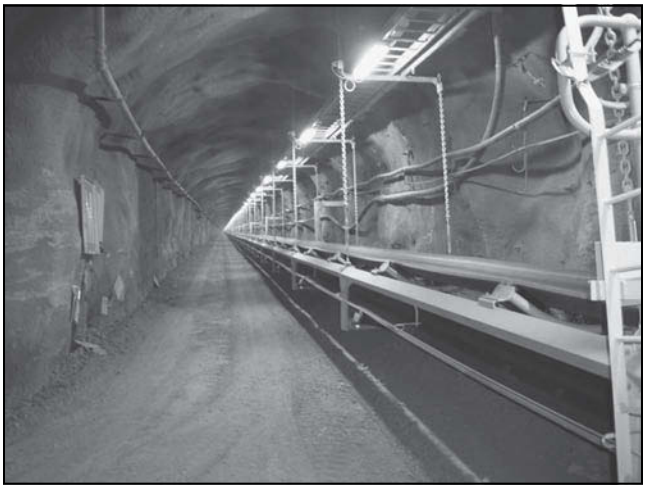
Figure 12.6-12 Loading pocket with belt conveyor feed



of mobile equipment (such as trucks and load-haul-dumps [LHDs]). Figures 12.6-12 and 12.6-13 illustrate typical loading pocket arrangements for both methods of ore handling.

Special Purpose Drifts

Conveyor, ventilation, and access drifts are three primary types of major lateral development that belong to the category of special purpose drifts. Common characteristics among all three underground openings include size (normally constructed to the smallest practical cross section to meet the service requirement), stability of the final excavations (usually over the life of the mine), and slope of the drift (to maximize equipment productivity in tramming).



Conveyor drifts are normally constructed with a minimum cross section to accommodate the associated equipment while allowing for access, maintenance, and material spill cleanup. They may or may not be inclined, depending on the vertical distance the conveyor has to travel. The belt conveyor equipment is normally supported from the back of the drift, as shown in Figure 12.6-14, usually with rock-bolted chain supports or on the sill of the drift with steel supports on concrete pedestals as shown in Figure 12.6-15. The former method of support is more cost-effective and can be installed faster. Depending on the size, capacity, and layout of the conveyor equipment, the drift may be overexcavated at the head and tail ends or transfer points to accommodate additional equipment such as drives, motors, take-ups, transfer tower structure, chutes, and access platforms (see Figure 12.6-16).

Access drifts have similar characteristics to conveyor drifts except that they are sized and constructed to accommodate

Figure 12.6-14 Belt conveyor supported from back of drift

Courtesy of Northparkes Mines.
Figure 12.6-15 Belt conveyor supported on sill of drift

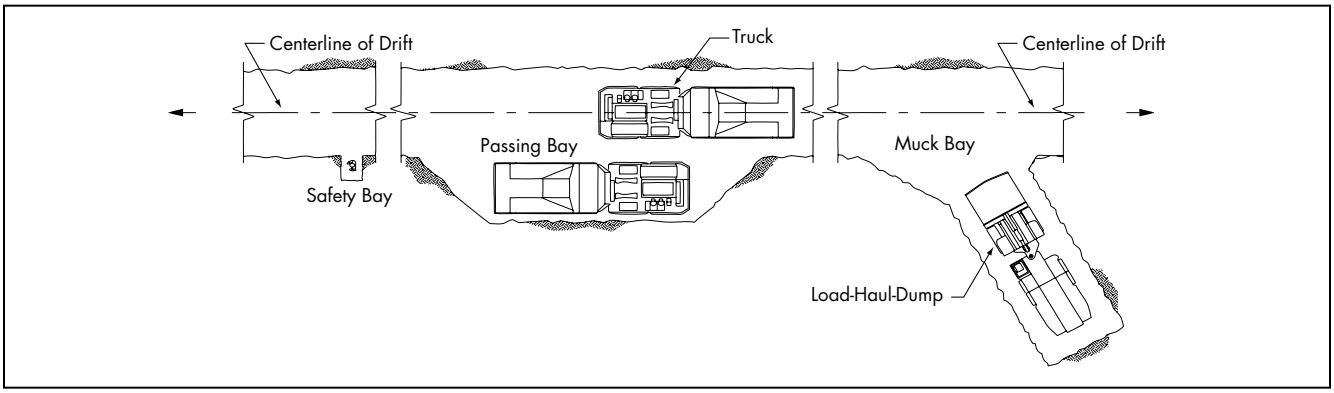
mobile equipment and utility lines where applicable. Passing bays (to accommodate two-way vehicular traffic), muck bays, and safety bays (where personnel and vehicular traffic interact) may be incorporated into the construction depending on the use of the drift, as in Figure 12.6-17. The layout and construction of an access drift must take the following into consideration: type and size of haulage equipment to be used (trucks and LHDs or rails); clearance requirements around equipment for passage of mine personnel; routing of ventilation ducts, pipes, electric cables, and other utilities as shown in Figure 12.6-18; vertical distances between successive mining levels; presence of spiral ramps; maximum slope of invert to minimize tramming effort and maintain equipment productivity; type of sill construction; and drainage requirements.

Ventilation drifts are essential for moving air into and from the underground mine workings. These drifts are the primary link between the ventilation shafts or ventilation decline and the underground mine environment, and are classified as follows:

- Intake drift—for taking fresh airflow from a fresh-air intake facility to the mine workings
- Exhaust (return) drift—for taking the mine's return air from the underground workings to an air-exhaust facility

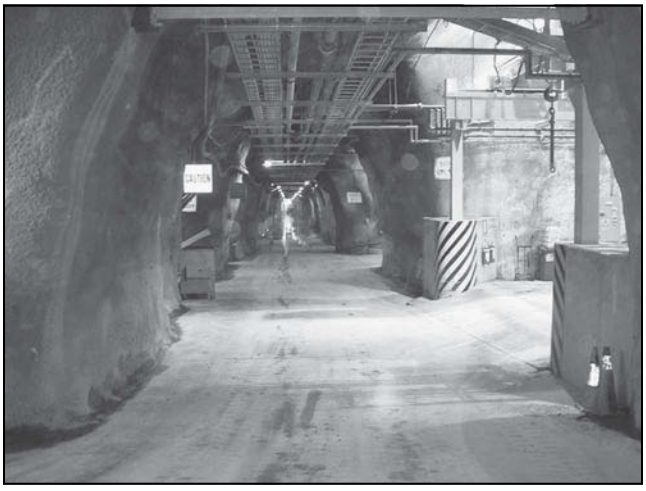
Most mine operations normally use the primary and secondary accesses for ventilation. However, large underground operations with large ventilation airflow requirements may require dedicated ventilation drifts, shafts, and raises. These ventilation routes are usually not accessible to personnel and equipment traffic because of the high velocity of air being moved.

Primary considerations in ventilation drift design and construction include the ventilation fan size and airflow velocity, total length of the ventilation circuit, excavation cross-sectional dimensions, roughness of the excavation wall (to limit friction losses in airflow), and stability of the excavation. The fan and associated equipment can be installed underground in the drift, at the ventilation shaft collar, or at the portal, depending on the system design and operating requirements. Figures 12.6-19 and 12.6-20) illustrate a ventilation decline and an underground ventilation drift, respectively. The setup in Figure 12.6-19 represents a ventilation system used



Courtesy of Northparkes Mines.
Figure 12.6-16 Underground conveyor drift and equipment at transfer point

in the interim (i.e., during initial mine development) until the required lateral development and permanent ventilation raise is completed. Fresh air is heated and, with the aid of booster fans located downstream of the heaters, drawn through heating plants and discharged through vent ducts that extend down the decline to the working face at all times. Return air is exhausted up the decline and at the portal.



DESIGN, CONSTRUCTION, AND MAINTENANCE

Development openings and their associated infrastructure are unique in terms of design approach and design methodologies. The interrelationship between various components of the infrastructure usually requires multiple design iterations. This can be further complicated by the intrinsic variation of the mechanical properties of the host rock in which the development occurs. Design methods are established on sound engineering principles combined with empirical concepts, research, and extensive practical experience. Because the design process can sometimes be quite involved, only the salient points concerning design criteria and design methodologies are addressed in this section.

Figure 12.6-20 Underground ventilation drift with fan

Underground mine infrastructures are normally designed and constructed with four primary materials of construction: steel, concrete/shotcrete, wood, and rock. In most modern mines, wooden structures have been completely replaced by steel and concrete components. Other types of construction materials (such as polymeric materials and carbon-fiber reinforced polymer) have recently been introduced in the underground mine environment but have not gained widespread acceptance because of limited performance data. Steel, concrete, and the host rock will continue to be the primary materials of construction in underground mine development for the foreseeable future because of their proven durability and the ability to accurately predict their behavior under service.

Design Aspects

The following key aspects must be addressed at various stages of the design of underground openings and related infrastructure:

- Scope of work—Including, but not limited to, the extent of work to be performed, the different engineering disciplines that will be involved, and battery limits
- Functional requirements—Including the intended purpose and performance requirements, end results to be achieved, effect of the underground environment on performance, size of excavation necessary, and location within the global infrastructure plan
- Design criteria—Including the key factors and information that govern the design development, size, shape, capacity, and ultimate performance of the completed facility
- Design development—The initial and final design of the facility must consider the following:
  - Duty requirement of the excavation
  - Maximum size of excavation needed to satisfy duty requirement
  - Geotechnical characteristics of the surrounding rock
  - Access limitations
  - Constructability
  - Materials of construction to be used
  - Impact of the facility's construction and operation on the mine environment
  - The underground environment's impact on the facility's serviceability
  - Possible methods of assembly of the various equipment
  - Supporting structures underground
  - System operating costs
- Planning and engineering—Including the potential impact of the new facility on existing operations, resource requirements (e.g., can engineering be completed in-house or must it be contracted out to a consultant?), and schedule for completion of engineering

Construction Aspects

The techniques, installation methods, and equipment normally employed during construction and installation depend on the type and size of the overall facility. The construction phase normally starts with planning of the various stages of construction and installation of the complete facility. The primary stages during construction and installation are

- Project preplanning,
- Procurement,
- Construction and installation,
- Schedule and resource management, and
- Closeout and commissioning.

Construction and installation aspects of the underground development must address the following:

- Safety—Implementation of a comprehensive and practical safety program. There are fundamental differences between the protocols of construction project safety and the safety protocols implemented by the mine operation group.
- Resource requirements—Ascertaining whether the work should be outsourced to an independent development contractor. (The mine may or may not have the equipment and/or skilled personnel available to self-perform construction.)
- Contractual—Preferred method of outsourcing (competitive bidding, single source, alliance, etc.).
- Construction resources—Materials, equipment, and services that can be supplied by the mine during construction (i.e., electric power, compressed air, water, concrete, shotcrete, etc.).
- Planning—Emphasis on minimizing interference with other ongoing mine operations.
- Infrastructure—Underground and surface infrastructure necessary to support the construction and installation work.
- Safeguards—Adequate lighting around stationary operating equipment, guards around rotating equipment, and so on.
- Access requirements and interface with existing mine operations.
- Construction equipment—Various pieces of equipment needed for each phase of the development, size, and capacities of equipment with respect to underground access.
- Waste handling—Removal of rock generated from excavation.
- Ventilation—Ensuring adequate ventilation of the construction area.
- Constructability—Construction methods and approach for each phase of the development.
- Installation sequencing—Consideration of construction equipment limitations.
- Construction management—Determination of whether the mine has the resources to dedicate toward management and procurement of supplies and equipment during construction and installation.
- Concrete—A versatile component in underground mine construction. It is used in almost all facets of underground development, from ground support to foundations for structures.

Blasting is a routine activity in underground hard-rock mines, and the resulting blast-induced vibrations, if left uncontrolled, can have detrimental effects on concrete structures. The level of impact of blast vibrations on a concrete structure is dependent on variables such as the distance of the structure from the blast initiation, the age of the structure, size of the structure, and type and amount of explosives used. Because it is common practice for concrete construction to occur in close proximity or adjacent to underground excavation development, blasting around newly constructed concrete structures should be considered during the design and installation

phases of underground mine development. The hydration and crystallization process in concrete normally occurs within 24 hours of placement. This period is very critical in all concrete structures because it is when the hardening and strength-gain process starts to occur. Normal concrete usually attains about 30%–40% of its compressive strength within 3 days and about 60% within 7 days of placement. Thus, blasting in close proximity to major new concrete structures is not advisable before 3 days following placement. Between 3 to 7 days following the concrete installation, blast vibrations adjacent to major concrete structures should be limited to that which produces a peak particle velocity of not more than 25 mm/s. After 7 days following concrete placement, a peak particle velocity of 50 mm/s or less should be used as a guide to limit blast vibrations until the concrete reaches its maximum strength around 28 days.

Project Preplanning

Tasks that are normally accomplished during preplanning include the following:

- After the contract has been awarded, become familiar with and understand the contract documents and general conditions of the contract. Arrange for independent services such as inspections and nondestructive testing, training, and so forth. This is particularly applicable to underground mine development contracts that are outsourced to an independent contractor.
- Determine and secure the various construction equipment (drill jumbo, LHD, haul truck, access platforms, mobile cranes, etc.) required for completing the work.
- Understand the ground conditions and plan the excavation, muck handling, and ground support sequence in accordance with the excavation designs.
- Establish procurement protocols and determine the long-lead items. Review their manufacture and delivery schedules and verify when they should be procured in order to avoid schedule disruptions.
- Establish availability of services and supply of all construction materials.
- Implement subcontracts for various fabrications (such as for miscellaneous steel structures, pipe spools, etc.).
- Plan the site set-up and administrative aspects of the site office, office equipment requirements, required project personnel, and so on (depending on the contractual arrangement).
- Arrange for transportation and schedule mobilization of resources to site.

Procurement

Procurement involves soliciting of suppliers and services; leasing of equipment; and purchasing and marshaling of permanent equipment such as pumps, electrical gear, overhead cranes, crushing equipment, lifting devices, and any other special item associated with the permanent installations. One aspect of the procurement process that must be addressed in the initial stage of planning is the on-site management of materials and equipment that are delivered for the construction of mine infrastructure projects. Planning for such undertakings (involving either a single major project or multiple small- to medium-size construction activities) must consider the logistics of transportation, sequencing of material delivery, and the need for adequate lay-down space and warehousing. It is advisable to manage construction project–related procurement separate from that of mine operations. A list of critical spare parts should be developed during the procurement stage. The procurement process can become lengthy when dealing with multiple vendor selection, whether prequalification-based or otherwise. Mine operations normally establish service agreements with suppliers and contractors that can be capitalized on in order to fast-track the procurement process.

Construction and Installation

Excavation methods. Raises, orepasses, and other vertical or inclined openings can be excavated by either drilling and blasting or semicontinuous methods such as raise boring, raise climbing, or drop raising. Ground conditions and rock type ultimately influence the excavation method chosen.

The most commonly employed excavation method for underground service facilities in hard-rock mines is drilling and blasting. Each drill-and-blast cycle follows a repetitive pattern consisting of blasthole drilling, charging and blasting, ventilation and dust removal, scaling, muck handling, and ground support, as described in the following paragraphs.

Work at the face is normally started by the mine survey crew that sets controls for the excavation and demarcates the excavation limits and layout of the blasthole drill pattern. The blasthole drilling sequence is normally arranged in a manner that maximizes drilling productivity.

Blasthole lengths are selected to complement the length of each round, which in turn are dictated by ground conditions and the maximum unsupported roof span allowed. Short rounds require short drilling depths, accomplished with a single-boom feed during fully mechanized drilling. All subsequent activities (face advancement, etc.) can be completed quickly because there are no equipment-related delays for handling drill rod extensions. In contrast, longer rounds require longer drilling depths, accomplished with multiple-boom feeds. Longer rounds can result in blasthole drilling inaccuracies, which can lead to increased drilling times, increased charging and blasting times, longer muck handling times (due to larger muck volumes), and larger roof spans to be supported.

After drilling is complete the holes are flushed, loaded with explosives, and prepared for the blast initiation.

Upon completion of charging and blasting, the blastholes are flushed with water (or other flushing agent, depending on the underground requirements). Out-of-reach blastholes are normally accessed with a work platform or basket. All equipment at the face is receded to a safe location prior to initiating the blast.

After the charging and blasting phase is complete, the face is ventilated to remove dust and fumes. Depending on the distance to the new working face, the vent duct and fan system may need to be extended to ensure that adequate fresh air reaches the working face.

Any loose rock on the excavation walls are removed by scaling. This process can be completed manually (by a worker in a basket with a scaling bar) or mechanically with a mechanized scaler. Manual scaling can be time-consuming and difficult. Mechanized scaling, on the other hand, is quicker and does not expose mine personnel to difficult working positions.

The muck handling phase commences after it has been determined that no potential rockfall hazards are imminent. Muck removal can be accomplished by one of the pieces of muck handling equipment listed in Table 12.6-1, or a combination thereof. For short rounds, high mucking rates may

be attained with only LHDs, depending on the muck volume and haul distance. For long rounds or where a large volume of muck is involved, other equipment combinations (such as trucks and LHDs) may be necessary in order to attain the required mucking speeds.

Hauling the muck away as soon as possible frees up the face for advancement and ultimately improves work cycles. As the distance to the face increases, the haulage distance and time increase as well. To free up the face for subsequent rounds, muck can be temporarily moved into muck bays excavated at regular intervals from the working face. The muck can later be hauled from the muck bay to the final dump location (as a separate operation off the critical path of other face-development activities) while the face is being further developed.

Ground support normally commences after the muck has been hauled away from the face. The type of required ground support depends on the excavation size and ground conditions. In poor ground conditions, it may be necessary to perform multiple ground support activities (initial and final) instead of a single activity at the end of each round. If the ground is fractured and roof stability becomes critical, initial ground support (such as with shotcrete and mesh) can be installed immediately after scaling to stabilize the excavation before mucking out completely. Final ground support (bolting, final shotcrete, etc.) can be installed after the muck has been completely removed and the excavation fully exposed for the next round.

Consideration should be given to the benefits of using the same drill jumbo for drifting and ground support installation; however, it may prove to be more cost-effective overall to obtain a separate jumbo for the ground support exercise. With a single jumbo, the bolt holes could be drilled while the muck is being hauled away. In large excavations and where the excavation completion schedule is critical, separate jumbos for blasthole drilling and ground support installation may be warranted.

Excavation sequence. Ideally, underground openings are excavated full face, depending on the excavation layout, ground conditions, and operating range of available equipment. In openings where the cross-sectional dimensions exceed the operating reach of available equipment (particularly in fractured rock), the face may be advanced by multiple headings in order for the following to occur:

- Limit the unsupported roof span of the excavations.
- Prevent collapse.
- Maximize equipment operating range per round.
- Reach the back and promptly install ground support.

Large excavations for pump rooms, crushers, and similar facilities can be developed by driving a top heading followed by a single bench or multiple benches several rounds behind the top-heading development. Other excavation techniques for large, regular-shaped openings include driving a pilot drift and slashing the back of the excavation on retreat. Factors that influence the excavation sequence include rock properties, ground conditions, equipment operating range limits, and imposed limits on blast vibrations.

Major construction equipment. Several types of major equipment are used for the various work phases. Examples of the major equipment used in the construction of underground

Table 12.6-1 Work task, major equipment, and selection criteria

Excavation Development
1. Blasthole Drilling • Equipment—Drill jumbo (with a two-feed boom plus one with a work basket), air-leg drill • Criteria for selection—Access drift dimensions; equipment operating range or excavation dimensions (face area, maximum height); excavation layouts and turning radii requirements; length of each round, number, length and diameter of drill holes per face; maximum single drill rod length that can be handled; construction schedule; and number of working shifts per day
2. Charging and Blasting • Equipment—Examples include ammonium nitrate and fuel oil (ANFO) loader or ANFO cassette on cassette carrier truck, and emulsion loading units. • Criteria for selection—Fixed-frame or articulated-frame vehicles must meet underground access requirements; integrated units that can be used with available mine utility vehicles; type and size of mining operations
3. Ventilation and Dust Removal • Equipment—Ventilation fans and ducts • Criteria for selection—Volume of fresh air required at the face; system resistance to deliver air to the face • Comments—Flexible vent ducts (vent bags) can be installed quicker and are best suited for temporary applications; rigid vent lines have less resistance and allow the system to operate on negative pressure.
4. Scaling • Equipment—Work basket with scaling bar or mechanized scaler • Criteria for selection—Size of excavation; equipment reach
5. Muck Handling • Equipment—LHD, LHD-haul truck, or excavator-haul truck combinations • Criteria for selection—Clearance and access requirements; desired mucking productivity; haul distance; tramming surface; and haul road condition and grade • Comments—Hydraulic excavators may be used in medium to large excavations where ample room exists for maneuverability.
6. Ground Support • Equipment—Drill jumbo, handheld drills, work platform, work basket, scissor lift, rock-bolting jumbo, shotcrete equipment/truck or shotcrete cassette on cassette carrier truck • Criteria for selection—Similar to that of blasthole drilling • Comments—Ground support may be staged (initial and final) depending on ground conditions.
Fit-out and Installation of Permanent Equipment
1. General Lifting and Erecting • Equipment—Mobile rough terrain crane(s) with telescopic boom, work platform (telescopic boom), scissor lifts, heavy-duty forklift, portable light towers, portable welders, portable generators, portable air compressors • Criteria for selection—Available working room, equipment reach, maximum single load to be picked, etc.
2. Concrete Work (including bulkheads, dams, equipment foundations, slabs, etc.) • Equipment—Concrete truck(s), concrete pumps, vibrators • Criteria for selection—Equipment productivity; available access to the work area; distance from concrete source to the final placement location
3. Steel Structures (all major steelwork, access platforms, ladders, etc.) • Equipment—Similar to General Lifting and Erecting • Criteria for selection—Similar to General Lifting and Erecting
4. Mechanical and Electrical Equipment (pumps, piping, valves and fittings, switchgear, cable trays, and cable runs, etc.) • Equipment—Similar to General Lifting and Erecting • Criteria for selection—Similar to General Lifting and Erecting

CHAPTER 12.7

Tunnel Boring Machines in Mining

Lok Home and Odd G. Askilsrud

A tunnel boring machine (TBM) is a device used to excavate tunnels in a circular cross section through a variety of soil and rock strata. TBMs can bore through hard rock, sand, and almost anything in between. Tunnel diameters can range from ~1 to about 16 m (3.3 to 52.5 ft); tunnels smaller than that are typically created by horizontal directional drilling rather than by TBM.

This chapter describes mechanical excavations in soft/moderate to very hard rock and in rock-mass conditions ranging from marginally self-supporting to massive. TBM types discussed include state-of-the-art open, shielded, and other types of machines that incorporate specific features to suit particular applications, all using disc cutters. Mechanical tunnel excavators that create noncircular cross sections, such as mobile miners, mobile tunneling machines, roadheaders, and drum miners, are not discussed in this chapter, although they also serve important roles in civil and mining applications. These machines are discussed elsewhere in this handbook.

TBM TYPES

TBMs are normally classified into three groups:

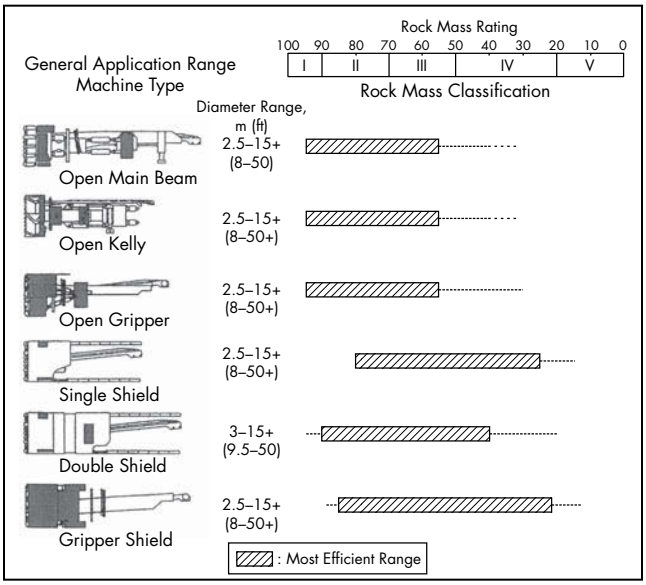
1. Open-type machines: main beam, Kelly drive, and open gripper
2. Shielded-type machines: single shield and double shield
3. Soft-ground machines: hybrid, earth pressure balance, mixed shield, and slurry

A feature common to all TBM types is a rotating cutterhead that does the following: (1) presses forward and against the rock face under high pressure; (2) uses individual disc cutters placed strategically on the cutterhead; (3) performs muck removal by means of buckets; and (4) is supported by a main bearing with the structure being moved forward by a thrust system composed of cylinders. All TBMs have a backup system of power units and muck-removal systems.

Shielded-type machines are seldom used in mine applications because of the difficulty in removing the shields. A third shielded-type machine, the gripper shield, was designed to actively support the ground from the cutterhead to behind the TBM where rock support can be installed and has been used in a wide range of geological conditions. However, it is no longer available because of limited acceptance in the industry.

Because most mining applications take place in moderate to hard rock, soft-ground machines are not discussed in this chapter.

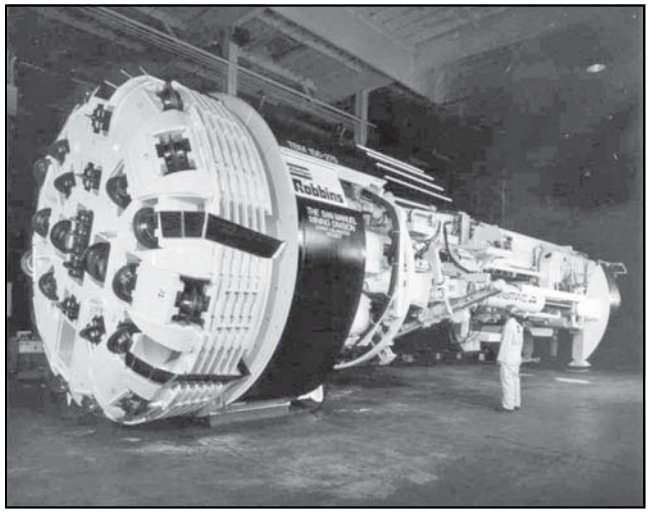
GENERAL TBM APPLICATIONS



Compared to their use in civil-engineering applications, TBM use in mining has been relatively modest since the first successful hard-rock TBM was introduced by James S. Robbins in 1957.

TBMs in mining have ranged in diameter from ~1.7 to 7.6 m (7 to 25 ft). They have been used predominantly in soft to moderately hard formations. Mine applications at times place severe restrictions on component size and weight so that equipment can be lowered down existing shafts, transported to a designated assembly and launching area, and, after tunnel completion, removed. TBM systems in some mines must include explosion-proof equipment. Such equipment has been used for access to coal mining in Germany, England, and Canada.

Detailed study is required to select the proper TBM system for a project. Such study involves reviewing geological design reports, geological profile drawings, and baseline design or equivalent reports prepared by the mine owner or a consultant depicting anticipated conditions along the drive and required design parameters. Important factors to consider include the following:



- Rock types
- Rock strength parameters from a testing laboratory
- Rock mass characteristics, including stand-up time at the actual tunnel depth, profile, and alignment of the proposed tunnel
- Tunnel diameter
- Temporary and permanent tunnel-support requirements
- Water and gas
- Geological profile
- Mucking requirements

Figure 12.7-1 General application ranges for various TBM types

Courtesy of The Robbins Company.

Figure 12.7-2 Main-beam TBM

Figure 12.7-1 can be a useful tool for discussion purposes in the planning stage. The chart shows typical TBM types and their most efficient application ranges based on rock mass rating.

The estimated TBM advance rate is based on rock strength and fracturing characteristics, in-situ condition of the rock mass, machine characteristics, and operating condition in the tunnel. The actual TBM advance rate is equal to the product of the average instantaneous penetration rate in millimeters per cutterhead revolution (inches per revolution), cutterhead speed (rpm), shift hours per day, and machine utilization (percent).

TBM DESIGN FEATURES

Important design features to consider for achieving efficient rock chipping include effective thrust load on the cutterhead and cutters, layout and spacing of cutters, and diameter and tip width of the cutter rings.

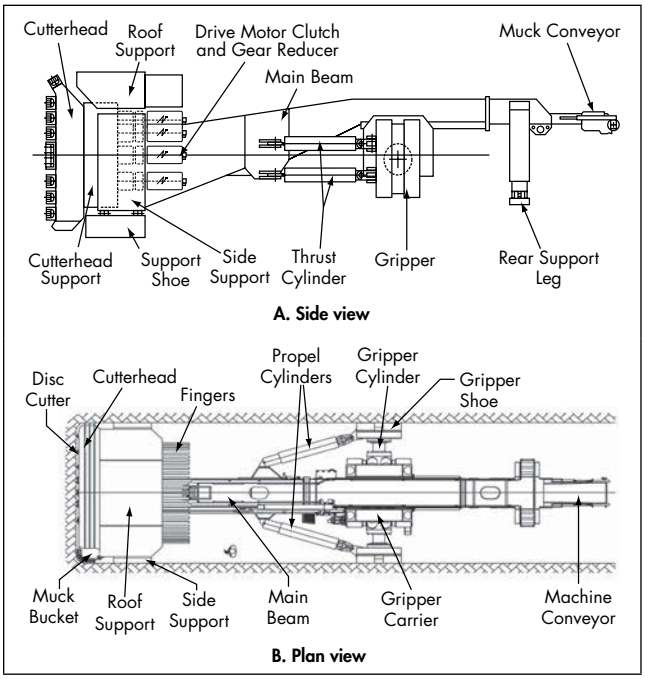
The nominal load capacity of a single-disc cutter has evolved from 89 kN (20,000 lb) for the 300-mm (12-in.) cutter of the 1950s to >312 kN (70,000 lb) for the 500-mm (20-in.) largest-size cutter of today. Today's state-of-the-art hard-rock TBM typically has a flat-face cutterhead with single tracking center, face and gauge cutters, each of which provides concentric kerfs on the rock face during excavation. Kerf spacing (center-to-center spacing of cutter tracks) is nominally ~90 mm (3.5 in.) for the face cutters, decreasing into continuously tighter spacing for the gauge-cutter positions. A flat-type cutterhead normally consists of nine cutters in the curved gauge area. A typical 4.6-m (15-ft) TBM hard-rock cutterhead with 432 mm (17 in.) back-loading cutters is shown in Figure 12.7-2. Single-disc cutters (483 mm or 19 in.) in wedge-lock housings are shown in Figure 7.1-4 in Chapter 7.1.

Selection of cutter diameter and cutter characteristics is determined by the application study and/or specific requirements of the application. State-of-the-art cutter rings for hard-rock applications are made of tool steel, specifically heat-treated so as to reduce the number of cutter changes and downtime for the anticipated ground conditions during the drive. The cutter hub assembly includes high-capacity tapered roller bearings and seals capable of supporting multiple cutter-ring changes.

Early during TBM design, it must be decided whether the cutterhead should have front- or back-loading cutters. Front-loading cutters are faster to change but require miners to enter and work beneath unsupported ground in front of the machine. Back-loading cutters can be changed from behind the cutterhead and under the protection of a shielded structure. The largest individual cutters 500 mm (20 in.) weigh up to 190 kg (425 lb). Cutters are moved and installed by means of a cutter-handling system normally designed for the specific TBM.

Other design features vary by TBM type. For further information on TBM cutters, see Chapter 7.1.

Main-Beam TBM



The main-beam TBM (Figure 12.7-3) is suited for high-strength rock and short faulted zones. Ground support methods can include ring beams, bolting, and shotcreting.

A main-beam TBM consists of four main elements: (1) cutterhead, (2) cutterhead support and main beam, (3) gripper and thrust assembly, and (4) conveyor assembly.

The gripper assembly with one set of grippers forms the stationary anchoring section of the TBM. It transmits thrust and torque to the tunnel wall during boring and carries part of the machine weight. The anchoring force is approximately 2½ to 3 times the total forward-thrust force.

The machine is forced forward a stroke at a time by hydraulic cylinders connected to the anchoring section and main beam as the cutterhead rotates against the rock face. At the end of a stroke and after the cutterhead stops rotating, the rear support is lowered to the invert, the grippers are retracted from the tunnel wall and moved forward equal to the stroke of the thrust cylinders, the grippers are again energized against the tunnel wall, and rear support is retracted so that boring can start again.

The front supports, support shoe, and extendable side and roof supports provide ground contact immediately behind the rotating cutterhead to stabilize the TBM during tunneling. The

Courtesy of The Robbins Company.

Figure 12.7-3 Main-beam TBM

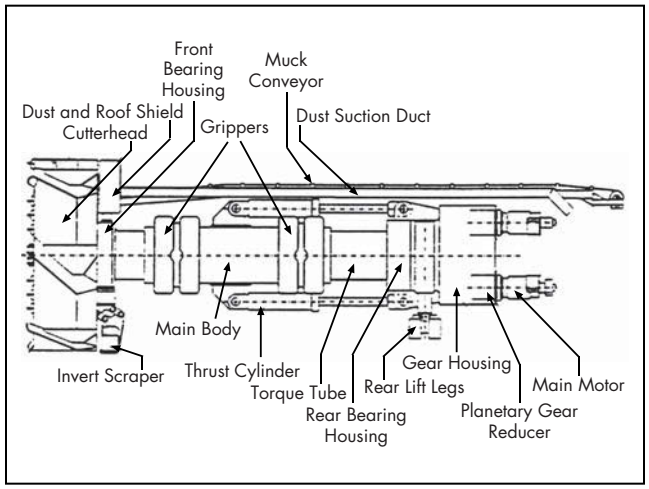
cutterhead is typically driven by water-cooled electric motors located on the cutterhead support, each directly mounted to a gear reducer with output pinions. Drive pinions engage with the large ring gear, which is connected to the cutterhead. The cutterhead itself is supported by the main bearing.

The main-beam TBM has essentially become the industry standard open TBM mainly because of its ease of operation and ample room around the cutterhead area for ground support.

Kelly-Drive TBM

The Kelly-drive TBM (Figure 12.7-4) is suited for high-strength rock and short fault zones. Ground support methods can include ring beams, bolting, and shotcreting.

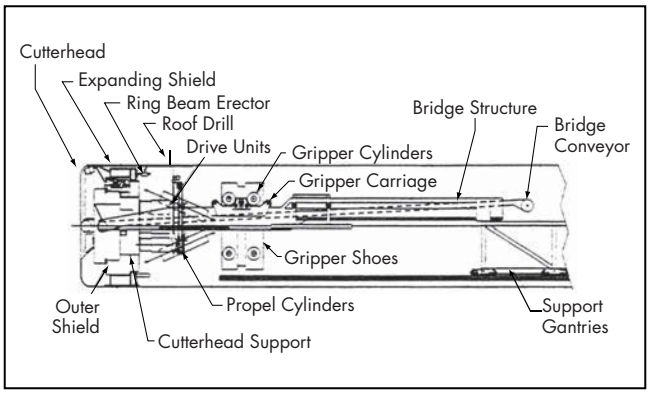
The Kelly-style TBM consists of two main elements: the anchoring section and the working or moving section.



The gripper assembly with two sets of grippers forms the stationary anchoring section. It transmits thrust and torque to the rock during boring and supports the weight of the machine. Four grippers in the radial direction are arranged horizontally in pairs and controlled individually.

The working section includes the cutterhead, front bearing housing, torque tube, rear bearing housing, and drive train. Cutterhead rotation is controlled by motors at the rear of the machine coupled to gear reducers and pinions. A common ring gear turns the drive shaft through the center of the torque tube to transmit rotational power to the cutterhead. Hydraulic pulling cylinders develop thrust that is transmitted from the main body through the rear bearing housing and drive shaft.

Use of this type of TBM has declined, mostly because of the limited access around the TBM for installing ground support.



Open-Gripper TBM

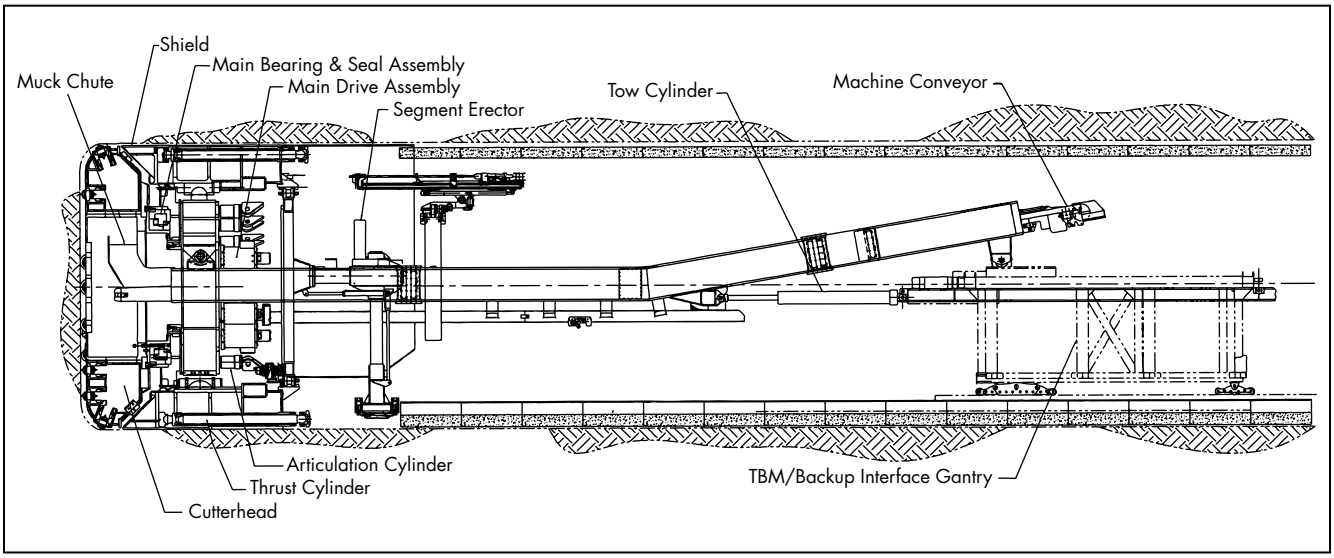
The open-gripper TBM (Figure 12.7-5) is suited for high-strength rock and short fault zones. Ground support methods can include ring beams, bolting, and shotcreting.

Courtesy of The Robbins Company.

Figure 12.7-4 Kelly-drive TBM

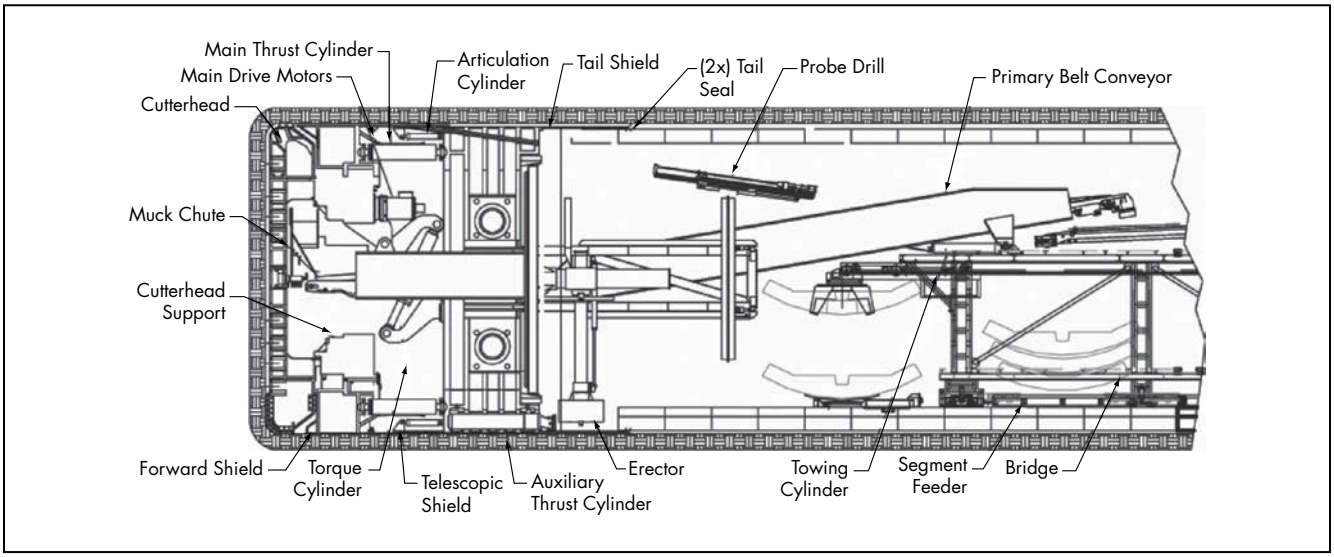
Courtesy of Construction and Tunneling Services, Inc.

Figure 12.7-5 Open-gripper TBM



The TBM has expanding supports close to the excavation face and a simpler gripper design (no main-beam or Kelly-drive structures) than do the other types of open-type TBMs described. It typically uses an arrangement of lattice-type (diagonal pattern) thrust cylinders to react to cutterhead torque and correct roll. Advantages can include low cost, short overall length, and tight turning radius.

The machine consists of a cutterhead, forward expanding shield, and gripper assembly. The cutterhead and cutterhead drive are the same as typically seen on main-beam and gripper-shield TBMs. This configuration provides cyclic advance of the machine in the following sequence: bore, regrip, bore.



A bridge structure spans from the TBM cutterhead support to the first platform car. The bridge carries the grippers and also provides space to install muck-haulage rail and a mounting for the forward conveyor, material-handling equipment, exhaust duct, and tunnel-support installation equipment.

Single-Shield TBM

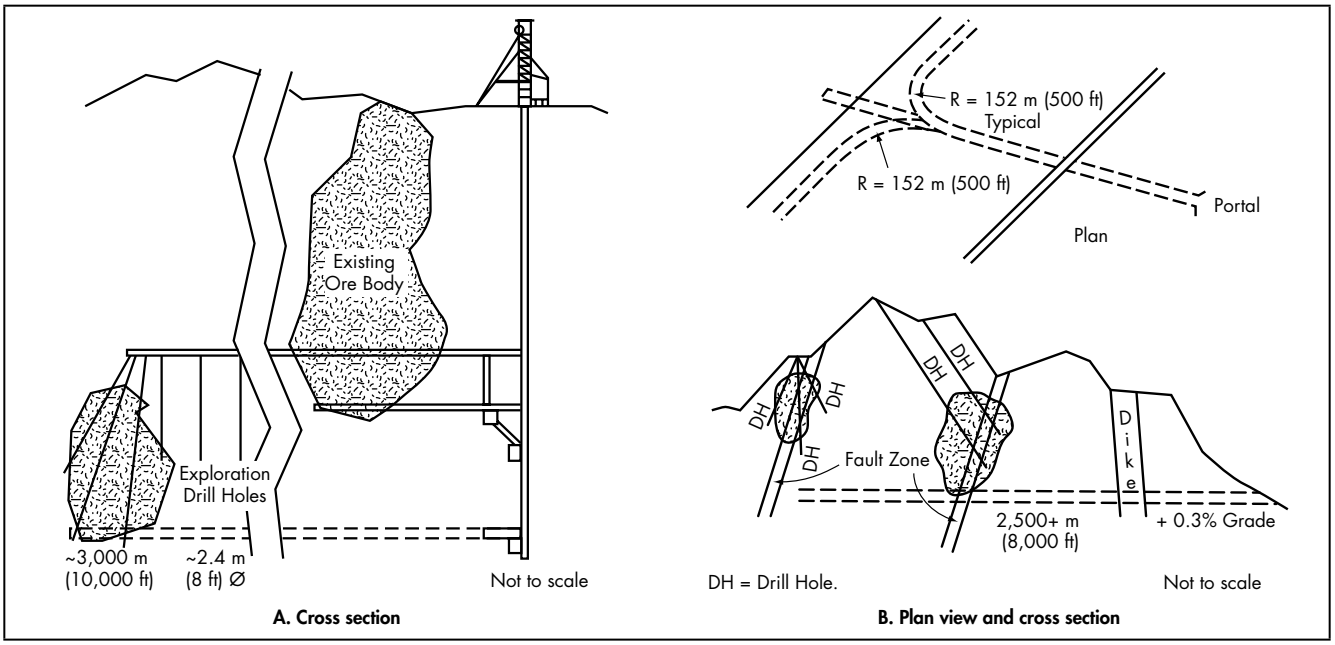
A single-shield TBM (Figure 12.7-6) performs boring and lining installation in sequence. Lining, typically concrete segments, is used as an anchoring station to propel the machine during boring. The machine can be used in hard as well as soft

Courtesy of The Robbins Company.
Figure 12.7-6 Single-shield TBM

Courtesy of The Robbins Company.
Figure 12.7-7 Double-shield TBM

ground, and is well suited for tunnels in mixed ground and loose formations with low stand-up time.

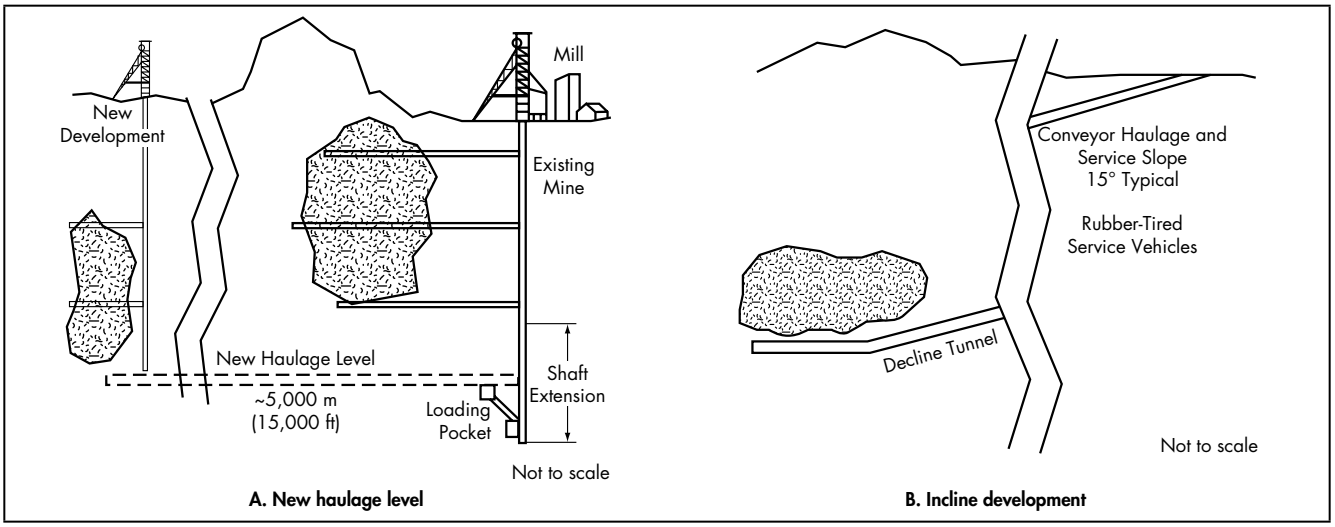
The main section consists of a cutterhead, cutterhead support with integrated ring gear, main bearing, and drive units. Thrust cylinders are located in the rear part of the machine and act against the tunnel lining. Complete lining rings are installed inside the shield by a segment erector.



Steering is done by individual control of the oil volume supplied to separate groups of thrust cylinders. Steering can be enhanced by the articulation cylinders, which bias cutterhead support in relation to the shield.

Double-Shield TBM

The double-shield TBM, also called a telescopic-shield TBM (Figure 12.7-7), can be used in hard as well as soft formations. It is used when there is a risk of unstable ground conditions. Normally, the tunnel walls are used to anchor the machine, which allows installation of segmental lining during boring. If the walls cannot take the gripper pressure, the machine can push off the lining instead.



The working section at the front of the machine has a cutterhead, cutterhead support with integrated ring gear, main bearing, and drive units. A telescoping section between the anchoring and working sections includes hydraulic cylinders for thrust and steering. The anchoring section at the rear of the machine has two horizontal grippers that transmit thrust and torque. Auxiliary cylinders transmit these reactions to and propel the machine from the lining. A segment erector is installed inside the tail shield.

Steering is done by individual control of the oil volume supplied to separate groups of thrust cylinders. Steering can be enhanced by the articulation cylinders, which can off-angle

Figure 12.7-9 Mine openings for haulage by rail, rubber tire, or conveyor

the working section in relation to the anchoring section to bias the cutterhead in the proper direction.

If segment lining is being placed, an electronic guidance system is mandatory to ensure correct line and grade for installation of the segment ring within the tail shield.

TBM MINING APPLICATIONS

Underground openings in mines can be associated with exploration, access to and development of ore bodies, haulage (by train, conveyor, or rubber tire), ventilation, drainage/dewatering, movement of supplies and labor, safety, or a combination of these. Figures 12.7-8 through 12.7-13 show examples of some underground openings in mines.

A key consideration for TBM mining applications is the type of muck-removal system. Tunnels under consideration for TBM application are generally close to mine boundaries, because only long-distance tunnels could justify capital investments in TBM equipment. Tunnel cross sections are generally relatively small, because muck must be transported and hoisted without interrupting full-time mining.

Haulage of muck has historically been done by rail. Rail haulage is often the lowest option in terms of capital and operating costs and still reasonably flexible, but conveyor haulage is also common today, especially for longer tunnel drives. However, conveyor systems are not always suitable for TBM applications, because their minimum turning radius is ~200 m

(660 ft), while a custom-designed TBM may be able to bore a curve radius of ~100 m (330 ft).

Haulage by rubber-tire vehicles may be considered for larger tunnels with diameters of ~7 m (23 ft) or more. The invert is then typically backfilled with concrete or good-quality rock materials to provide a roadbed. Vehicle passing stations may be required at intervals to maintain a reasonable TBM utilization.

Another consideration for TBM mining applications is incline and decline. Declines have been limited to a maximum grade of ~15°, however, because a typical muck-removal system uses conveyor belts. Inclines can be quite steep since mucking can take place as safely contained gravity flow along the invert. In civil works, inclines have exceeded 45°.

Alignments are further determined by the end use of the excavation, geologic conditions, and other management or owner constraints such as property boundaries.

TBM VERSUS DRILL-AND-BLAST EXCAVATION METHODS

TBM excavation methods have both advantages and disadvantages compared with conventional drill-and-blast methods.

TBM Advantages

High Rate of Advance

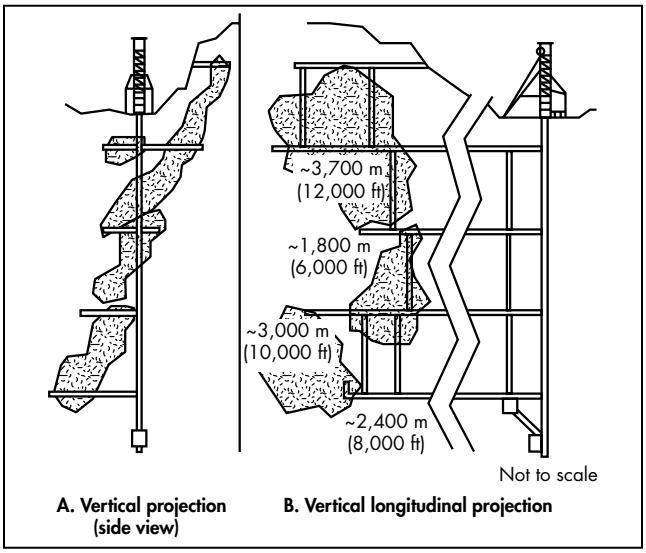
Instantaneous excavation rates of 1–6 m/machine hour (3–20 ft/machine hour) are regularly achieved by TBMs with diameters of 3.5–5.5 m (11.5–18 ft). Overall advance rates per day, week, and month depend on the overall TBM system utilization and work schedules. Faster ore-body development shortens the time period of capital use and capital cost.

With TBM use, fewer headings are operated at one time, making supervision and planning easier and management effort more concentrated and focused.

Some types of geological environment can be more effectively supported if support is installed relatively quickly after excavation.

No Blast Vibration or Blast Fumes

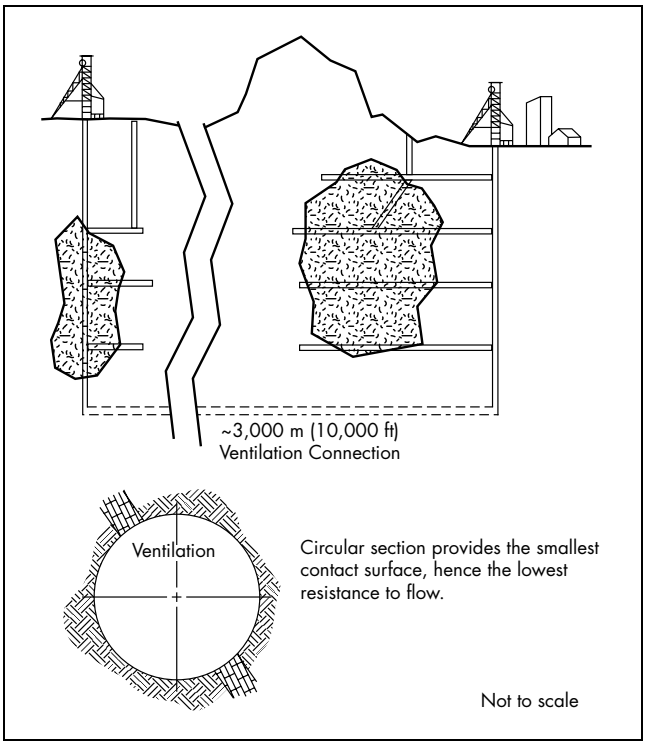
TBMs enable work to be carried out continuously in the heading without delays for clearing gases from blasting from the heading or ventilation system. No workers need to be removed from other headings or work places to safety refuges for a blasting cycle. However, other drill-and-blast work in the mine can cause interruption in the TBM heading.



Reduced Ground Disturbance and Support

Mechanical excavation is well known to be less destructive to the structural integrity of material surrounding the excavated opening than is drill-and-blast excavation. Less ground support is required with significant reduction in material costs and installation time.

Roof bolts and steel ribs are the two predominant support systems used with TBM excavation in mines. Yieldable steel sets have commonly been employed in deep German coal mines for TBM drifts. Installation of ground support in larger tunnel cross sections can largely be automated.



Reduced Lining Costs

Where a completed excavation must be lined with shotcrete or concrete, the smooth uniform surface created by TBM excavation reduces costs of the lining material and raises the possibility that lining installation can be automated.

Figure 12.7-10 Mine opening drifts for development access and haulage

Source: Moulton 1997.

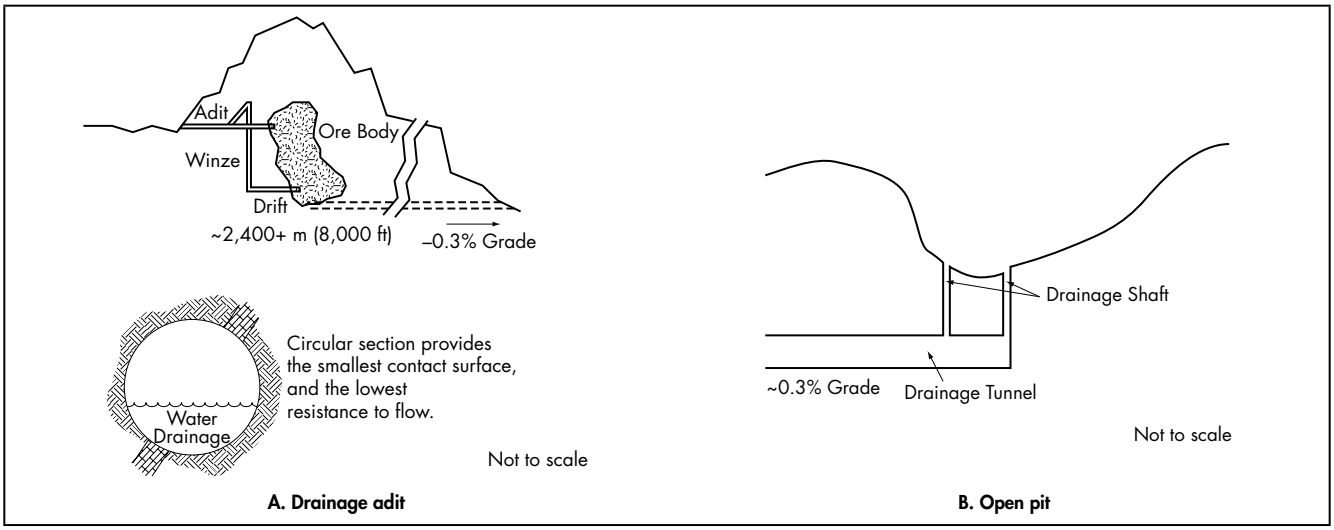

Figure 12.7-11 Mine openings for ventilation

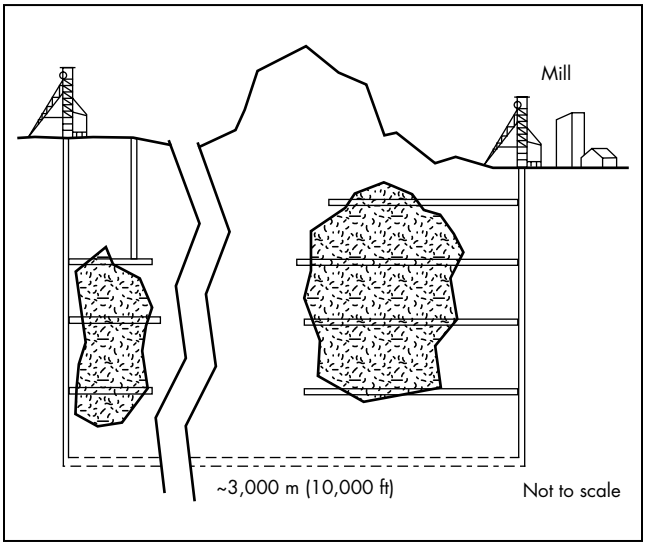
Uniform Muck Size

Mechanically excavated materials essentially all pass through a 100-mm (4-in.) grizzly used for coarse screening.



Suitable for Automation

The uniform size of mechanically excavated materials makes material handling ideal for automation. Less wear and tear occurs on transport equipment such as rail cars, trucks, or conveyors in the tunnel.

Figure 12.7-12 Mine openings for water drainage

Source: Moulton 1997.

Figure 12.7-13 Multiple-use mine openings for ventilation, safety, drainage, haulage, and supplies

Vertical transport by means of loading pockets and hoist conveyances can be automated, minimizing maintenance costs. Ore that is encountered in a heading can be partially segregated and sent to the concentrator, eliminating primary crushing costs.

Reduced Labor Costs

A rapid rate of advance reduces the unit cost of excavation. In most western countries, both crew size and rate of advance are larger for TBM than for drill-and-blast operation. Consider the following typical average progress for a tunnel of small cross section, ~10 m^2 (108 ft^2), each with two 10-hour work shifts per day:

- TBM operation:
  - Crew size: 4 to 7 (assume 6 for the following calculation)
  - Rate of advance: ~140 m (460 ft) per week
  - Productivity: 140 m/week ÷ 72 shifts/week = 1.94 m (6.4 ft) per shift
- Drill-and-blast operation:
  - Crew size: 2 to 3 (assume 3 for the following calculation)
  - Rate of advance: ~38 m (125 ft) per week
  - Productivity: 38 m/week ÷ 36 shifts/week = 1.06 m (3.5 ft) per shift

Good Safety Record

TBM excavations are considered relatively safe compared with drill-and-blast excavations because the latter incur greater risk to workers from falls or ground-related accidents, even in supported ground. Most TBM systems have protective canopies for workers in ground support installation work zones.

Both excavation methods involve some heavy lifting, which, if not properly performed, can lead to back injuries. A typical 432-mm (17-in.) single-disc-cutter assembly weighs about 136 kg (300 lb). Back-loading cutters normally required in mining applications are best changed with slings and hoists using proven cutter-handling systems. Back-loading cutters can normally be used for TBMs with diameters of ≥4 m (13 ft).

Lower Manning's Factor

TBM excavation in hard rock leaves a smooth circular profile with a roughness coefficient that is lower than that for a typical drill-and-blast operation. The cross section of an unlined TBM tunnel therefore needs to be only about two-thirds of the area of an unlined drill-and-blast tunnel to carry the same water flow.

Circular Cross Section

A circular profile typically gives the most stable cross section. TBM excavation requires substantially less ground support in fairly massive to massive hard-rock conditions.

Improved Ventilation Characteristics

The smoother rock surface of a TBM excavation means reduced friction and improved possibility of excavating longer drives from a single heading.

Less Concrete When Lining Is Required

A TBM tunnel has substantially less overbreak than does a blasted tunnel. Large savings in concrete and concrete placement may be realized.

No Muck Bays or Passing Bays

No muck bays or passing bays are needed for TBM tunnels with diameters of >3.5 m (11.5 ft) because all advance is centerline advance.

TBM Disadvantages

High Capital Cost

TBM costs vary widely with size, supply, and power requirements. The cost of a typical open-type TBM excluding roof drills, ring erectors, and other ground support or probing equipment is about US$1.7 million per meter of diameter (2009 price levels). A simple backup system in a heading with a diameter of 3–4.8 m (10–16 ft) varies from US$1.2 to $2 million, depending on facilities, storage, muck-transport systems, and so on. A system with a diameter of 3.6 m (12 ft), with spares and cutters, thus costs about US$8 million. A used, fully reconditioned, technically comparable system costs about 65%–75% of this amount.

Repair and maintenance work are necessary during the life of a machine. The life of a TBM system has been suggested at times to be ~15 km (50,000 ft) of tunnel excavation, although this varies widely depending on technical obsolescence, operating and maintenance practices, and application. Conditions in the marketplace external to the mine can have a large impact on equipment life and salvage value. A number of TBMs have bored more than 25 km (80,000 ft) of tunnel. Generally at least 2.5 km (~8,000 ft) of tunnel are necessary to justify the use of a TBM system; this includes equipment salvage value.

Large Value of Spares and Cutter Inventory

The recommended inventory of major spare parts, including main bearing, ring gear, drive unit (motor, clutch, gear reducer, and pinion), propel cylinder, and gripper cylinder are in the range US$600,000 to $800,000 (2009 price levels). Inventory of minor spare parts adds another US$60,000 to $100,000 of capital cost. US$300,000 can be spent for initial cutter mounting, cutter spares, and cutter repair tools and fixtures.

Long Lead Time for Delivery

Design and manufacturing time for a new TBM with a diameter of 3.6–5.5 m (12–18 ft) is typically a minimum of 10 months. The time for a smaller TBM, with a diameter of ~2.6–3.0 m (8–10 ft), may be as low as 8 months. Delivery time ex-works varies with actual supply, clarity of product definition, and subsuppliers' workloads.

Reconditioning and modification times for existing equipment is ~65%–95% of these values, depending on the particular equipment, its location, and the scope of work required.

Large Components That Are Difficult to Transport

To reach the high thrust and torque levels required for TBM excavation, components must be large and heavy, and are therefore difficult to move through existing mine shafts or mine drifts. TBMs are also often difficult to remove from completed tunnels.

Boring of TBM drifts from shafts can be challenging. Transport from the surface and assembly underground, as well as removal from the mine, require careful planning and preparation. At times transport and assembly must take place without interrupting full-time mining. Plans and methods for slinging and lowering heavy components down the shaft must be devised early during machine design. Machine components and support systems must be designed to be small and light enough for accommodation in the shaft and by the hoist. The existing hoist configuration, controls, or brakes may also require modification, and special transport or handling devices may be required to lower large components down the shaft or move them along the level.

Limited Range of Application in Varying Ground Conditions

TBM design is determined by the requirements of the particular application—the more uniform or consistent the geologic environment, the easier and more reliable the design.

Competent moderate hard rock, requiring moderate ground support and with no major water inflows, is ideal. However, mines are normally associated with geologic nonconformities that result in mineral deposits, and it is to be expected that all or part of an underground excavation will require some type of rock support. Machine design can, within limits, accommodate hard rock to caving or squeezing ground.

For mining applications, a high degree of flexibility is generally desirable. Today's machines can operate in varying ground conditions because of their variable-frequency drive motors for controlling cutterhead rpm and torque. They can be equipped with effective systems for probing, pre-excavation grouting, shotcreting near the cutterhead, rock bolting, ring beam installation, and application of mesh and lagging. In addition, they can be furnished with the McNally system, a longitudinal roof-support system for operation in bad ground conditions (McNally 2010).

Consumable Costs Can Be High in Hard, Abrasive Rock

Cutter costs can be a very significant part of the overall TBM costs. In soft to medium-hard sedimentary rocks such as are associated with limestone and other nonabrasive rock types, cutter costs are typically as low as US$1.00/$m^3$ ($0.75/$yd^3$) or less. However, in hard, massive quartzites, they can reach US$20/$m^3$ ($15/$yd^3$) or more due to the high abrasiveness of the rock combined with low instantaneous penetration.

When cutter costs are high, machine utilization drops because of downtime for cutter changes and for cutterhead maintenance and repairs.

Several laboratories can test rock samples needed for TBM application studies. Most TBM manufacturers and some TBM consultants can provide estimates on instantaneous penetration and cutter consumption based on these lab test data, anticipated rock-mass characteristics, and proposed machine and cutter specifications.

Limited to Circular Cross Section

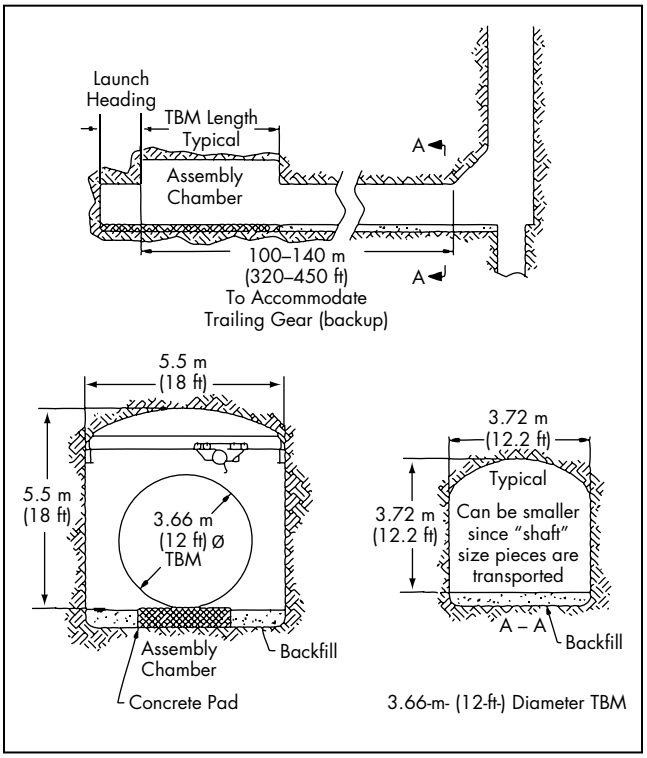
When a heading is intended for haulage, the circular cross section produced by a TBM may limit the choice of haulage method and equipment. This is particularly true when rubber-tired haulage trucks or load-haul-dump units are to be used. The diameter of the excavation must be increased and the invert may require a concrete cast floor as a roadbed.

In some rock burst conditions, a TBM-produced circular cross section, although usually advantageous for ground support, can also be a detriment. In highly stressed and brittle rocks, the surface stress of the circular opening can be quite

high compared to that in rock that has been deeply fractured and stress-relieved by use of drill-and-blast methods.

Limited Turning Radius

A typical TBM has a minimum turning radius of ~200 m (660 ft), although custom-designed TBMs may be able to bore a radius of ~100 m (330 ft). Backup equipment, conveyors belts, mining cars, mucking solutions, and so on must all be able to negotiate a curve so created. In contrast, a drill-and-blast operation has basically no limitations regarding curve radius.



Substantial Preparation at Work Site

Site preparation for most mine projects that involve adits is not unusually difficult. However, for a TBM application, there must be ample room at the portal site, cranes for lifting large pieces, and adequate supply of power. Other requirements are basically similar to those for drill-and-blast headings.

When an underground work station is planned, adequate hoist capacity and ample length for assembling the trailing gear are needed. A typical overall length for a TBM with a diameter of 3–5 m (10–16 ft) can be 100–140 m (320–450 ft). The underground assembly chamber for a 3.66-m (12-ft) TBM is usually sized as follows (Figure 12.7-14):

- Width and height: ≥1.5 times the TBM diameter, depending on the type of hoist
- Length: Length of the TBM, ~20 m (65 ft)

For safety and cost reasons, it is desirable that the assembly chamber be constructed in good ground, close to the launch point for the drive.

Source: Moulton 1997.

Figure 12.7-14 Example of an underground TBM assembly chamber

Requires Substantial Crew Training and High Mechanical and Electrical Skill Levels

A TBM system is essentially a crude moving processing plant or factory. Material is removed and sized in a cutting process from its in-situ state. The process from that point on involves several electrical, mechanical, hydraulic, lubrication, compressed-air, cooling-water, wastewater, ventilation, material-handling, and storage systems along with monitoring and control of these systems. These systems must be maintained in a hostile environment of water, dust, vibration, and varying temperature. Some of these systems may not be in common use with other machines or systems in the mine operation.

Mine operating personnel must be trained in the use and maintenance of these systems and how they relate to the overall TBM production process. Training is largely accomplished in the TBM manufacturer's shop during floor testing and machine disassembly, and at the work site during final assembly and full-load testing. TBM operators receive training by visiting or temporarily working at other sites and by working with the TBM supplier's field service personnel.

Instead of training mining crews, a better solution can be to use contractors who specialize in TBM work. A TBM contractor must be carefully selected and must understand mine priorities and operations requirements.

Requires Large Power Supply

Most TBM systems today use total power in the range 1,000–2,600 kVA or more for TBMs with diameters of 3–5 m (10–16 ft). Total power includes power for cutterhead, hydraulics, ventilation, conveyor, lighting, pumping, cooling, and other systems.

The power required to operate a TBM system may not have been planned in the mine's initial design stage, as many mines are more than 25 years old. Even today, mine infrastructure planning does not usually include provision for the use of mechanical excavation equipment in major headings. The large power requirement usually necessitates addition of high-voltage distribution cables in the shaft and addition of underground substations.

Vary Excavation Diameter

Normally, it is not practical to change tunnel diameter during a drive, because of costly downtime. The TBM design itself may allow a change of ~1 m (3.3 ft) or more from a minimum established diameter. Possibilities with regard to diameter increases should be based on the original TBM design criteria and the upcoming project application, including desired diameter, length of drive, and rock-mass and rock-strength characteristics.

DESIGN AND OPERATING PROBLEMS AND SOLUTIONS

Historically, design and operating problems have arisen with TBM applications in the mining industry. Samples of past problems and their solutions are given in Table 12.7-1.

Since 2000, several important improvements have been implemented in TBMs and auxiliary equipment that decrease downtime and increase TBM utilization:

- Water-cooled motors and hydraulics
- Larger-diameter cutters
- Higher-capacity cutter bearings and cutter ring with improved abrasive resistance characteristics

Table 12.7-1 TBM design and operating problems and their solutions

Problem	Solutions
Ground fall on personnel between cutterhead and face while changing cutters	• Developed back-loading cutters that can be changed from inside the cutterhead • Replaced bucket lips from inside the cutterhead
Undercutting of an unstable face with dome cutterheads, causing collapse of the tunnel crown	• Developed flat-face cutterheads with smooth surfaces
Front-mounted cutter housings rip blocks of material from the face, blocking cutterhead rotation	• Developed flat-face cutterheads with smooth surfaces
Large distance from initial cutting of face to provision of adequate ground support, causing fallout and caving. Massive ground support effort required	• Developed flat-face cutterheads with short standoff distance and narrow rim bar to reduce the distance to the first adequate support of the excavation
Methane fire	• Implemented early detection of gas and shutdown of equipment • Increased ventilation • Implemented better sensing of hot materials, particularly cutters • Interlocked water sprays with cutterhead rotation
Probe drilling in advance of boring limits advance	• Implemented state-of-the-art high-capacity hydraulic drills that enable probe drilling during cutter changes and/or TBM system maintenance
Additional machine waste heat in deep mines detrimental to work-crew efficiency	• Upgraded to water-cooled electric motors, gearboxes, and cutterheads
Low utilization in hard abrasive rock in deep mines	• This is not a good application for TBMs. More research and development is needed, particularly for cutters
Entrapment by squeezing ground	• Implemented adjustable shield designs • Avoided stoppages or delays for weekends or holidays in zones of squeezing
Inadequate support for gripper pads	• Increased gripper shoe area to reduce ground load • Implemented timber cribbing or shotcreting in gripper-pad areas as necessary
Running ground cave-in	• Used higher torque at low speed on cutterhead with ground treatment • Applied shotcrete early to stabilize ground
High repair and maintenance of open-type cutter mounting	• Added breasting plates to smooth rock-contact surface • Designed and built new cutterhead
Equipment not suitable for geology	• Modified TBM to meet conditions
Small size of TBM limits workspace for ground support installation	• Installed shield for temporary support and placed permanent support behind TBM
Cannot hold curve-alignment radius	• Implemented modern laser guidance systems • Designed a short TBM • Reduced TBM stroke • Implemented steering by means of "crabbing"
Large blocks of rock have damaged TBM muck chute and conveyor system	• Installed grill bars • Decreased size of bucket openings • Replaced bucket lips from behind • Lowered speed and increased torque
Plugging of muck-flow passages in the cutterhead	• Removed grill bars • Increased size of bucket openings • Smoothed the contact surface • Used foam injection to lubricate muck
Ground caving above cutterhead	• Stabilized the ground by grouting and filled the void with quick-setting grout • Installed spiling or combinations of the above • Installed a McNally roof-support system

Source: Adapted from Moulton 1997.

- High-efficiency variable-frequency electric drives
- Improved hydraulic probe-drill schemes and pre-excavation grouting solutions
- Faster-setting grout

OPERATIONAL AND MANAGEMENT PROBLEMS AND SOLUTIONS

The following typical challenges can arise in a TBM mining application:

- Failure on the part of mine managers, due to categorization of the TBM as a "mine research project," to commit fully to the decision to use a TBM
- Failure on the part of direct supervisors and miners to commit fully to the success of the TBM system
- Failure to obtain acceptance of new technology due to unrealistic expectations
- Failure on the part of machine suppliers to fully understand the unique mine operating conditions and priorities related to design challenges, operating costs, performance, and the high skill levels required of personnel
- Lack of jobsite preparation and coordination with other mine activities
- Lack of training of operating and maintenance personnel

Several TBM projects have been considered failures when original schedules, costs, and full desired end benefits were not achieved. However, most had acceptable results when compared to realistic alternates. The solution to these

problems is to keep expectations realistic, fully identify mine requirements, and possess adequate design experience.

A summary of mine projects in the Western world is presented in Table 12.7-2 by date and original TBM manufacturer. The summary may not be complete, but the large number of projects listed should indicate that there is enough experience in the industry to know what to do and what not to do when applying TBMs to mining applications.

Many market studies, in attempting to identify the worldwide need for mines, have estimated the total annual drive lengths of horizontal openings. The total number is very large. Of this total, much is not really suitable for TBM excavation. However, when drive lengths are sufficiently long and when mine owners, operators, equipment suppliers, and contractors focus on a common result that benefits each of them, they can commit to their mutual success and achieve it. A good example of such commitment is the case history that follows.

TBM MINING CASE STUDY

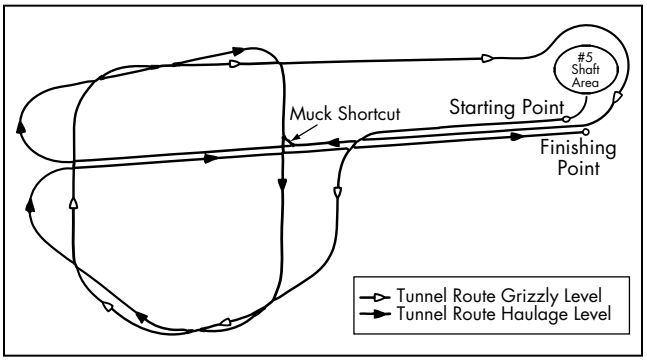
The Magma Copper Company's San Manuel mine in Arizona and the Stillwater Mining Company's platinum mine in Montana, both in the United States, are examples of successful TBM use in mining. Many comprehensive reports concerning these projects are in the public domain. TBM use in the San Manuel mine is discussed here in detail.

Mine Location and Layout

The San Manuel mine is located about 72 km (45 mi) north of Tucson, Arizona. In order to secure future production, it became necessary to develop the Lower Kalamazoo ore body 1,050 m (3,450 ft) below surface for a modern block-caving operation. The base of the mass to be caved would be accessed by drifts on two levels from the existing No. 5 shaft.

Based on a feasibility study, it was decided to use a TBM rather than traditional drill-and-blast methods because of the very tight schedule for starting production in the new ore body. Because of a lack of qualified labor and the short construction time, it was determined that an experienced TBM contractor was needed.

The development layout was designed specifically for TBM use (Figure 12.7-15). The TBM tunnel route consisted of 9,826 m (32,235 ft) of tunnel circling the ore body on three levels: (1) the 3,440 grizzly level, (2) the 3,570 haulage level, and (3) the 3,600 conveyor-gathering drift level.



The grizzly level consisted of 3,963 m (13,000 ft) of TBM tunnel with slight grade changes to provide two permanent dewatering sumps. The level has five curves, with radii in the range 152–107 m (500–350 ft) and a total curve length of 1,031 m (3,383 ft).

The haulage and conveyor-gathering drift levels are accessed from the grizzly level by means of two parallel decline tunnels with grades of ≤5.7%, which accounts for the remaining 5,863 m (19,235 ft) of the TBM tunnel route. These decline tunnels have two curves, with radii in the same range as for the grizzly level and a total curve length of 1,255 m (4,119 ft).

Mine Geology

The geology of the San Manuel mine is quite complex, with rock structure ranging from very weak to reasonably strong. The area geology is described briefly as follows (Atlas Copco Robbins 1996).

The ore bodies resulted from porphyritic intrusion of granodiorite at the end of the Cretaceous period into pre-

Source: Janzon 1995.

Figure 12.7-15 TBM tunneling scheme in the San Manuel mine

Cambrian quartz monzonite. Mineralization along the contact zone was shaped originally like a hollow ellipse, which later was split and displaced by faults and intersected by numerous dikes.

The TBM's excavation route included the stable quartz monzonite of ~150–180 MPa (22,000–26,000 psi) unconfined compressive strength, two mineralized haloes, and a mineralized core. The bore path also crossed the San Manuel fault six times and the Virgin fault five times. The San Manuel fault was flat, dipping in an ~1-m- (3-ft-) wide clay zone that followed the bore some 30 m (100 ft) at a time, but it influenced the drive for a total of about 190 m (600 ft). The Virgin fault dipped steeply but a series of related minor faults produced poor rock conditions for about 500 m (1,650 ft) of the tunnel.

In addition, where dacitic, andesitic, and rhyolitic dikes contacted the granodiorite and quartz monzonite, weak zones 0.2–0.6 m (0.5–2 ft) wide affected the bore for approximately 180 m (600 ft). Along most of the TBM's path, hydrothermal metamorphosis had weakened the rock further by veining, fracturing, and jointing. Unsupported wall stability ranged from <30 minutes to months, and the critical zone with the shortest stand-up time was anticipated to be ~170 m (560 ft) in length.

Although none of the rock masses could be considered an "excellent" TBM environment, comprehensive studies and the 1992 geotechnical report (Janzon 1995) concluded that the rock conditions would permit mechanical excavation and that stability, even in the weakest sections, would be adequate for TBM passage and ground support installation. The report actually favored the TBM approach because the TBM machine's low-level vibrations would destabilize hydrothermally altered rock far less than would shock waves from blasting. The report concluded that TBM tunneling would be substantially faster than drill-and-blast excavation.

Mine Equipment Selection

TBM equipment design for the project was based on three parameters: geology, logistics, and tunnel geometry. It was decided to use a hard-rock main-beam TBM.

The TBM was ordered in 1993, before the TBM contractor was selected, in order to meet the construction schedule. Mine management conducted detail studies and held discussions with outside consultants, machine manufacturers, and all potential contractors, then placed the TBM order with The Robbins Company.

The machine (shown assembled at the factory in Figure 12.7-2) is relatively short to allow boring of tight

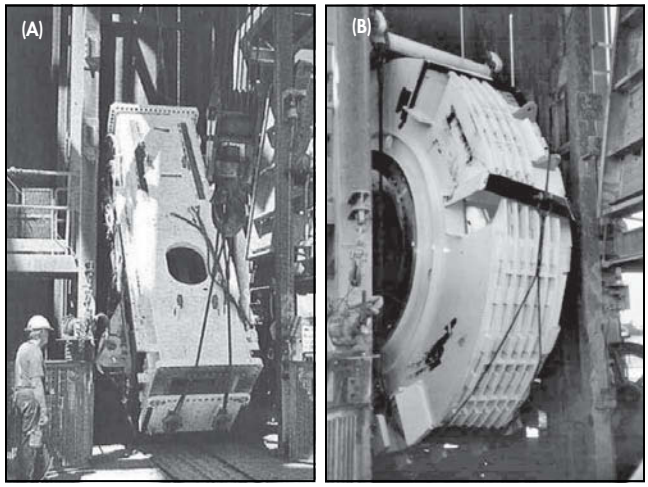
curves. It has back-loading cutters, roof drill fixtures, a ring beam erector for installing W6×20 ring beams, invert thrust system, finger shield, soundproof operator station on the backup, including a closed-circuit TV for monitoring selected areas along the TBM and backup. Specifications for the TBM are listed in Table 12.7-3.



The TBM for the San Manuel mine was custom designed to be lowered down the mine's access shaft piece by piece and assembled underground. The cutterhead and main beam were built in two pieces to meet the space and weight limitations of the access shaft and its 24-t (26.5-st) hoist (Figure 12.7-16). Components were limited in physical dimension to $2 \times 4 \times 12$ m ($6.75 \times 13 \times 39$ ft). More than 65 components were lowered down the shaft. Large components were suspended beneath the service cage; other parts fit inside the cage.

A further requirement was that all transport and assembly operations had to take place without interrupting full-time mining. Assembly of the machine was essentially complete in 114 shift hours, which was proof of excellent planning and a dedicated work crew.

The TBM contract was awarded to Frontier Kemper Constructors, Inc./Daniel Haniel GmbH (FK/DH). The contractor designed and manufactured the trailing gear and support equipment to fit the same logistical criteria and requirements as specified for the TBM. The 143-m- (470-ft-) long backup equipment consisted of 16 frame cars to house all electrical, hydraulic, ventilation, cooling, and muck-handling equipment. Because of the many short-radius curves, the contractor selected rail haulage using Mühlhäuser 10-m^3 (13-yd^3) muck cars and Brookville 27.2-t (30-st) locomotives. A California switch was selected and moved; permanent switches were installed, two on the grizzly level and one on the 3570 haulage level.

Mining Setbacks and TBM Modifications

TBM progress in the initial 1,830-m (6,000-ft) tunnel was not as expected. A number of problems plagued the operation. For example, clay plugged the cutterhead; a large cavity ($h \times w \times l = 9 \times 6 \times 5$ m [$30 \times 20 \times 16$ ft]) developed above the tunnel profile; loose material fell through the finger shield; steering problems developed because of failure to maintain proper alignment in the curves; and some machine problems developed. In addition, stand-up times in highly fractured areas were not as predicted, because rock often turned to rubble immediately or within minutes in the crown or along the tunnel sidewalls.

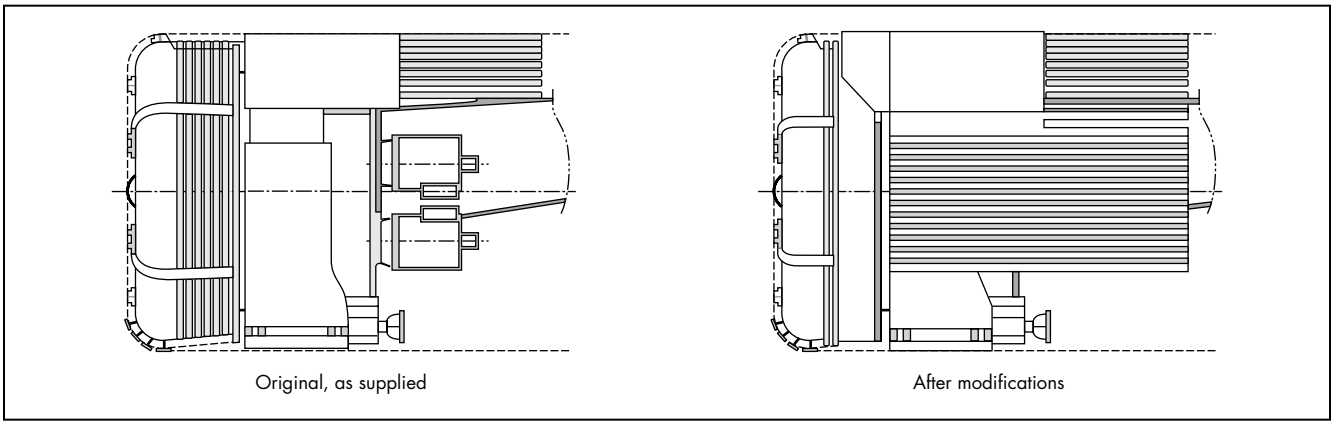
Figure 12.7-16 Two TBM components being lowered down the mine's No. 5 access shaft: (A) part of main beam; (B) split cutterhead



To achieve the planned rate of advance, the TBM needed to be modified quickly. An evaluation team consisting of Magma Copper, the TBM manufacturer, the contractor, and two outside consultants recommended the following modifications:

- Replace two of the gauge cutters with two additional muck buckets and close the peripheral side buckets off to reduce ingestion of rock behind the gauge cutters.
- Extend the roof support forward by a canopy to limit cutterhead exposure.
- Add fingers to the side supports to increase the surface area of the support.
- Improve starting and breakout torque by reducing cutterhead rpm from 12.2 to 9.3.
- Replace the two 1,300-kVA transformers with two 1,600-kVA transformers.

Some of these modifications are shown in Figure 12.7-17.

Early on, because of the highly variable ground conditions, the use of rock bolting had been abandoned, roof drill fixtures had been removed, and the operation had moved to exclusive use of ring beams to support the rock. Doing so not only saved labor but also provided more room in the congested work area immediately behind the cutterhead support.

The modifications greatly improved TBM performance in all areas. Cutterhead starting problems and ingestion of muck from above the cutterhead were eliminated, fallout of material from the sidewall was reduced to acceptable levels, and bucket plugging occurred only in areas of high clay content. A curve with a radius of 109 m (350 ft) was accomplished by means of "crab steering" without plowing the sidewalls. A beneficial side-effect of lowering the cutterhead speed was more efficient transfer of muck from the cutterhead buckets to the muck chute and machine conveyor belt. The results of the

modifications, measured by comparing the lengths of advance before and after modifications, are shown in Table 12.7-4.

The Magma Copper Company concluded the following (Van Der Pas and Allum 1995):

> Advance rates achieved after completion of the modifications have proven that the decision to utilize a TBM for the initial development of the Lower Kalamazoo was the correct one. Even though the TBM was designed to the best interpretation of conditions likely to be encountered, as so often happens in underground construction work, the conditions encountered did not exactly match the assumptions that were the initial basis for the project. The correct analysis of the problems by TBM operations personnel, the TBM Evaluation Team, The Robbins Company and the consultants resulted in the successful modifications. Careful planning, scheduling and teamwork by operations personnel allowed the modifications to be completed on schedule and as planned....
>
> Many individuals and individual organizations spent a great deal of time and effort to determine what was required to make the project a success. It was the ability of those groups of people to focus on solutions to the problems instead of who to blame that built the foundation to success. The formation of a joint management team enabled both Magma and FK/DH to function side by side while solving the daily coordination problems as created by both organizations. Commitment to a successful project by the owner, the contractor, and the equipment manufacturer created a true working team. That team collectively was able to generate the results needed to prove that TBM technology in a deep underground copper mine can be a success.

CONCLUSIONS AND RECOMMENDATIONS

Excavation of strategic mine openings by TBM methods is safe, fast, and economically feasible when

- Geological conditions are suitable for the intended mechanical excavation method;
- Length and alignment of the heading is amenable to the equipment selected;
- Operating and maintenance personnel are properly trained and committed to the success of the method;
- Mine management is committed to the priority and success of the work;
- Proper equipment, methods, and support supplies are selected; and
- The scope of work justifies the capital expenditure.

TBM manufacturers are prepared to make the following modifications to standard civil-engineering TBMs in order to expand successful use in mines:

- Lower machine capacity to enable consistent daily advances of 10 to 15 m (33 to 50 ft). This results in smaller, lighter TBM components and more room around the cutterhead for ground support.
- Tighten the turning radius to <100 m (330 ft).
- Create a total system that enables continuous concrete invert installation and access by standard mine vehicles, and muck removal by conveyor.
- Facilitate modern ground support techniques that allow loose rock to be held in place and rock support to be installed while boring.

With a good working relationship between the mine and suppliers, as took place at the San Manuel mine, beneficial use of TBMs in mines can be achieved.

ACKNOWLEDGMENTS

This chapter is based largely on work by Bruce G. Moulton, a retired mining engineer and former president of Construction

and Tunneling Services, Inc., who has kindly allowed use of his paper, "Tunnel Boring Machine Applications In Mining" (Moulton 1997). The information herein reflects technical information, project summaries, and price levels as of October 2009.

CHAPTER 12.8

Underground Ore Movement

Martyn Bloss, Paul Harvey, Don Grant, and Cameron Routley

INTRODUCTION

This chapter provides an overview of the common ore-handling system components available to underground mining operations, including loaders, trucks, orepasses, crushers, conveyors, rail haulage, hydraulic haulage, and other systems. Shafts are described in more detail in Chapter 12.4.

Context Within the Underground Mine

The ore-handling strategy has considerable impact on the value of any underground mining operation. The definition of *ore handling* is any process that moves or transforms ore from one state in the overall value chain to the next more valuable state. In this context, every major process in the mine can be considered ore handling, including those that do not physically move ore. These include resource drilling, mine planning, mine development, production drilling, production blasting, and backfilling. As such, although this chapter mainly considers the physical movement of ore, it is only one component of the total ore movement. It is, therefore, important to consider a more holistic and integrated view when developing the physical ore-handling strategy, because this strategy is most likely to be influenced by (and complementary to) all value-adding processes within the mine, whether physical or not.

Poor ore-handling decisions can lead to underperformance of the mine, high production variability, declining performance over time, and unexpected costs. In addition, opportunities could be lost if little consideration has been given to future changes in mining strategy or expansion options. Value of the business could also be reduced if the ore-handling system is not flexible enough to respond to external influences such as changes in metal prices, technology, and license-to-operate conditions. A successful ore-handling system will demonstrate

- Planned variability within limits over the expected life of the operation,
- Practical and effective maintenance programs to maintain high equipment availability without creating long-term throughput bottlenecks,
- Good cost management, and
- Optionality to respond to changes in business strategy and external influences.

Because an ore-handling system can be the most inflexible component of the overall mining system, a mine's ability to adapt to future business conditions is linked directly to its ore-handling system's ability to respond to such changes. Planning for the future should therefore be a significant consideration in any ore-handling system design process.

Waste handling also needs to be considered as an integrated part of the ore-handling strategy. Because business value impacts (e.g., costs, destination, downstream processing) associated with handling ore and waste will be different, the two material streams cannot be considered in isolation. For example, if the financial cost of disposing waste separately exceeds the cost of including it in the ore stream, then the waste should be included in the ore stream.

Strategy

With reference to Figure 12.8-1, each step in a mining system value chain consists of an upstream buffer (stockpile) of ore, an ore-handling process that upgrades the ore to another value state, and a downstream buffer. The downstream buffer then becomes the upstream buffer to the next ore-handling process. A real system may be more complex in some parts than the simple series value chain shown in Figure 12.8-1, but the linkage between buffers and ore-handling processes remains unchanged.

Bottlenecks

Based on the theory of constraints (Goldratt and Cox 1992), any manufacturing process contains a single bottleneck, or a

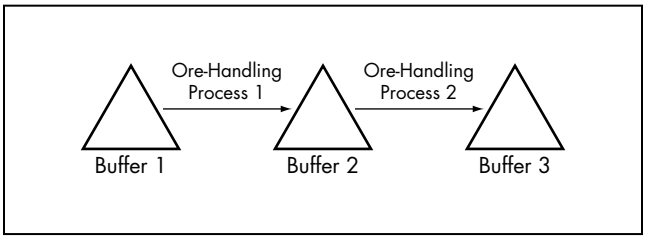

Figure 12.8-1 Linkage between ore-handling processes and supporting buffers

process that controls the output rate. By definition, the bottleneck has the lowest rate of production. Controlled systems have a clearly identified bottleneck that is stable, meaning it does not migrate from one process to another over time. Because of their predictability of performance, controlled systems are more amenable to cost efficiency and continuous improvement, whereas uncontrolled systems have high throughput variability and significant unplanned interruptions.

The process of developing a controlled ore-handling system is to

- Identify where the bottleneck is (or should be); and
- Establish capacities and rates for upstream and downstream buffers and ore-handling processes, respectively, in order to stabilize the bottleneck at the designed location in the value chain.

When this is achieved, the overall performance of the underground mine can be managed to achieve a desired outcome. If throughput is fixed, then cost efficiencies can be achieved by ensuring that only the minimum work required to maintain the buffers at the desired levels is undertaken. If throughput is to be increased, efforts should be focused on maximizing the rate of ore movement through the bottleneck, because this is the rate-limiting step in the overall value chain. Resources allocated elsewhere in the mine will not impact overall throughput. As the rate through the bottleneck increases, its location may migrate to another ore-handling process. At this stage the exercise is repeated at this new location, with the establishment of new buffer capacities and so forth, and an ongoing drive to increase the rate through the new bottleneck. This is continued until a new throughput level is achieved.

For an operation to run effectively there must be a single, well-defined bottleneck. Attempting to match all rates of the process will only lead to poor control of the overall operation, as the bottleneck will shift in response to short-term variability in the performance of each individual process.

The choice of the most appropriate bottleneck location depends on many factors. Foremost is whether the mining operation is currently in an operating state or the design phase. For a new operation, there is an opportunity to optimally locate the bottleneck from the start of the project. Ultimately, the constraint on mine throughput is the resource footprint and the rate at which this resource can be exploited. However, from a valuation perspective (e.g., net present value), sensitivity analyses for various operational configurations should be undertaken to establish the best location for the bottleneck. As a guide, the process in which the capital cost per ton of incremental ore is the greatest should be considered as optimal for locating the bottleneck. This is because over time it is likely that the bottleneck will naturally migrate to this location through continuous improvement of lower capital cost processes, so the sooner this is established, the greater the opportunity to bring forward (in time) positive cash flows to the business. This will not always be the case, however, because a good business case may be made for installing latent capacity initially in high capital items if expansion is planned in the short to medium term and the cost (in present value terms) of expanding these capital items is far greater at a later date. Essentially, the appropriate choice of bottleneck needs to factor in both initial and future plans for the operation.

If the operation is currently in production, an initial choice for the bottleneck is the most practical location to stabilize production in the short term. This allows control to be established and an effective process of debottlenecking to commence. Without this initial control, frequent shifts in the bottleneck will make any attempt at continuous improvement difficult to establish and progress. At the same time, a vision of the bottleneck's long-term location should be established, together with a plan for gradually migrating the bottleneck to this location. Once again, sensitivity analysis of various configurations should be undertaken to establish this optimal position, with a likely outcome being the process that has the highest capital cost per ton of incremental ore.

By definition, because the bottleneck is the only process that is 100% utilized at any given time, nonbottleneck processes cannot be 100% utilized, unless buffer capacity is unlimited and high-cost stock buildup was not being effectively managed. Therefore, nonbottleneck processes must cycle through periods of high and low utilization, according to the buffers' capacities. This is a difficult concept to manage in a mining operation where high utilization is demanded for all equipment and people. One option is to manage buffer levels between high and low trigger values, by deliberately under-resourcing with permanent equipment and people, and employing contractors for fixed periods of time when required. In that way, utilization of the mobilized resources is always high. This concept is described in Figure 12.8-2.

Bloss (2009) describes a practical example where the theory of constraints was applied to the underground mine at Olympic Dam in South Australia to increase throughput by 18%.

Buffers

As described in Figure 12.8-1, an effective ore-handling strategy needs to include the application of buffers between all processes in the ore-handling stream. Buffers exist in a number of forms; for example, as stockpiles, storage bins, orepasses, broken ore stocks within stopes, drilled and developed ore stocks, ore reserve, and mineral resource. They exist between two processes in the value chain in order to provide surge capacity so that variability in performance of either process can exist with minimal impact on the other process. Buffers are particularly important in order to protect the bottleneck, as, by definition, lost production through the bottleneck is lost to the system and cannot be recovered. As a default starting point, it is good practice to assume that a buffer is required between every pair of processes and that any decision not to provide a buffer is justified explicitly as part of the mining strategy. In that way, inadvertent omissions of critical buffers are minimized.

Some key aspects that need to be addressed during designing any buffer include the following:

- What is the size of buffer required?
- What is the required life?

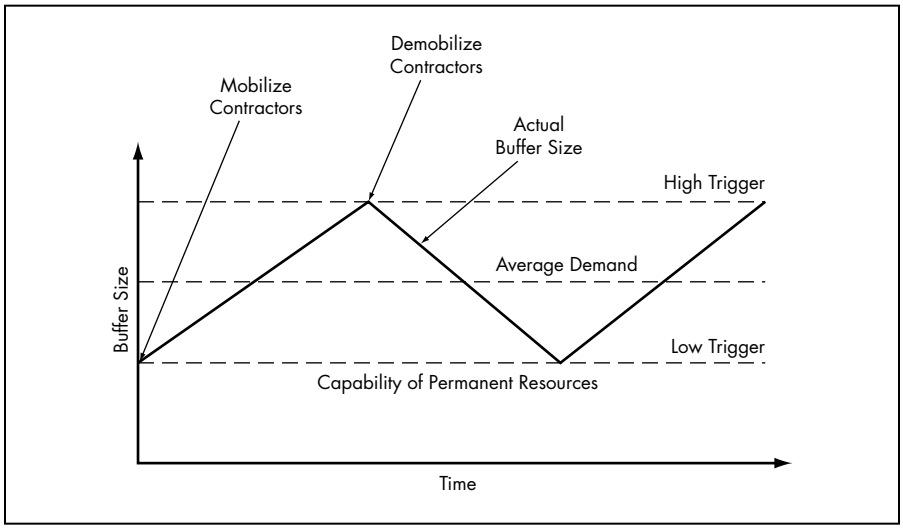

Figure 12.8-2 Use of contractor resources to manage buffers in nonbottleneck processes

- What options are available to provide a buffer of the required size and life span?
- What are the capital and ongoing operating costs of the first three options?
- How can it be designed to minimize operational downtime (e.g., blockages)?
- How can it be effectively maintained in a serviceable state (including replacement options) without adversely impacting future mine throughput?
- How effectively does the buffer integrate into upstream and downstream processes?
- What optionality exists for expanding the capacity of the buffer (enlarging, duplicating) to meet future strategic scenarios?
- Are there requirements for separating the ore into high/low/waste grade or according to other specifications?

Maintenance, Contingency, and Optionality Plans

In order to plan for future uncertainties, management strategies for each buffer and ore-handling process should include maintenance, contingency, and optionality plans. Maintenance plans protect throughput during ongoing operations and discrete and planned periods of major maintenance work. Contingency plans manage the risk of reduced performance as a result of unforeseen events. Optionality plans consider the potential for either a change in mining strategy or future capacity expansions. In many cases, these management plans are complementary. For example, provision of a redundant orepass can be an effective strategy to manage both maintenance and operational issues but can also be built into an optionality strategy in which the additional pass can be used, for example, to increase throughput in the mine or to segregate ores of different grades.

Table 12.8-1 describes some examples of maintenance, contingency, and optionality plans that could be employed to various components of an ore-handling system.

Selection Process

Materials handling is generally a big investment and can be the largest single investment in any new mine. The selection process needs to balance the knowns (capital cost, current operating conditions) against the unknowns (future operating conditions). This is not a trivial exercise, as the future operating condition has many dimensions, most of which are difficult to quantify with certainty. These include the following.

- **Safety:** Is the ore-handling system capable of adopting ongoing improvements in safety systems, processes, and technology (e.g., automation)?
- **Revenue:** Will changing metal prices affect business decisions that could impact the choice of ore handling?
- **Cost:** Will the cost of handling ore increase excessively?
- **Throughput options:** Does the ore-handling system provide the flexibility to increase throughput if required, without significant financial hurdles (including business interruptions)?
- **Geographic footprint:** Will the changing mining footprint over time adversely impact production cost and/or throughput?
- **Ground conditions:** What will be the impact of deteriorating ground conditions (directly relating to ore handling) on production cost and/or throughput?
- **License to operate (company strategy and regulations, government regulations, etc.):** Will mandated changes to operating practices (e.g., health, safety, environmental) impact the ore-handling system such that production costs and/or throughput are adversely affected?
- **Availability and reliability:** Will maintenance performance decline excessively and will the cost of sustaining performance be excessive? Can major maintenance works be carried out without adversely affecting mine performance?
- **Maintenance support:** Will the maintenance support be adequate? This can be an issue if new and/or specialized technology has been employed, where maintenance support can be problematic in terms of either speed of response or quality of service. A risk–reward evaluation is recommended to determine whether the benefits of the technology are outweighed by the reduction in equipment availability as a result of substandard maintenance support.
- **Replacement and/or major maintenance:** Is there scope for replacing/ maintaining key infrastructure, if required, without significant business interruptions?

Table 12.8-1 Examples of maintenance, contingency, and optionality plans

Component of Ore-Handling System	Maintenance Planning	Contingency Planning	Optionality Planning
Loaders/trucks	• Good availability track record • Fast response of spare parts • Duty/standby equipment • Major component change-out plan • Flexible fleet configuration • Good maintenance support—large skills base developed and maintained	• Capability to increase/decrease resources on demand • Flexible fleet configuration • Remote and automation capability	• Capability to increase resources on demand • Haulage routes capable of being expanded to account for changing mine's geographic footprint or mining strategy • Capability to adopt latest technology into fleet • Highly flexible to respond to different mine configurations
Orepasses	• Designed in best possible ground conditions, based on rock quality and both virgin and induced stresses over time • Good access for regular inspection and remedial work • Good monitoring and reconciliation systems (tons in versus tons out) implemented • Good understanding of long-term deterioration due to stress conditions and planned maintenance program • Artificial support options • Provision of backup pass • Simple design • Management of rock size going into pass (sizing)	• Provision of backup passes • Provision to duplicate passes if required due to failure of existing passes—passes have limited life, and, if small in number, premature failure could be a major issue • Good access for regular inspection and remedial work • Good access to manage hang-ups	• Provision for additional passes • Limited optionality for each individual pass—long lead time to design and install
Chutes	• Simple, robust, and reliable design • Integrated planned maintenance schedule	• Effective plan for unblocking chutes	• Fully automatable
Trains	• Duty/standby equipment • Good maintenance support—specialist skills required • Integrated planned maintenance schedule	• Latent instantaneous capacity • Critical spare parts inventory • Good maintenance support • Fully automatable	• Provision for additional capacity • Provision to expand rail system • Designed and constructed for long life and optionality—no option for long shutdown periods • Control of systems to optimize performance
Storage facilities (bins, stockpiles)	• Provision of backup storage facility—shutdowns are long and costly	• Adequate capacity storage (buffer) between all ore-handling processes • High-capacity buffers supporting bottleneck	• Provision for additional storage facilities • Optionality to split into different material streams (ore, waste, etc.)
Conveyors	• Latent instantaneous capacity • Good maintenance support • Integrated planned maintenance schedule	• Latent instantaneous capacity • Critical spare parts inventory • Good maintenance support	• Provision to increase belt speed • Provision to duplicate belt system • Provision to extend system to new mining areas
Crushers	• Latent capacity • Good maintenance support • Integrated planned maintenance schedule	• Latent capacity • Critical spare parts inventory • Good maintenance support	• Latent capacity • Provision to duplicate crusher
Shafts	• Latent instantaneous capacity • Good maintenance support (noting the extreme skills shortage in this field) • Integrated planned maintenance schedule	• Latent instantaneous capacity • Critical spare parts inventory • Good maintenance support	• Provision to increase skip weight/speed • Provision to duplicate shaft • Automation

- **New technologies:** Can the system take advantage of new technologies to add value (e.g., reduce costs, increase throughput)?
- **System robustness:** Is the system capable of effectively responding to unplanned variability in key input characteristics and maintain planned throughput? Some examples are
  - Particle size changes;
  - Presence of undesirable material (e.g., rock bolts, cables);
  - Presence of backfill material, clay, or other sticky waste material (e.g., fine, high moisture content potentially causing significant blockages in chutes and transfer points);
  - Water content changes;
  - Major unplanned failures of internal, upstream, or downstream processes; and
  - Changes in spatial distribution of ore supply.
- **Change in mining method:** Will potential future changes in the mining method be adequately serviced by the ore-handling system?
- **Change in ore-handling system:** Can possible additions, changes, or enhancements to the ore-handling system over time be adequately integrated into the existing system and implemented without adversely affecting system availability?
- **Continuous improvement:** Is the ore-handling system capable of facilitating ongoing improvement in order to increase operational efficiency?

- **Short-term operational variability:** Can the system adequately manage short-term operational variability through effective use of upstream and downstream buffers? This is particularly important if the ore-handling system is the business bottleneck.

A common selection process, described in Table 12.8-2, is based on the development of a matrix in which the various ore-handling options are assessed and ranked against key design and operational criteria. Each criterion is assigned a weighting based on the importance of that criterion to the selection. For each ore-handling option, a performance score is then assigned to each criterion. The weighted scores are then totalled, and the highest score is used to determine the preferred option.

Although this process is relatively simple and efficient, and can achieve good stakeholder buy-in, it has a number of potential shortcomings:

- The ore-handling options will be based on experience and may not include a broad enough choice.
- All relevant selection criteria, particularly those that relate to future uncertainty, may not be considered.
- The weighting assigned to each selection criterion may be subjective.
- The score assigned to some selection criterion for each ore-handling option may also be subjective.
- The summing of weighted scores for each ore-handling option to determine an overall score may not reflect the true relative impact of each selection criterion.

There is a risk that the selection outcome will be biased toward those options that prioritize currently known aspects of the design (e.g., capital and operating costs) over future unknown aspects. If, for example, two options have similar appeal in the current time frame, but the less attractive has greater optionality in the future, this option should be the preferred option. For this reason, it is recommended that this process be used as only one component of an overall selection study.

Table 12.8-2 Example of a common ore-handling selection process*

Ore-Handling Options	Selection Criterion				Total Weighted Score
	1	2	3	4	
Weighting	40	30	20	10	
Option 1	2.0	6.0	1.0	8.0	3.6
Option 2	7.0	7.0	3.0	1.0	5.6
Option 3	8.0	2.0	9.0	5.0	6.1
Option 4	6.0	6.0	7.0	7.0	6.3

*All scores are from a total of 10.

Comparison Between Ore-Handling-System Options

The following discussion compares the three most common ore-handling systems: shaft, conveyor, and truck. These systems usually contain other supplementary ore-handling components, including loaders, orepasses, and crushers. In this comparison, it is assumed that a significant vertical lift is required to bring the ore to the surface, therefore limiting the application of rail as a primary ore-handling system.

In assessing the relativity of these systems, notably, other issues not related to materials handling may often affect the choice of system. For example, if a decline system is required for access and provision of routine services to the underground, the incremental cost to also utilize this access for trucking, for example, may be much lower than the total cost. Hence the decline option may be cost-effective relative to other ore-handling options.

Cost

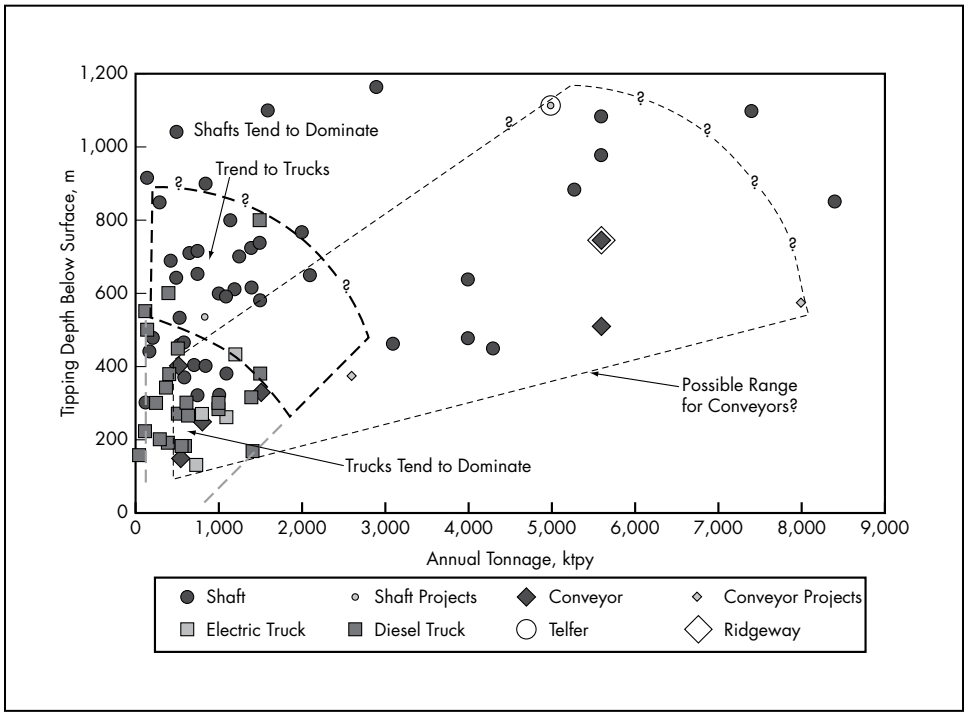
Shaft systems usually attract the highest capital cost; however, as depth increases, the alternatives become progressively more expensive, and the capital cost difference relative to shaft systems decreases. Once installed, however, shafts attract a relatively low operating cost.

Conveyor systems have recently been demonstrated to be cost-effective relative to shaft systems. Pratt and Ellen (2005) demonstrated negligible capital and operating cost differential between the two systems during a selection study at the Telfer operation in northern Western Australia. The shaft option was preferred due to other factors such as physical impact on the orebody, footprint required, and flexibility to service future economic ore zones.

Trucks are usually lower in capital cost but have higher operating costs. Recent improvements in trucking technology have increased the depth to which trucking costs remain economically attractive. Pratt and Ellen (2005) suggest that trucking is not economically viable over a range of mining rates from 1.5 Mt/a (million metric tons per annum) to 6 Mt/a below a depth of 650 m.

Figure 12.8-3 describes the capability of established underground mine haulage systems at the Telfer and Ridgeway gold mines in Australia. The choice of system is largely based on the cost efficiency as a function of depth and throughput.

Safety



All options have safety risks that need to be managed. For shafts, risks are associated with working at heights during inspection and maintenance work, and interactions with personnel during operations. For conveyors, fires and personnel interaction with the moving belts are of particular concern. For trucks, fires and vehicle-to-vehicle and vehicle-to-pedestrian interactions are the highest risk issues, all of which can be managed effectively through the application of adequate design and appropriate procedures. Some examples are presented in more detail later in the chapter.

Timing

Truck haulage via a decline offers a particular advantage in the ability to access ore progressively as the decline is sunk. In this way, positive cash flow can be generated earlier in the mine life compared to alternative systems where installation must be achieved to full depth prior to ore production. In cases in which a surface access decline is being established in a mine where the ore will ultimately be hoisted using a shaft, it may be advantageous to utilize truck haulage up the decline early in the mine life, prior to commissioning of the shaft. Examples of this application include the BHP Billiton Cannington mine in northwest Queensland, Australia, and Newmont Mining's Leeville mine in northern Nevada, United States.

Optionality

Because mines typically evolve over time, the ability of a mine to vary its operating strategy, in order to optimize production

Source: Pratt 2005. Reprinted with permission from the Australasian Institute of Mining and Metallurgy.
Figure 12.8-3 Capability of established underground mine haulage systems

in response to changes, can often be a function of the optionality embedded within the ore-handling system. Although shaft and conveyor systems can be inflexible because of the limited number of fixed feed points, trucking systems are flexible because generally trucks can travel to most locations in the underground mine. Where fixed infrastructure ore-handling systems are employed, the tendency is to introduce hybrid systems (e.g., trucks feeding shaft) as the mine evolves in order to respond to changes.

In situations where the underground mine capacity needs to expand to increase business value, the potential is often related to the configuration and current utilization of the ore-handling system. If the existing system is based on trucks, the expansion can typically be achieved incrementally by adding trucks as required until the capacity (e.g., ventilation, traffic congestion) of the decline system is reached. Following this, additional access would be required at significant cost. Increasing throughput in fixed systems such as shaft hoisting and conveyors is relatively cheap up to a point where the systems' utilization is at the industry benchmark. Following this, higher utilization will probably require duplication of the existing system at significant cost. This is likely to be justified financially only if there is a step increase in throughput or the geologic footprint has evolved substantially enough that a duplicate system is justified to maintain or create a step change in expected efficiencies and associated operating costs.

LOADERS

Loaders move ore and waste from the development face, stope, pass, or stockpile to the next step in the ore- or waste-handling system. The types of loaders include

- Rubber tired,
- Rail mounted,
- Track mounted, and
- Shuttle loaders.

Loaders are most commonly a single-function unit but in certain applications can be part of a multifunction unit. The most common form of the latter is a continuous miner, which can cut coal from a coal face, load the coal into a transport vehicle, and also install roof support (when equipped to do so).

Rubber-tired loaders in metalliferous mines are referred to by many different names around the world, according to local preference. These include loader, load-haul-dump (LHD), scooptram, scoop, bogger, digger, mucker, and underground loader. An underground loader is shown in Figure 12.8-4.

Underground loaders are typically the first component of the ore-handling system. Loaders extract ore from the stope and either dump (tip) directly into an orepass or load into a truck that hauls the ore to an orepass or surface stockpile. The size of the loader fleet will be determined according to the following factors:

- Mining method
- Geometry of the stope/ore working face
- Size of underground excavation
- Geometry of the ore-handling system
- Production rate based on planned strategic objectives
- Productive operating time or availability and utilization per shift
- Loader productivity
- Geometry and condition of the tram/haul route
- Capital and operating costs

The mining method will determine the relative proportions of stope ore, development ore, and waste. The geometry of the stope or ore working face may limit the size of loader that can be used. Ground conditions will determine underground

Source: Caterpillar 2009.
Figure 12.8-4 2900G Elphinstone loader

excavation dimensions, which in turn will impact fleet size and equipment selection. The geometry of the ore-handling system will determine the proportion of material required to be rehandled. Sweigard (1992) provides a good overview of the equipment selection and the fleet size estimation process. This information allows mapping of loader tram segments to determine quantities of ore movement required to achieve the nominated production rate. Typical units of measurement are metric tons per operating hour (t/h) and ton-kilometer per operating hour (t·km/h), which is based on the one-way length of the tram. Preliminary estimates of total operating hours per year or total ton-kilometers per year for various sizes of loaders allow for an initial estimate of loader fleet size.

Further details on loader productivity are available in Sweigard (1992) and the various underground equipment manufacturers' specifications (e.g., available on the Caterpillar, Sandvik, and Atlas Copco Web sites). Gradeability/speed/rimpull charts similar to Figure 12.8-5 and equipment dimensions (Caterpillar 2004) provide useful specifications for determining loader performance in differing conditions. The calculation for estimating truck fleet performance is performed using a similar methodology.

Loaders tend to be as large as development allows, and tram distances are minimized to maximize productivity per loader. Loader trams greater than 250 m become less effective. To allow production to continue when the stope brow becomes open, the loader requires line-of-sight remote or tele-remote capacity. The loader bucket may also use different tooth configurations to assist digging in the stope drawpoint.

Safety Considerations

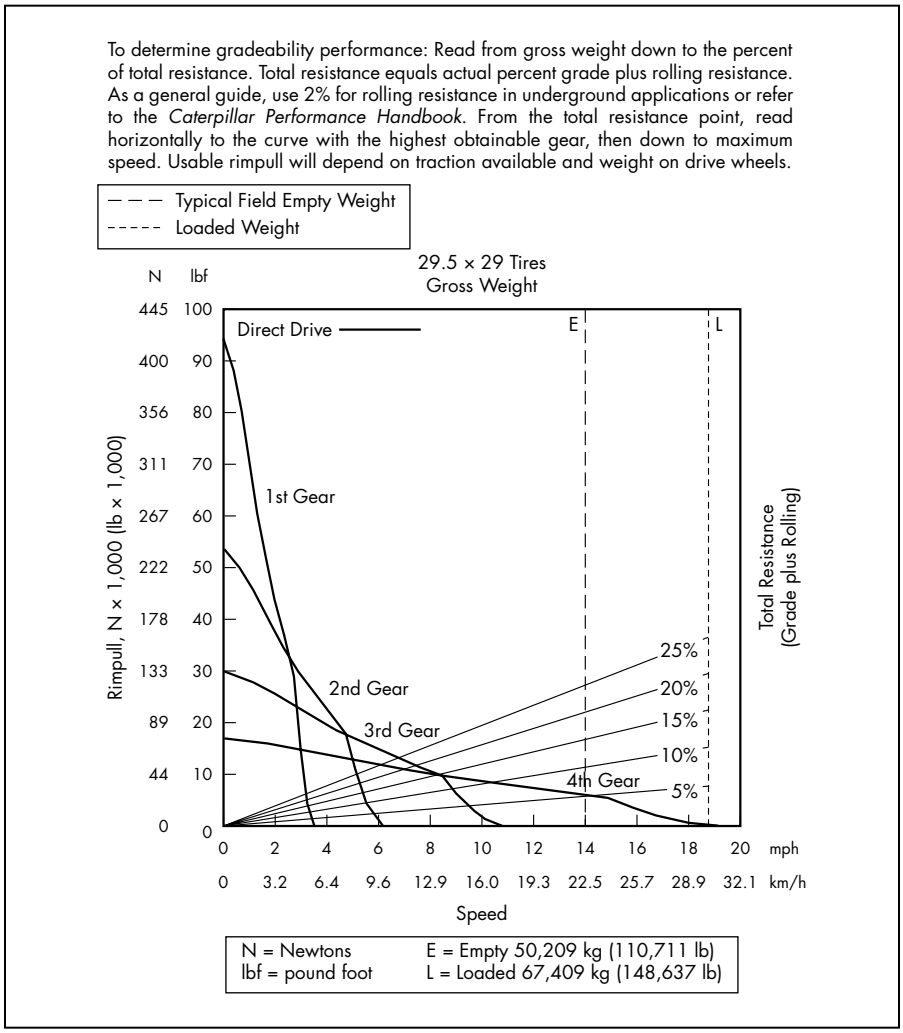
Safety issues that need to be considered during the design phase and implemented during the operations phase include the following.

- Light vehicle, heavy vehicle, and pedestrian interaction: Some strategies that can be employed to manage this issue include separating heavy vehicles from light vehicles and pedestrians, detection and collision avoidance systems, traffic rules, and visual and audible signalling systems.
- Remote loading at the stope drawpoint (operator interaction): The most effective method is to isolate the operator from the machine by using tele-remoting systems.
- Loading at a stope brow or orepass and initiating a mud rush or air blast: To manage this situation, a good understanding of the stope's material characteristics is required, together with strict controls and procedures regarding the methods of extraction from the drawpoint to ensure predictable behavior of material flow from the drawpoint.
- Fire on the loader: Minimizing risks and consequences of loader fires requires quality equipment design, effective preventive maintenance programs, well-trained operators, reliable automated onboard fire prevention and firefighting systems, and sound procedures for managing fires.
- Equipment failure during operation: Minimizing risks and consequences of equipment failure requires quality equipment design, an effective preventive maintenance system, well-trained operators, and controls that minimize personnel exposure to loader operations.
- Open holes (including tipples): Effective hard and soft controls are required to minimize risks associated with operating around open holes, including solid barriers, good lighting and signage, and procedures.
- Operator ergonomics: The well-being of personnel during loader operation and maintenance is paramount to sustainable operations. High-quality, fit-for-purpose design, both within the operator's cabin and wherever personnel work on the loader, is critical to achieving this objective.

Design and Construction Issues

Underground access development needs to be purposely designed to accommodate selected loaders and trucks. As a general rule, all rubber-tired equipment should operate in development with gradients of at least 1:50 to minimize water ponding and to provide good road conditions. Key development components are

- Drawpoints,
- Tramming drifts (drives),
- Tipple accesses,
- Stockpile bays, and
- Truck-loading bays.



These components are described in detail in the following sections.

Drawpoints

Drawpoints provide access to the stope for loaders to extract ore from the stope. The design of a drawpoint needs to consider horizontal and vertical clearances relative to the access walls and back, and gradient of the access. Ideally, the drawpoint should be angled relative to the tramming drive (e.g., 60°) to facilitate ease of entering and exiting. It also needs to be of sufficient length to accommodate the loader while digging the muckpile, without being too long to trigger poor ventilation conditions. At mines where remote loading from the stope is required, a safe operating position needs to be designed into the drawpoint area to protect the loader operator. Figure 12.8-6 shows a tele-remote setup in a Canadian mining operation.

Tramming Drifts (Drives)

Similar to drawpoints, the main design considerations for tramming accesses are clearance, gradient, and orientation geometry.

Source: Caterpillar 2004.

Figure 12.8-5 Caterpillar gradeability/speed/rimpull chart for Elphinstone 2900G

Tipple Accesses

Once again, clearance, gradient, and orientation of tipple accesses are the main design considerations. Back heights above the orepass and in the approach to the orepass are critical to facilitate the dumping (tipping) of the loader bucket and truck tray. If back height becomes problematic, trucks equipped with hydraulic ejector beds and plates should be considered. A steep upward gradient into the orepass reduces the potential for mine water to accumulate and flow into the orepass. Orientation of the tipple access to the main tramming drift (drive) can be perpendicular or angled. A perpendicular access allows loaders to approach from both directions without the requirement for a turnaround bay.

Stockpile Bays

Stockpile bays provide surge capacity and can improve overall ore-handling system utilization. They allow loaders to keep producing while waiting for trucks or full orepasses to clear. Stockpile bays need enough capacity to minimize delays to other parts of the development or production cycle.

Courtesy of Atlas Copco.

Figure 12.8-6 Tele-remote station at a stope drawpoint in Canada

Truck-Loading Bays

Truck-loading bays need to consider back height for loading and localized gradient and geometry constraints. Detailed access development design criteria can be obtained from the different manufacturers' equipment handbooks. Examples of the information available in the equipment handbooks are illustrated in Figure 12.8-5. Generally, maximum efficiency and minimum cost are achieved if the loader is sized to load the truck on the same level, rather than from an elevated loading ramp.

Operational Aspects

Stope Mucking

The productivity of a loader is dependent on a number of factors that facilitate the removal of ore from the drawpoint. Ore size distribution should be relatively homogeneous with minimal oversize or high percentage of fines. Oversized rocks slow the production rate because they must be resized either in the drawpoint or in nearby bomb bays. Processing oversized material in the drawpoint also introduces safety issues, which need to be managed. A high percentage of fine material (e.g., from the failure of a backfill mass) can create difficult operating conditions throughout the ore-handling system, particularly if water is present. Both oversize and fines issues can be better controlled through drill-and-blast design, geotechnical design, and the placement of quality, engineered backfill.

Good physical operating conditions include good ventilation for visibility and water sprays to help suppress dust. Drawpoint brows need to be supported to minimize wear over their anticipated lives. Brow wear can lead to a reduction in effective drawpoint length, making loading difficult, and increases the tonnage of ore that needs to be mucked by remote control.

The ventilation system needs to be monitored, because changes in airflow can occur when the stope brow opens. Additional consideration is required in uranium mines where air transit time becomes a factor in limiting radon residence time. A ventilation quantity of 0.06 $m^3/s/kW$ of engine power is a good standard to meet acceptable environmental conditions within typical mining operations.

Tramming

Loader operators generally prefer to tram with the loader bucket at the rear when loaded and the front when empty. This reduces the occurrence of loaders driving over rocks that fall from the bucket while tramming.

The following key aspects need to be considered and implemented in a practical manner to achieve the best cycle time results:

- **Road maintenance:** Well-maintained roadways are critical for achieving maximum loader speeds and reducing equipment maintenance issues associated with continuous vibration of critical loader components.
- **Drainage:** The establishment of well-drained roadways will also increase achievable tramming speeds, reduce road and vehicle maintenance, and reduce collision with submerged objects that are not visible.
- **Ventilation:** A well-ventilated roadway will provide good visibility of the tramming route, allowing higher loader speeds and reducing the potential for vehicle collision.
- **Lighting:** The installation of lighting on the tramming route can allow higher loader speeds; however, lights should only be considered on a tramming route that is in use for a significant time period.
- **Tram geometry:** This includes the drift (drive) size or available clearance, the gradient (uphill or downhill loaded) and length of tram, and the number of corners or bends in the tram.

Loader Costs

Budget capital cost estimates can be provided from equipment manufacturers. The maintenance change-out program will determine ongoing sustaining capital requirements, depending on the frequency of rebuilds and major component change-outs. Loader operating costs are dependent on labor, fuel and lubricants, tires, bucket wear, maintenance consumables, and equipment damage.

A remote loading operation typically has a higher operating cost resulting from reduced productivity. The ability to estimate the cost of maintenance depends on the relative proportion of predictive and preventive maintenance to breakdown maintenance. Equipment suppliers can provide budget estimates for the majority of consumable operating costs. Equipment damage is difficult to estimate because it is related to a number of factors, including road conditions, visibility, operator experience, equipment clearance dimensions, mining method, tram geometry, and stope drawpoint conditions. A loader performing remote operation into an open stope will have a higher exposure to rockfall damage from unsupported areas of the stope.

Loader productivity and utilization will depend on the activity; for example,

- Development loaders: <4,000 h/yr;
- Sublevel open stoping production loaders: ~4,500 h/yr; and
- Block cave and sublevel cave production loaders: >5,000 h/yr.

Technology

Production Management Systems

A number of commercially available production management systems are used in underground mining operations, including Micromine's PITRAM and Modular Mining's Dispatch. Numerous operations have also developed their own in-house systems, which capture data and allow managers to monitor performance to determine whether operational targets are being achieved. The data are collected using radio communication or tag readers located throughout the mine.

Automation

Automation and remote control technology have been available for underground loaders for more than 20 years. Numerous automation systems are being developed by equipment manufacturers, mining companies, research organizations, technology companies, and various partnerships between these groups. The level of advancement with these automation systems and their ability to operate practically and cost-effectively in the challenging underground environment are still under debate. Substantial progress has been made, and cost-effective, practical automation solutions will be an important part of the future for improved loader productivity and operator safety.

Maintenance

All maintenance programs can be broken down into preventive and breakdown components. Both are required to minimize the risk of fatalities, injuries, and incidents arising from the use of mobile equipment underground and to maximize equipment productivity.

An effective predictive and preventive maintenance program that is prioritized over breakdown maintenance will reduce the potential for personnel injury and increase equipment utilization as a result of the following aspects:

- Replacement of components before they fail and while the equipment is not operating prevents potentially serious consequences, including injury to personnel and damage to associated components.
- More predictable scheduling of maintenance activities allows for better matching between supply of, and demand for, maintenance resources. Breakdown maintenance tends to create boom-and-bust work cycles that cannot be effectively managed using a fixed level of resources.
- More predictable availability of equipment allows for more efficient utilization, as a result of better matching between availability of equipment and supply of operators.

Best practice equipment availabilities are generally achieved by reducing the frequency of breakdown maintenance and increasing mean time between equipment failures. To maintain high availability throughout the useful life of equipment, a well-planned component change-out program is essential. The operating life and timing of major equipment rebuilds will have an impact on capital and operating cost profiles for the mine. Costs of preventive maintenance and major component change-outs need to be consolidated with other operating costs to determine an overall cost per ton-kilometer. This measure can be used to determine the effectiveness of the maintenance program.

TRUCKS

Trucks are used for long or inclined hauls to orepasses or directly to the surface. Commonly available trucking options include

- Diesel or electric articulated dump trucks, or ADTs (Figure 12.8-7);
- Diesel or electric rigid dump trucks;
- Diesel road trains (Figure 12.8-8); and
- Diesel, electric, and battery shuttle cars (Figure 12.8-9).

Trucks can be side loaded near the ore source (e.g., stope drawpoint), or side loaded or chute loaded at the bottom of an orepass.

Safety Considerations

Safety issues that need to be considered during the design phase and implemented during the operations phase include

- Light vehicle, heavy vehicle, and pedestrian interaction;
- Chute loading (the key to minimizing risks is to ensure that the design of the chute fully accounts for the material flow characteristics and the loads that the chute will be subjected to, so there are no unexpected failures in the chute);
- Equipment failure;
- Fire on the truck;

Courtesy of Atlas Copco.

Figure 12.8-8 Ninety-ton road train exiting Sirius mine portal (Western Australia)

- Tipping into open holes; and
- Operator ergonomics.

Selection Criteria

Selection of the appropriate size and type of truck fleet depends on the following key factors:

- Ore reserve tonnage
- Production rate
- Haulage distance
- Depth below surface
- Lateral extent of the mine
- Mining method used
- Integration with upstream and downstream materials-handling processes

Truck haulage is generally the preferred option where the ore reserve is not large enough to justify the capital for a shaft or conveyor hoisting system. For hoisting shaft or inclined conveyor systems, the lateral extent of the mine, distribution of ore, and throughput requirements determine the most effective solution for upstream delivery to a centralized hoist, from a choice of trucking, rail haulage, or conveyor.

ADTs have traditionally been used because of their flexibility and ability to maneuver throughout the ore body in variable conditions. Road trains, electric articulated, and rigid-body trucks have been utilized with varying degrees of success depending on road conditions (grade, vehicle clearance, and road maintenance) and environmental conditions (temperature and visibility).

Figure 12.8-9 Shuttle car in operation in a potash mine

Courtesy of Joy Mining Machinery.
Figure 12.8-10 Coal shuttle car being loaded

Underground coal and potash mines have a unique application for trucks, given the typically narrow seams that are mined. Specialized shuttle cars are used to transport the coal or potash. These are low-profile AC-electric trucks designed to interact effectively with high-capacity continuous miners or roadheaders. They remove material that has been cut by the mining machine and transfer it directly to a main conveyor, which creates an efficient ore-handling system. Shuttle cars can operate in seam heights down to 1.2 m with a capacity of 8 t (e.g., Figure 12.8-10).

Design and Construction Issues

Access design considerations discussed in the "Loaders" section can also be applied to trucks (equipment clearance, gradient, and ground conditions). Additional considerations include

- Side-loading bays,
- Orepass dump point (tipple) configuration,
- Chute-loading systems, and
- Decline haulage access.

Side-Loading Bays

Side-loading bays facilitate the efficient loading of a truck. Side loading of trucks can be performed on level ground (Figure 12.8-7) or with the loader elevated above the truck, utilizing a perpendicularly configured side-loading bay. The latter configuration can be used when the loading point is fixed over an extended time frame and truck spotting times have a significant impact on truck productivity. To facilitate efficient truck loading and reduced spillage, the loader can be elevated 1.5 m above the truck.

Orepass Dump Points (Tipples)

Orepass tipple configuration for trucks requires additional height and length of back stripping compared with a loader configuration. It is also necessary to be able to reverse into the tipple. Additional development may be required to achieve efficient truck tipping.

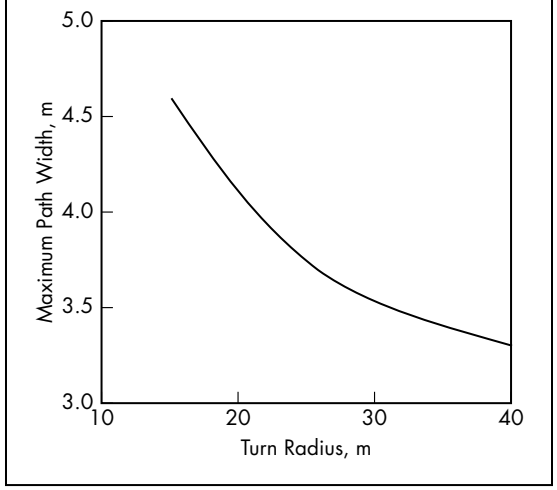
Road trains dump (tip) to the side and therefore require a significantly different layout for an underground tipple. To accommodate side dumping (tipping), a truck loop is generally required. Consideration for a turning radius and a straight section at the dumping point can add a significant amount of underground development as compared with other truck dumping layouts.

Chute-Loading Systems

Truck loops and truck-reversing bays are two commonly used configurations for loading trucks from chutes. When sufficient tonnage is available (e.g., 3 to 4 million t), a truck loop configuration can achieve higher productivity. For lower tonnages, a chute that requires trucks to reverse provides an option with less capital. To further reduce capital costs in low-tonnage, short-term situations, ore can be side loaded into trucks at the bottom of orepasses. To facilitate chute loading of multiple trailers, road trains require a truck loop configuration.

Decline Haulage Access

Decline (or ramp) haulage provides access for trucks to haul ore from underground to a surface stockpile. Design considerations include clearance, gradient, geometry, and frequency and geometry of passing bays. Declines can be designed as a series of long straight sections or as a circular spiral. Passing bays can be designed parallel with or perpendicular to the decline, depending on ground conditions. In most Australian decline trucking operations, stockpile bays are developed every 150 m during construction and then utilized for passing bays. Block light systems are also commonly used to control traffic flow.



ADTs, large rigid-chassis trucks, and road trains with power trailer are effectively used to haul ore long distances to surface stockpiles. Figure 12.8-8 shows a road train exiting a decline portal, and Figure 12.8-11 shows design information for drift (drive) size and road train turning requirements. Robertson et al. (2005) provides a good overview of the future direction of trucking. Because decline haulage trucks usually have to share the decline with other vehicles, numerous traffic control systems are available to reduce the hazard of vehicle interaction.

Trucking Costs

Many factors that influence trucking costs are similar to those for loaders (see the "Loaders" section). The differences are primarily due to the specific functions of the equipment. Loaders are generally more influenced by loading conditions, whereas trucks are more influenced by haulage conditions (road conditions and haul distances).

The two technologies described under "Technology" in the "Loaders" section have similar application to underground trucks and should be considered if justified cost-effectively.

Turn Radius, m	Path Width at 30°, m	Path Width Maximum, m
15	4.2	4.6
20	3.9	4.1
25	3.7	3.8
30	3.5	3.5
40	3.3	3.3

OREPASSES

Orepasses provide a low-cost method to move ore and waste downward between operational horizons in a mine. Initial capital is the dominant cost associated with an orepass system, with lower ongoing sustaining capital and operating costs.

Orepasses can be constructed as one long section or as multiple shorter sections depending on the geometry and/or timing of access to the top and bottom of the orepass and the relative operational and safety aspects during construction.

Flow of material in the orepass is critical to its success. A number of factors need to be considered to maintain continuous flow conditions. Early origins of material flow were analyzed by Janssen (1895), who determined that the weight of the material in the bin or orepass was actually transferred to the walls rather than the bottom of the orepass. This produces the potential for arching, where broken material stabilizes in the pass and prevents material flow. Strategies for avoiding this are discussed in later sections, for example, when considering orepass width.

Safety Considerations

The safety issues that need to be considered during the design phase and implemented during construction and operation include the following.

- **Risks during construction:** The main risks are people working below vertical openings from which material can fall and people falling into open holes. Thorough risk assessments need to be undertaken to ensure that key risks are identified and managed.
- **Clearing of blockages:** Clearance in orepasses involves drilling hang-up holes into the immediate vicinity of the blockage and feeding explosives into the pass to free the blockage.
- **Fall prevention:** Stop (bumper) blocks, orepass covers, signs, barricades, and flashing lights are used to prevent people from falling into or driving equipment into orepass open holes.
- **Mud rushes:** These hazards occur when material containing a high proportion of fines is dumped (tipped) into an orepass and the orepass becomes blocked. When mine water or natural groundwater mixes with the fines in the orepass, there is the potential for a mud rush. The severity of a mud rush depends on the amount of fines in the orepass and the proximity of personnel and equipment to the bottom (discharge point) of the orepass during a mud rush. Management of mud rushes includes understanding material flow properties and developing procedures for managing undesirable combinations of materials that report to the drawpoint. Typically, pedestrians are isolated from any orepass loading activity, and, in cases where mud rushes are likely, remote loader operations are common.

Design and Construction Issues

Orepass design is largely dependent on the geometry of the ore body and the strength of the rock mass in the mine. Hadjigeorgiou et al. (2005) provide a good review of orepass practice in Canadian mines.

Inclination Angle

Orepass inclination angles are generally greater than 60° and should have at least a small amount of inclination from vertical to allow the dumped material's energy to be dissipated on the orepass footwall and therefore prevent free fall of the material to the orepass bottom. Orepass fingers that connect to chutes can be as low as 50° in order to reduce the amount of energy transfer from the ore in the orepass onto the chute.

Length

The length of an orepass is dependent on the vertical distance between stope extraction level(s) and the common ore-handling level. Orepasses are sometimes extended upward to allow more cost-effective dumping (tipping) of development material from upper levels of the stope. The orepass system can be constructed using one or two longer sections or a larger number of shorter sections, depending on access available for construction. The length of each orepass section generally determines the excavation method. Typically, Alimak raising and raise borers can construct longer orepasses, whereas drilled and blasted drop raises and conventional raises are used for shorter-length holes.

Orientation

The orientation of an orepass can be a critical design consideration in rock masses with dominant structures. The most favorable orientation is as close to perpendicular to the dominant structure as practical. In situations where the orepass needs to be oriented parallel with the dominant structure, additional support, liners, or a redundant orepass should be considered.

Shape

The shape of an orepass is dependent on the excavation method. Raise boring will ream a circular shape, while Alimak, drop

raising, and conventional raising typically excavate a square or rectangular shape. If high stress is believed to be a stability issue for the orepass, circular shapes can be excavated with drill-and-blast methods.

Width

The width of an orepass is dependent on size distribution of the broken material, characteristics of the wall rock, and capacity requirements of the orepass. It generally needs to be no greater than five times the dimension of the largest particle that enters the orepass, as described in Table 12.8-3.

Recent work by Hustrulid and Changshou (2004) indicates that the ratios in Table 12.8-3 are conservative. Their work recommends considering size distribution and orepass wall conditions in the design, which will usually lower D/d ratios being practically achieved. Rock mass strength of the orepass wall relative to the predicted induced stress levels and orientation also needs to be considered when sizing the orepass.

Quality of the rock mass in orepass walls will partially determine what orepass size is achievable. Empirical design methods can be used to determine stable spans, and, if high stress fields exist in the mine, numerical modeling should be considered to understand possible future states of stress (magnitude and orientation) in the orepass walls.

Surge capacity requirements of the ore-handling system need to be considered when designing each individual orepass. When the ore-handling system downstream of the orepasses is taken out for maintenance, the loader and truck operation will stop when the orepasses are filled. Effective surge capacity in the ore-handling system allows the components of the system to be less dependent on each other. Surge capacity is generated by expanding the dimensions of the orepass and/or developing strategically located stockpile bays. Enough surge capacity needs to be designed into the orepasses to increase operational flexibility of the total ore-handling system. How much surge capacity can be installed has practical and cost limitations, and the amount of surge required will depend on the benefit realized by smoothing out interruptions in ore flow due to downstream process variability. Surge capacity from several hours to a week should benefit any mining operation if this surge supports the operational bottleneck. Where downstream process variability is significant, consideration should be given to installing the maximum possible surge capacity.

Material may become captured in certain areas of the orepass, and this reduces the effective capacity of the orepass. Sections of the orepass that have changes in direction or angle are more likely to create areas for captured ore and are more susceptible to blockages.

Construction

Orepasses can be constructed using a raise boring machine (Figure 12.8-12), drop raising (long-hole winzing), Alimak raising (Figure 12.8-13), or conventional handheld raising. The most common methods for longer passes are a raise bore machine or Alimak raising. The preferred construction method depends on the specific requirements of the orepass, the geometrical layout of the ore-handling system, and local preference and experience. In the past, Alimak raises were more popular in North America but are becoming less common because the Alimak platform operators are exposed to vertical openings. Alimak raises have the advantage of providing access to install ground support during construction, which can provide long-term orepass stability. The Alimak raise climber shown in Figure 12.8-13 runs on a special guide rail using the Alimak rack-and-pinion system. The guide rail contains three pipes providing compressed air and water for ventilation, scaling, and drilling. Drop raises are commonly used for short orepasses (60 m or less) as blasthole deviation becomes greater at 60 m. Conventional handheld raises are generally limited to short finger raises that connect chutes to the orepass.

Table 12.8-3 Orepass design to prevent interlocking arches

Ratio of Orepass Dimension (D) to Maximum Particle Dimension (d)	Relative Frequency of Interlocking
$D/d > 5$	Very low; flow almost certain
$5 > D/d > 3$	Often; very uncertain flow
$D/d < 3$	Very high; no flow almost certain

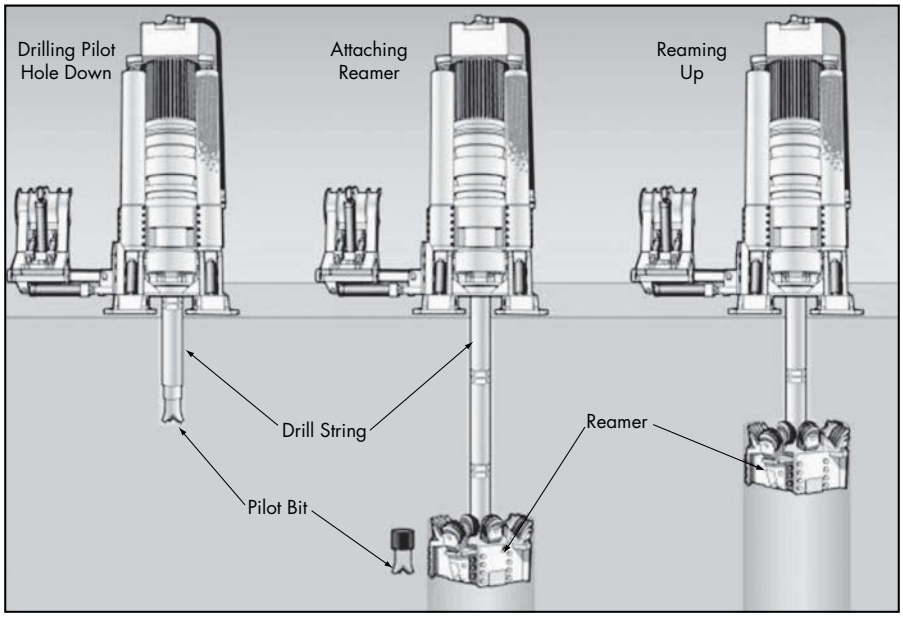
Support Systems

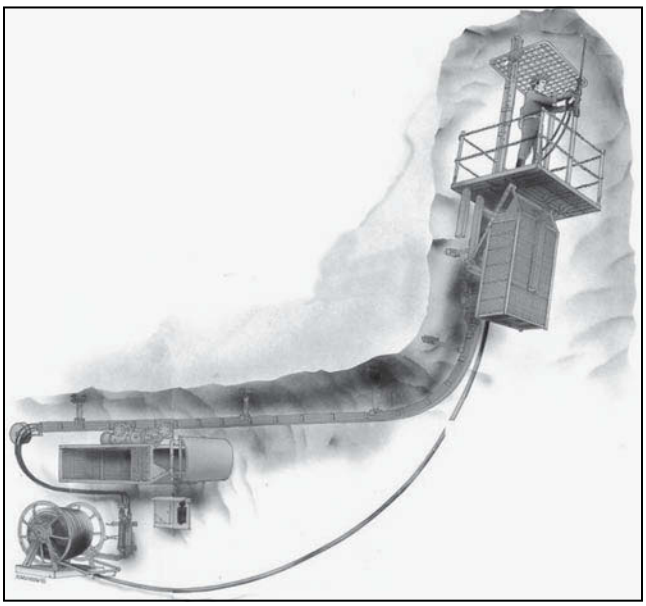
Ground support requirements for orepasses depend on rock mass and induced stress conditions, orientation of the orepass relative to geological structures, size and inclination of the orepass, planned mode of operation (choke fed or open), and planned life span of the orepass.

The type and method of ground support depends on the excavation method. For example, if an Alimak raise is used, it will need to be supported with rock bolts and mesh to protect operators during the construction phase. Ground support systems include metal cans or rings, concrete liners, specialized wear-resistant sprayed-on shotcrete, mesh, and rock reinforcement systems such as rock bolts and cable bolts. In some cases the cost of ground support can exceed excavation, and therefore the decision can be made to leave the orepass unsupported. This option is justified if life expectancy of the orepass in an unsupported state is sufficient. A replacement plan and monitoring program needs to be well defined and communicated to management. Rehabilitation of an orepass, sometimes considered in order to extend its life, can be a time-consuming and costly exercise, which can be avoided by installing ground support at the construction stage or by planning to construct replacement orepasses. Hadjigeorgiou et al. (2004) provides additional details of the different orepass support systems.



Ventilation

Good ventilation at orepass tipples and the extraction horizon is essential to maintaining a productive ore-handling system. Exhaust air from the orepass needs to be removed quickly from operating areas. Good ventilation can be provided by designing and constructing a parallel return air system, which provides effective exhaust capacity at each tipple and the extraction horizon. Spray bars can also be used to suppress dust. A number of ventilation design systems for orepasses are reviewed in Calizaya and Mutama (2004).



Operational Aspects

Key considerations for safe and efficient operation of an orepass are

- Controlling material size entering the orepass,
- Controlling material flow,

Courtesy of Atlas Copco.
Figure 12.8-12 Raise bore machine drilling a pilot hole and reaming an orepass

Courtesy of Australian Contract Mining.
Figure 12.8-13 Alimak raise system

- Continuously monitoring the orepass for wear and stability, and
- Maintaining good ventilation.

Over time, wear of the sidewalls can make an orepass inoperable. With good condition monitoring, orepass refurbishment or replacement can be planned in a proactive and controlled manner. If wear in an orepass goes undetected and makes it unserviceable, the ore-handling system can be disabled for an unacceptable period of time.

Orepass monitoring is an effective tool that can be used to understand the condition and potential life of an orepass. A number of monitoring techniques are available, including quantitative physical surveying of the orepass using probe hole drilling to determine the orepass profile (costly and time-consuming), a cavity monitoring system (e.g., Optech's), cavity autoscanning laser system (e.g., Measurement Devices Ltd.'s), or other laser scanning devices. Other qualitative methods include orepass camera surveying to obtain a video of the orepass, production data to determine a tonnage reconciliation of material movements, and other data captured by operations (i.e., number of hang-up blasts per time period and type of material blasted down during hang-up blasts). Orepass wear is largely caused by structural failure, stress failure, material impact, and abrasion and blast damage (Hadjigeorgiou et al. 2005). The orientation of an orepass relative to dominant structures can have a significant impact on its long-term stability.

The control of material size in an orepass is facilitated using grizzlies, scalpers, mantles, and orepass rings at the entry point. Material flow in the orepass can be controlled by chutes with chains or gates, or a plate feeder at the orepass exit point. When the orepass bottom has no control, a loader is used to control material flow. When oversize material (producing interlocking arches) and/or fines (producing cohesive arches) are introduced to the orepass, the probability of hang-ups increases and can cause delays. This either reduces throughput or increases the cost to maintain throughput by implementing an alternate ore-handling option.

Oversize can be introduced to the orepass by loaders dumping (tipping) elongated, shaped material through the size controls at the entry point of the orepass or from internal fall-off within the orepass. Reestablishment of material flow in the orepass usually requires some form of blasting to provide vibration or sometimes water flow to initiate material flow.

A comprehensive review of methods for releasing blockages is discussed in Hadjigeorgiou et al. (2004). Depending on the severity of the hang-up, it can be a long process to reestablish material flow, and redundant or alternate orepasses should

be considered at the design stage. Choke feeding of material in the orepass can limit internal fall-off by providing confinement to reduce the effect of high-velocity material impacting the orepass walls. In choke-fed orepasses, the material should be continually drawn to reduce the risk of hang-ups.

Fine material can come from backfill falloff within the stope, raise borer cuttings, or highly fragmented development material. The cohesive nature of fine material can cause blockages, especially when the material is not periodically moved in the orepass. The issues with fine material can be magnified if water is simultaneously introduced into the orepass, which increases the potential for a mud rush at the orepass exit point.

Cost Considerations

Cost estimations need to consider the expected life of an orepass and future cost of replacement. Budget capital cost estimates can be obtained from mining contractors or in-house project teams that specialize in raise boring or Alimak raising. Initial capital cost of orepass controls (chutes, feeder, and chain controls) and material sizing systems (grizzlies, orepass rings, rock breakers, etc.) can also be estimated by specialized mining contractors. Ongoing sustaining capital costs for replacement of chutes, plate feeders, grizzlies, orepass rings, liners, and rock support systems need to be factored into overall cost estimates.

Orepass operating costs include mechanical and electrical maintenance on control systems and rock breakers, and drilling and blasting costs associated with clearing orepass blockages. A good orepass design, potentially at a higher capital cost and followed up with disciplined operating practice, will minimize future operating costs and increase productivity of the orepass system.

Advantages and Disadvantages

Advantages of utilizing orepasses include

- A high-capacity system for vertical transport of material,
- Low operating cost, and
- Buffer capacity.

Disadvantages of utilizing orepasses include

- High capital cost,
- Good technical design required;
- Subject to ongoing operational challenges—for example, hang-ups;
- Performance subject to ongoing ground conditions; and
- Difficulty to maintain if ground conditions deteriorate.

CRUSHERS

Material size reduction in many operations is often required for productive and reliable materials handling. By crushing ore underground, an operation can reduce wear on equipment, reduce clearances required in materials-handling processes, increase hoist skip or other conveyance capacity (reduce material void ratio), reduce oversize handling issues such as hang-ups or blockages, and increase secondary crushing and processing productivity.

Crushers are typically required ahead of conveyors and shafts. Where the material is transported to the surface by trucks, underground crushing is generally less justified because a greater size range is capable of being transported in this manner. Although the material needs to be crushed prior to being processed, in most cases the crushing process is more cost efficient when undertaken on the surface.

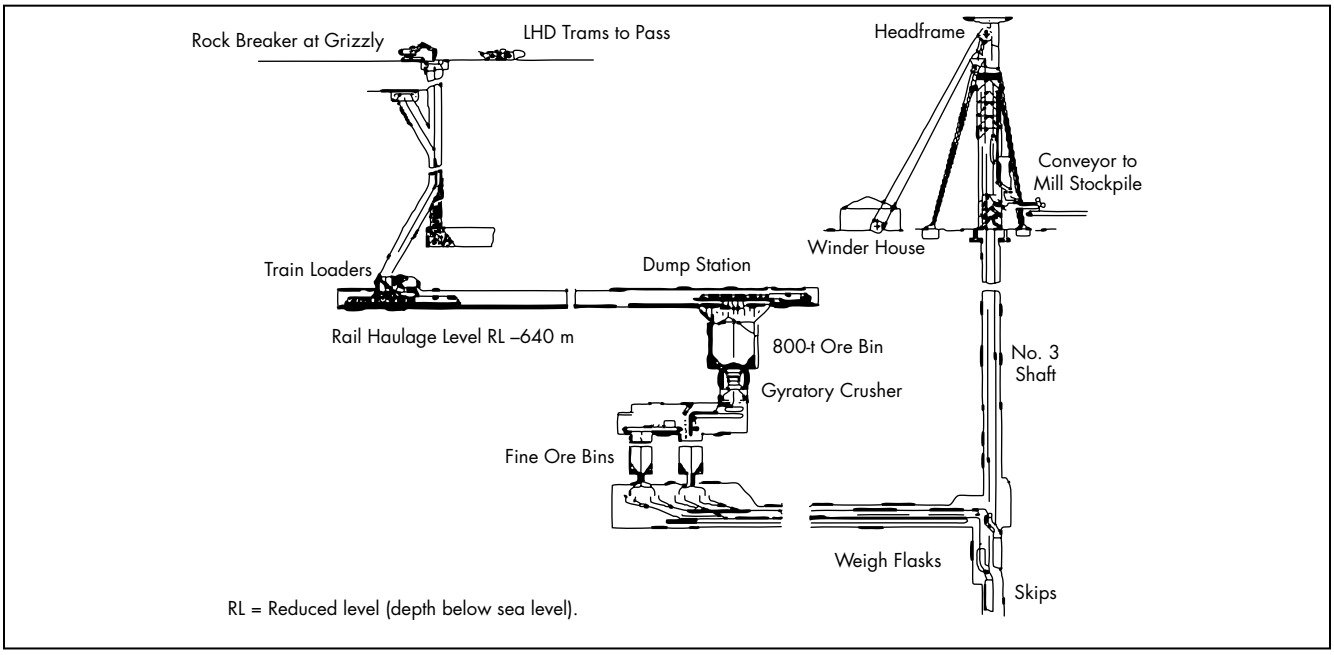
In operations where underground crushing occurs, uncrushed material is usually delivered to the primary crusher by dump trucks, wheeled loaders, trains, or orepasses. A feeder device such as a plate feeder or apron feeder can be used to control the rate at which this material enters the crusher. The feeder often contains a preliminary grizzly or screening device, which ensures an appropriate material feed size is received by the crusher.

Safety Considerations

The modern crushing plant includes the following safety features:

- Safety guards around all moving equipment (Boyd 2002).
- Emergency stop facilities on components where personnel access is required (Boyd 2002).
- Dust abatement, suppression, or collection equipment: Dust emissions must comply with the latest regulations for the jurisdiction. Designers must make provisions for the installation of equipment to control these emissions.
- Spillage prevention and collection facilities: Spillages from feeders, chutes, and conveyors should also be minimized.
- Noise abatement devices and controls: Because crushers, screens, and dust-collection fans all contribute to high noise levels, strategies need to minimize such exposure to personnel (e.g., engineering solutions, restricted access, or personal protective equipment).
- Fire protection systems: Fires are major hazards in any underground mine, and the potential for fires on conveyors is high. Protection through the use of automatic sprinklers or deluge systems is important to managing this risk.

Design and Construction Issues



Crushing plant design can be split into three main components: process design, equipment selection, and layout. The first two are often dictated by production requirements and design parameters. The layout can reflect input preferences and operational experience of a number of parties in order to provide a balanced, workable, safe, and economic plant design. Because many underground crushing facilities are located within purposely built rock excavations, it is vital that access and maintenance of all components is sufficiently allocated during the design phase. This should include suitable lifting equipment for major component maintenance or replacement, as large mobile crane access in many underground locations is not possible.

The fundamental goal for a crushing plant design is to provide an installation that

- Meets the required production rates and material sizing,
- Can be constructed within capital constraints,
- Operates at competitive cost, and
- Complies with safety and environmental regulations.

The following critical design parameters should be considered:

- Ore characteristics
- Geographical location

Courtesy of BHP Billiton Olympic Dam.

Figure 12.8-14 Ore-handling system at Olympic Dam mine

- Expected operational life
- Expansion potential
- Safety and environment
- Operability and maintainability

Figure 12.8-14 describes the ore-handling system at the Olympic Dam mine, including the primary cone crusher.

Underground Crusher Location

In underground operations, the excavations required for the installation of crushers and associated infrastructure can be substantial and are often the largest (unfilled) excavations within the mine. When considering an underground crusher layout and location, consideration should be given to

- Local and regional ground conditions,
- Proximity to planned and potential future production areas,
- Current and future stress conditions within the excavation, and
- Proximity to planned and potential future mine infrastructure.

Good geotechnical information is essential in the selection of a crushing plant location and the extent of ground support required.

Life of Mine/Expansion Plans

Planning for expansion should be considered in the design stage for underground crushing facilities. Expansion plans for most crushing plants can be incorporated in the early planning stages at much lower cost than waiting until the mine is up and running, particularly if the cost includes an interruption to normal production activities.

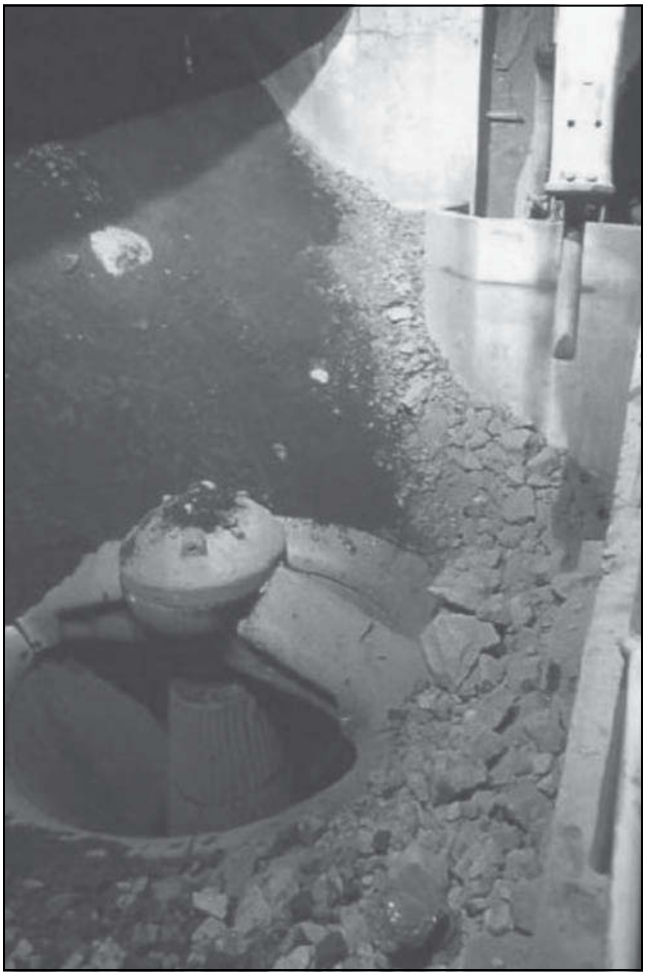
Crusher Selection

Crusher selection is dependent on many operation-specific variables including throughput rates, planned utilization, ore characteristics, material feed size, and required discharge product size. Many of the factors influencing underground crusher selection are common to surface crusher selection and are not covered in detail in this section.

As a guideline, the following can be applied: For a hard-rock mine application below 600 t/h feed rate into the crusher, a jaw crusher is the preferred option as the primary crusher. For feed rates more than 1,000 t/h, a gyratory crusher is the preferred option. Between these capacities, the choice will be dependent on other factors (Ottergren 2003). An example of a primary cone crusher is presented in Figure 12.8-15.

Equipment Overview

The major equipment in a primary crushing circuit usually includes a crusher, feeder, and conveyor. Secondary and tertiary crushing circuits have the same basic equipment items, along with screens and surge storage bins.



Grizzlies

A grizzly is a sizing device used to ensure a maximum passing size of material and to protect the crusher. Square mesh grizzlies get a more accurate maximum size of material than other shaped grizzlies but can be prone to plugging. Rectangular and nongrided grizzlies are less prone to plugging but can allow material of larger size to pass. Many grizzlies are rigidly mounted so that material must flow through them or be pushed through with equipment. Some grizzlies vibrate to encourage material on the grid to reorient and pass through. Grizzlies can be fed using a loader, truck, or conveyor.

Grizzlies also act as a metal scavenger to trap rock bolts, wire mesh, drill steels, and cables, removing them from the ore stream periodically by a loader from the top of the grizzly.

Rock Breakers

Fixed or mobile rock breakers are often used in conjunction with a grizzly. A modern rock breaker uses a hydraulic arm

Courtesy BHP Billiton Olympic Dam.

Figure 12.8-15 Primary cone crusher and rock breaker at Olympic Dam mine

with a pneumatic impact tip to move material around on the grizzly and impact oversize until it passes. Fixed rock breakers can be operated from a remote operator's cabin or even from the surface to reduce the installation size and ventilation needed underground. Before the advent of the modern rock breaker, oversize material feeding the primary crusher was a greater problem, and primary crushers were designed largely on the basis of gape (minimum dimension of feed opening) rather than capacity.

Additional and Optional Equipment

Other equipment items in crushing circuits can include the following:

- Overhead crane
- Freight elevator
- Service air compressor
- Sump pumps
- Air vacuum cleanup systems
- Rock grapple
- Conveyor belt magnets
- Conveyor belt metal detectors
- Belt monitoring systems
- Belt feeders
- Screw feeders
- Bin ventilators
- Apron feeder to the primary crusher
- Dust collection/suppression system
- Eccentric trolley removal cart
- Personnel elevator
- Air cannons
- Water booster pumps
- Service trolleys
- Conveyor gravity take-up service winch
- Conveyor belt rip detector
- Conveyor belt weigh scales
- Vibratory feeders
- Sampling station

Underground crushing installations are high-capital-cost items, due to fixed equipment costs and large-scale excavations required to house the system. Crusher installation capital-cost estimates should include equipment costs plus the following direct and indirect construction costs:

- Excavation and ground support
- Mechanicals
- Concrete
- Electrical
- Structural steel
- Instrumentation

Indirect costs can fall within a range of 40% to 60% of the direct costs.

Integration Aspects
