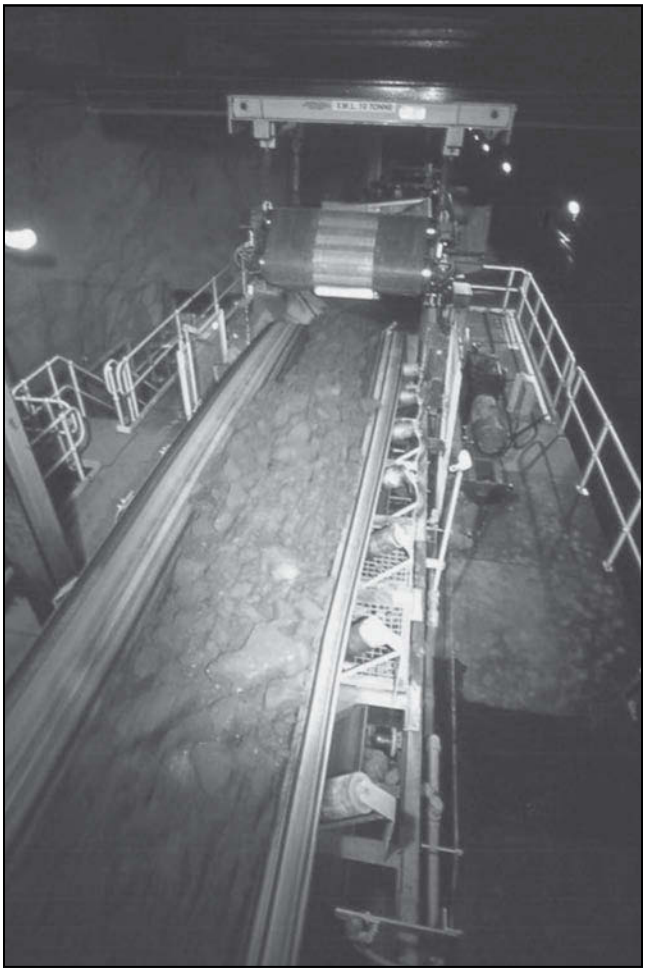
As mentioned in the introduction, each step in a mining system value chain consists of an upstream buffer, an ore-handling process that upgrades the ore to another value state, and a downstream buffer. The upstream buffer in most operations will be the storage capacity of uncrushed material available for crusher feed. Within typical feed crushing configurations this may be in the form of one or a number of stockpiles, or live capacity within one or a number of ore-passes. Downstream buffer is the capacity of crushed material storage between the crushing discharge and the next step in the materials-handling system (e.g., truck, conveyor or skip load, and transport). Where such upstream and/or downstream buffer is of limited capacity or nonexistent, operational variability around the crusher may adversely affect crusher uptime. Because of the high capital costs of large underground storage facilities for uncrushed or crushed material, it may not be possible to install large buffer capacity at this step of the materials-handling process. Therefore, crushing should not be the operation bottleneck by design, and the crushing and immediate upstream and downstream processes should have capacity in excess of the bottleneck process.

Technology

For the most part, advances in crusher design have moved slowly. Jaw crushers have remained virtually unchanged since about 1950. More reliability and higher production have been added to basic cone crusher designs that have also remained largely unchanged. Increases in rotating speed have provided the largest variation. Production improvements have come from speed increases and better crushing chamber designs.

The largest advance in cone crusher reliability has been in the use of hydraulics to protect crushers from being damaged

when uncrushable objects enter the crushing chamber. Foreign objects, such as steel, can cause extensive damage to a cone crusher and additional costs in lost production. Advancement in hydraulic relief systems has greatly reduced downtime and improved the life of these machines.



CONVEYORS

Mine conveyor systems have been utilized in underground mass mining for many years. Conveyor systems are commonly found in underground continuous coal mining operations, which use longwall and room-and-pillar methods. More recently, underground conveyor systems have been employed in large-scale, long-life metalliferous mines. Conveyors are more commonly used in operations where mine geometry and production flow allow conveyor haulage to be more efficient or cost-effective than other methods.

Inclined, troughed belt conveyors are more frequently being selected from a range of alternatives, which include shafts and trucks, for ore haulage in underground mass mining projects. Belt conveyor haulage systems are being operated with lifts exceeding those normally associated with truck haulage systems and approaching the limits of shaft haulage systems (Spreadborough and Pratt 2008).

Continued development of conveyor technology has resulted in increased confidence in and reliability of these systems. Reliability of conveyor-based haulage systems as a whole is impacted by the complexity of larger configurations constructed of multiple units or lifts. Modern conveyor installations have proven high availabilities (>85% are achievable in underground operations), which has added confidence to their use in recent times.

Figure 12.8-16 shows a typical conveyor in an underground metalliferous mine operation.

Courtesy of BHP Billiton Olympic Dam.

Figure 12.8-16 Typical conveyor in an underground metalliferous mine operation

Safety Considerations

In the selection of conveying options for an underground operation, several risk areas must be addressed, including

- Belt fires managed by self-extinguishing belt covers and auto detection and suppression systems;
- Belt failures addressed by belt-rip detection systems, monthly belt scans, and concrete bulkheads;
- Guarding requirements to prevent injury to personnel;
- Audible start-up alarms where personnel work near the belt;
- Emergency stop provisions in areas where access by personnel is required; and
- Dust management.

Selection Criteria

The selection of haulage systems for underground mass mining has historically focused on shaft haulage, trucks, and belt conveyors. The application of these alternatives in the Australian mining industry is summarized in Figure 12.8-3. Troughed belt conveyors are shown in this figure to be applied in the range up to 8 Mt/a production rate and 1,200-m lift.

Selection criteria for underground conveyor haulage include

- Inherent safety;
- Capacity (steady state and surge flow);
- Simplicity in design and operation;
- Dimensions (length, height, and width);
- Maneuverability/adaptability to various layouts;
- Cost (capital and operating);
- Reliability/availability;
- Operating life;
- Size of product handled, spillage, and carry-back;
- Dust and noise generation; and
- Automatic, remote operations.

The advantages of conveying material include high automation, minimal operational labor requirements and lower operating costs, and high reliability/availability.

The disadvantages of conveying material include high capital cost (therefore lower probability of duplication), a large footprint, and limited flexibility.

Belt conveyors for underground service usually have a more rugged design and operate at slower speeds than a comparable overland conveyor. Hard-rock mine belt conveyors normally require the ore to be crushed before it is conveyed or at least sized through a grizzly. Reasons for this include increased belt life due to reduced impact from lumps and elimination of tramp material, including rock bolts, rebar, drill steels, and scaling bars, which can seriously affect the integrity of the belt system.

Belt conveyor systems are less flexible than truck haulage and require a high initial investment. This generally means that belt conveyors are the economical choice when the

production rate is relatively high and the transport distance is significant. In certain applications, belt conveyor systems are selected for other reasons. For example, short conveyors are employed underground to optimize feed control to a loading pocket and prevent a run of fines from reaching the shaft.

Elements in a conveyor haulage subsystem can include

- Feed chute of dimensions appropriate for the material received,
- Belt to support the material and to transfer tractive forces to the material,
- Idlers to support the belt,
- Pulleys to resist belt tensions at changes of direction,
- Drives to provide driving and braking force,
- Take-up rollers to provide belt tension for no slip at the drives and for belt sag control, and
- Discharge or transfer chute.

Maintenance equipment at the haulage subsystem will typically include

- Monorails and/or cranes at drives and pulleys for change-out or repair,
- Belt clamps to resist belt tensions when installing or maintaining the belt (spring applied, hydraulic release, tested for holding capacity),
- Belt reel handling facilities, and
- Belt splicing/repair facilities.

Integration Aspects

When considering the conveyor components of the materials-handling system, consideration should be given to the upstream and downstream buffers. The upstream buffer in most operations will be the storage capacity of crushed material available for conveyor feed. In typical crushing/conveying configurations this may be in the form of fine ore stocks within dedicated stockpiles or storage bins. The downstream buffer may be underground storage at transfer points to the next step in the materials-handling system or surface stockpile storage capacity.

Technology

Advances in belt technology and particularly the development of stronger belt carcasses support the potential for further increases in capacity of inclined conveyor haulage systems. Vertical conveyors and hydraulic hoisting represent two potential technologies for haulage from underground mines.

The attraction of vertical conveying is due to the combination of a small footprint, continuous process, and overall energy efficiency. Limiting factors for vertical conveyors include tensile strength of the steel cored belts, safety of belt splices, and required production rate (Pratt 2008). Current precedence for the application of vertical or high-angle conveyors in a mining context is limited to a few hundred meters.

Other special types of belt conveyors include extendable systems, cable belts, and high-angle belts. To date, these special conveyor types have had few applications in hard-rock mines.

Conveyor Costs

Conveyor haulage systems are considered high in capital and low in operating cost compared with truck haulage. Generally, shaft haulage options attract higher capital costs and marginally lower operating costs for a similar-scale operation.

Operating costs will rise for conveyors as the complexity of the system increases with depth as a result of the addition of lifts and transfer points. This does not necessarily favor selection of shaft haulage over a conveyor system because other factors must be considered. Examples of aspects to be considered are horizontal transportation distances, confidence in geotechnical prediction for shaft and conveyor decline options, and other functional requirements of the mine. The actual selection of a haulage strategy for a large, deep mine will require evaluation of the trade-offs in risks and opportunities identified by the various options available.

Limits of Application

The slope of a high lift conveyor group is limited by the slope of the decline/incline development in which the conveyor is installed. This is normally in the range of 1:5.3 to 1:5.4 (10.5° to 10.7°) where the development is carried out using conventional rubber-tired equipment. Length and lift are limited by the belt carcass construction and the strength of the belt splice. The choice of belt construction is also limited by the troughability of the belt. Troughability is the ratio of the cross-belt sag to belt width and generally decreases with increasing carcass strength.

Future Applications

Advances in future designs will be fundamentally linked to the load-carrying capacity of available belt constructions and splice designs. Advances in conveyor technology continue to ensure success of conveyor systems in mass underground mining applications, including improved drive control equipment, belt condition monitoring, improved splice designs for higher strength and longer life, and improved chute designs.

RAIL HAULAGE SYSTEMS

Although belt conveying remains the dominant underground haulage system in coal mines, rail haulage continues to be favored in large tonnage (>5 Mt/a), long-life underground metalliferous operations.

Haulage by rail can be limited to ore and/or waste haulage, or can include integrated rail systems for transportation of personnel, materials, and supplies throughout the mine. Although the following discussion focuses only on the haulage of ore and waste from production areas to the hoisting system, it includes the consideration of interactions with other rail system users where required.

Prior to the emergence of trackless or rubber-tired mobile equipment in underground mining in the 1960s and 1970s, rail or tracked haulage systems were predominant. Many of today's rail haulage mining operations remain a legacy of that period. With improved productivity and performance of diesel mobile equipment and belt conveyors into the 1980s, this equipment has grown in popularity and application as significant methods of underground haulage. However, rail haulage continues to offer competitive operating cost, productivity, and throughput benefits over a range of applications in many underground mining settings.

Rail haulage systems consist of three primary types defined by their power supply: diesel, battery electric, and overhead trolley electric. A diverse range of systems are used around the world, from small-scale selective mines producing less than 100 ktpa to the largest bulk mining operations producing greater than 20 Mt/a.

Health and Safety Considerations

A fundamental consideration in haulage method selection and design is to ensure a safe and healthy workplace. Some of the key potential hazards that require consideration in rail haulage design and potential mitigating actions within a health and safety management system follow:

- High-speed equipment
  - Traffic management plan
  - System access control
  - Adequate lighting
  - Speed limits
  - Comprehensive equipment operating procedures
- Interaction between people and equipment
  - Equipment control systems
  - Physical barriers and guarding
  - Design for visibility
- Unmanned/automated equipment
  - Access control
  - Fail-to-safe control systems
  - Communication systems
- Overhead exposed conductors
  - Permit-to-work process
  - Isolation systems
  - Electrical protection systems
  - Entry height barriers
  - Water and dust management program
- Maintenance hazards
  - Custom-designed and fit-for-purpose maintenance facility
  - Regular inspection and maintenance schedules
  - High standard maintenance equipment
  - Isolation systems
  - Regular track cleaning program
- Mud rushes from chutes and orepasses
  - Water controls at all orepass entry points
  - Orepass monitoring
  - Regular chute inspections and/or continuous remote closed-circuit television monitoring
- Fire
  - Automatic fire suppression systems
  - Emergency response teams and training
  - Good housekeeping

Common and paramount in all the these circumstances are the underlying skilled workplace supervision, customized training programs, skills assurance process, good safety signage, and proactive maintenance programs that meet OEM (original equipment manufacturer) requirements at a minimum.

Selection Criteria

Selection of the preferred haulage system for a mine must consider a wide range of factors, including health and safety, economic, technological, reliability, operability, and flexibility.

Rail haulage can exist either as a stand-alone lateral haulage system or as part of an integrated system. In the case of the former, for example, rail provides for all lateral movement of personnel, materials, ore, and waste in the deep-level South African gold mines and northern Idaho (United States) silver mines. In the case of the latter, rail haulage can operate with mobile equipment, as at the Olympic Dam mine. Ultimate selection needs to match the shape, size, nature, and productive capacity of the ore body within the framework of an economically feasible operation.

The optimal haulage system for a mining operation is dependent on a variety of factors and their interrelationships, the more significant of which are discussed in the following paragraphs.

Health and Safety

Of fundamental importance are the design, installation, and operation of a safe rail system, as discussed previously.

Capital Cost

Rail haulage systems typically have a high capital cost and long construction time compared with alternative haulage systems. This is because economically competitive rail systems are often large scale by nature and require

- Long distances of tunnel development, which takes years to excavate;
- Orepasses and chute systems for train loading;
- Long-term ground support systems;
- High upfront equipment capital purchase costs for locomotives, rail, rolling stock, tipplers, trolley line system, and power reticulation equipment (where installed); and
- Large construction labor and installation costs.

Operating Cost

Converse to capital cost, rail haulage operating costs are among the most efficient per ton of material moved. This is driven by comparatively lower maintenance costs due to a more highly engineered and thus reliable system compared with diesel mobile equipment, requirement for a low number of operators, and better energy efficiency. Spare parts inventories may also be reduced.

Reliability and Operability

Well-engineered rail haulage systems can achieve high system availability (greater than 85% compared to diesel truck fleets, which range from 50% to 75% of total available clock time). The fixed nature of rail systems and repeatability of processes makes it highly attractive for automation, with the potential to deliver increased utilization. State-of-the-art systems, such as LKAB's 26-Mt/a rail system at the Kiruna mine in Sweden, CODELCO's 48-Mt/a Teniente 8 railway at the El Teniente mine in Chile, and BHP Billiton's 8-Mt/a rail system at Olympic Dam in South Australia, are highly automated, requiring high levels of technological support while delivering substantial unit operating cost and productivity benefits (Figure 12.8-17). Due to the fixed nature of rail systems, maintenance can be readily planned and scheduled, spare locomotives can limit production interruptions, while a smaller work force is typically required per ton hauled. Rail haulage systems require specific skill sets to maintain locomotives, high-voltage reticulation systems, communication systems, automation, and control systems.

Production Rate and Scale of Operations

Given the higher capital cost of rail haulage systems, they are typically used in operations with high production rates or long lives, in order to pay back the high upfront costs. Likewise, the high productivities and low unit operating costs offered by rail haulage favor their selection in mines with high throughput rates and/or long lives. However, smaller-scale rail systems

Figure 12.8-17 Underground rail haulage systems

are also competitive in mines where the reduced flexibility of a fixed horizon haulage system can be managed. This is particularly relevant in large flat-lying ore bodies where long-haul distances may exist, where larger openings for other forms of haulage cannot be considered, or where diesel mobile haulage systems are avoided because of environmental conditions (e.g., heat, gases, and fire risk).

Ore-Body Geometry

Rail haulage systems are by nature horizontal installations, and their selection must consider the lower flexibility of their fixed nature. In general, larger ore bodies are more suited to rail haulage as production is sourced from one or a few (albeit large) areas as opposed to disseminated, narrow-vein, or dispersed ore bodies where production comes from numerous locations in differing amounts at different elevations. However, rail haulage can be a competitive haulage option in such mines if the fixed nature of rail systems can be managed and matched to other aspects of the operations design.

Production Growth

Although diesel mobile equipment has the flexibility to travel wherever tunnel access is provided (flat or inclined), rail haulage is a constrained system. In order to support growth of operations to new areas or greater depths, rail haulages need to be extended or replicated to support mine growth or extension, or to sustain production from new areas. The 25-Mt/a rail haulage system of LKAB's Kiruna sublevel cave iron ore mine is a good case study, where major rail haulage horizons have been replicated at increasing depth in 300-m vertical increments on 10-to-15-year intervals as the mine has progressively moved its production areas downdip. Consideration at the design stage can enable rail systems to increase their productive capacity, if required, through measures such as adding more rolling stock, upgrading locomotive capacity, or increasing haul speeds.

System Life

The operational life of haulage systems and equipment is a key criterion in selection of haulage systems. Rail systems generally have a longer equipment life than mobile haulage equipment, which requires replacement nominally every 5 to 7 years. High throughput rail systems require longer operational life in order to provide an acceptable return on capital invested.

Mine Plan

Selection of haulage systems must be aligned and complementary to the mine plan. Rail haulage is more typically suited to deeper shaft hoisting operations where ore and waste need to be collected centrally for crushing, transport to, and removal from a single elevation, typically at depth. Development of ore bodies in areas of high topographic relief offers the potential for adit access and efficient rail haulage directly from the mine to the surface processing facility (such as Freeport-McMoRan Copper and Gold's deep ore zone mine at Grasberg in West Papua, Indonesia, and CODELCO's El Teniente mine).

Design Issues

Inclusive in the economic analysis of selecting a cost-effective haulage system are four key aspects for rail haulage design. Inherent to this analysis are capital and operating costs. The following factors need to be evaluated in a fully integrated design approach:

- Capacity
- System layout and geometry
- Materials properties and materials handling
- Equipment

Capacity

The required ore production rate is the primary driver of rail haulage system design. This will determine such key design parameters as tunnel layouts and size, equipment capacity, operating philosophy, the number of units in the fleet, integration with upstream and downstream production process capabilities, and haul speed. Consideration also needs to be given to whether the system is dedicated to ore haulage or is to be shared with movement of personnel and/or materials, and haulage of waste as well as ore.

Due to the fixed nature of rail haulage system infrastructure, consideration should be given at the design phase for the potential and likelihood of future increased production or extension of mining operations to new areas. In such circumstances, engineering designs should consider such key items as the adequacy of tunnel size and extent, maintenance facilities, power supply systems and infrastructure, track quality, and the number and configuration of orepasses and dumping (tipping) points.

System Layout and Geometry

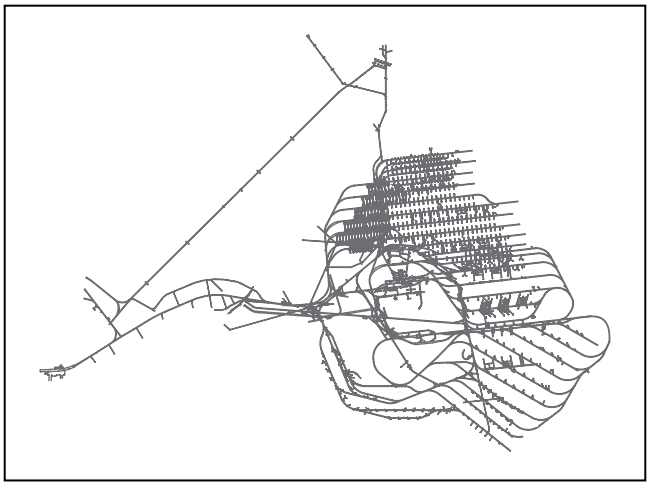
The layout and extent of a rail haulage system requires economic trade-off studies of numerous factors that impact the geometric design, including

- Physical dimensions and depth of the ore body;
- Degree of coverage required by the haulage system beneath the ore-body footprint;
- Primary mining excavation costs (including ground support, final preparation, and drainage);
- Trade-off between optimal rail haulage design and operation, and optimal production mining systems in the mine workings above;
- Single or dual direction of travel;
- Haulage speed (a key driver of productive capacity);
- Radii of curves, single or double rail, tunnel dimensions, gradient, maximization of straights, and super-elevation of curves;
- Number and location of ore and/or waste delivery points into the rail system;
- Number and location of ore and/or waste dumping (tipping) points from the rail system;
- Future operating cost impacts and benefits; and
- Suitability for future expansion.

With an inherent need for wide radius curves to accommodate rail equipment and a preference for straight sections, rail haulage horizons can lend themselves to potential mechanical excavation techniques such as tunnel boring machines. These are commonly applied in civil engineering rail projects and warrant consideration in the preliminary phase of mine rail haulage system design.

The schematic presented in Figure 12.8-18 demonstrates the preference for geometric rail loop layouts, wide radius curves, and long straights.

Material Properties and Materials Handling



Rail haulage systems must be designed to manage the physical attributes of the material(s) to be hauled. For example, the physical properties of the material will determine the strength of mechanical equipment against wear and tear, and flow properties will impact orepass and chute design and determine the potential need for lining of passes, bins, or chutes for longevity.

The key physical properties to be considered include

- Moisture content;
- Size distribution, proportion of fines (mud-rush hazard), and maximum lump size;
- Specific gravity/material density;
- Abrasiveness;
- Dust generation;
- Presence of deleterious materials, such as tramp steel, cemented backfill, and waste dilution; and
- Changes in material properties over time.

Careful management of these properties has a significant downstream impact on system operability through aspects such as

- Pass and chute maintenance;
- Spillage, which can cause safety hazards, derailments, and significant downtime or equipment damage;
- Train hopper wear and tear;

Courtesy of P. Crorkan-Tait.

Figure 12.8-18 Schematic of Teniente five-rail haulage design layout at El Teniente mine in Chile

- Downtime due to blockages, hang-ups, fines rushes, etc.; and
- Maintainability and maintenance cost.

Equipment

The selection of rail haulage equipment is a key component that must be fully integrated with all the previously discussed aspects of system design. Locomotive prime movers are typically powered by either battery electric, diesel, or overhead electric energy sources. The majority of large-scale, high-production underground rail haulage systems today are overhead DC electric inverted to AC-drive locomotives. Examples of such systems are shown in Figure 12.8-17.

Ore/waste hoppers and tipplers are available in various configurations, with capacities ranging from 1 t to more than 70 t per hopper. Hoppers can be either side or floor dumping (tipping), with a range of chassis, side-door, and floor opening designs available depending on various parameters. Train combinations can be sized to match production and rail system capability with rakes of up to 30 hoppers and total train payloads in excess of 1,300 t.

Rail haulage systems lend themselves to significant levels of automation. Design of remote control systems is critical to operating productivity and reliability, and needs to consider locally available skill sets, technical support, spare parts availability, mine communications systems, and environmental aspects such as water, humidity, dust, radiation, and gases. Train control systems must be fully integrated with the proposed operating philosophy for the haulage system, with the aim of preventing downtime and production delays, and minimizing maintenance.

Other equipment aspects to consider in system design include

- Rail gauge and installation quality;
- Control and communications systems;
- Switch design;
- Train loading points, passes, and chute design;
- Tippler design;
- Drainage and lighting; and
- Signaling.

The maintainability and operability of all equipment requires close attention. This includes access to all parts of the rail system for maintenance personnel and equipment in the event of derailment or breakdown; specialized equipment for rail maintenance; standby equipment, including spare locomotives and hoppers/ore cars; critical/insurance spares; and regular spare parts management.

HYDRAULIC HAULAGE SYSTEMS

Hydraulic ore transport is an often cited but rarely implemented ore transportation system in underground mining applications. While slurry pumping engineering is mature in a multitude of diverse surface applications, its serious consideration in underground environments is hampered by risks associated with

- The need to pretreat and prepare suitable material underground, beyond typical crushing and sizing arrangements;
- Pump and column wear considerations;
- Capital costs and equipment technologies for anything more than very small tonnage rates; and
- Lack of courage to lead change.

One well-established application of underground hydraulic transportation and hoisting is at the McArthur River uranium mine in Saskatchewan, Canada, operated by Cameco (H. Goetz, personal communication). McArthur River produces approximately 47,000 tpa of high-grade (average 17% U_3O_8 [triuranium oxtoxide]) uranium-bearing ore, from a depth of 640 m below the surface. The operation includes full ore preparation underground through a 600-t/d semiautogenous grinding mill, hydrocycloning, and 2 × 13-m-diameter thickeners. The thickener underflow feeds into a 200-m^3 thickener underflow holding tank that supplies the Wirth triplex piston/diaphragm positive displacement pumps (13 million Pa discharge pressure) for pumping up 2 × 100-mm-diameter columns in a single stage to the surface.

The physical characteristics and health and safety aspects associated with handling relatively low quantities of very high-grade uranium ore, with attendant high radiation levels, were a key driver in the selection of hydraulic transportation ahead of more conventional methods.

Hydraulic systems for transporting backfill are described in a separate chapter.

OTHER HAULAGE SYSTEMS

A small number of less common haulage systems are used in underground mines. These are typically selected because of highly specific geological environments, particular material properties, or unique operating systems and processes. These include the following:

- Rope scrapers/slushers—commonly used for ore haulage from operating stopes to orepasses in South African longwall gold and platinum mining operations. Slushers are also used for ore collection, haulage, and delivery into orepasses beneath established block caving operations.
- Monorails—traditionally a materials-handling system. Monorail systems can be either electrohydraulic friction or rack-and-pinion drive, and have been used in moderately dipping applications (up to 14°) in South African gold mines.
- Floor-mounted, rope-driven trap rail haulage systems—applied for haulage of equipment and ore/waste up or down steep inclines of up to 40°.

CHAPTER 12.9

Hoisting Systems

Peter Tiley

INTRODUCTION

When it has been determined that a mine will include an underground section, it is necessary to review what kind of system will be used to transport workers and material to and from the surface to the underground, as well as to haul ore and waste from the mine to the surface.

This chapter deals with the selection, design, operation, and maintenance of hoisting plants that operate in vertical or near-vertical shafts. The term *hoisting plant* is used to collectively describe the openings and the equipment being considered. Information on the design and technical considerations to be reviewed when selecting a particular component or arriving at an arrangement of the hoisting plant is provided.

SHAFT HOISTING SYSTEMS

A shaft hoisting system consists of the following major sections, starting from the bottom of the shaft:

- A loading station for ore or a service station for workers and material
- Shaft conveyances called skips for ore transport and cages for transporting workers and material
- Ropes that suspend the conveyances
- A shaft that connects the underground to the surface and that is equipped with a system to guide the conveyances as they move in the shaft
- A headframe, located on the surface, that supports either the hoist itself or supports head sheaves that direct the headropes from the top of the conveyance to a ground-mounted hoist and that provides the tipping arrangements for the rock
- A hoist and hoist room

The headframe also typically includes an ore storage area into which ore and waste are temporarily discharged before being transferred to some other surface facility.

HOISTS

Two basic types of hoists are commonly used today: drum hoists, in which the hoist rope is stored on a drum, and friction hoists, in which the rope passes over the wheel during the hoisting cycle. Within each category are several variations.

Drum Hoists

Figure 12.9-1 shows the various arrangements of drum hoists. Drum hoists are usually located some distance from the shaft and require a headframe and sheaves to center the hoisting ropes in the shaft compartment and maintain a rope fleeting angle of less than 2°.

Single-Drum Hoist

The single-drum hoist may be used for balanced or unbalanced operation. When used for unbalanced hoisting, the cost of the electric drive may become quite high for long hoisting distances and high tonnages. This is because the motor must be large enough to produce sufficient torque to handle the combined weight of the rope, conveyance, and payload in the absence of a counterweight.

These costs are, however, offset by the reduced size of the installation because there is one less compartment, conveyance, head sheave, and head rope to accommodate, as well as a smaller hoist foundation and building.

There is virtually no difference in the power costs for balanced versus unbalanced operation, because power costs are for the energy consumed, which is derived from the number of tons hoisted.

As the shaft gets deeper, the difference in the size of the electrical drive for balanced versus unbalanced operation becomes less significant because the mass of the unbalanced rope, which is the same whether there are one or two conveyances, begins to dominate the total unbalance experienced by the hoist.

Single-drum production hoists are unusual because their hoisting efficiency is halved for the same skip size, but they are fairly common when used for service duty in which the hoisting cycle time is not as significant.

In a balanced hoisting system, one rope winds off the drum as the other winds on. When used with a skip or cage in balance with a counterweight, a single-drum hoist can service one or more levels because the location of the counterweight is not important. When used with two skips in balance, the single-drum hoist is only suitable for single-level hoisting. Any rope adjustments to locate the conveyance must be done manually. For shallow shafts with one layer of rope, no dividing of the

Peter Tiley, Consulting Engineer, G.L. Tiley & Associates Ltd., Flamborough, Ontario, Canada

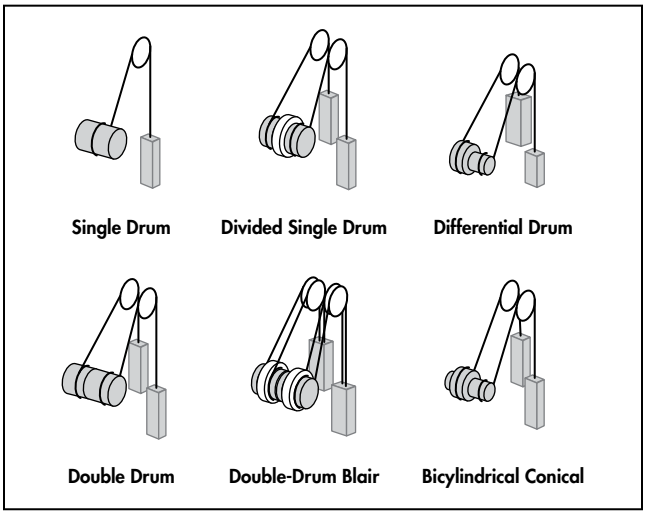

Figure 12.9-1 Drum hoists

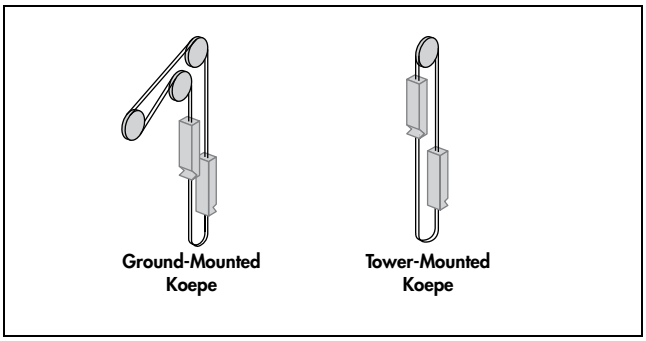

Figure 12.9-2 Friction hoists

drum is required. For deeper shafts, the drum must be divided to wind several layers of rope.

Divided Single-Drum Hoist

This type of hoist is used for deeper shafts with balanced hoisting when several layers of rope must be stored on the drum. Peak horsepower is less than with unbalanced hoisting because the skip weights are balanced. Because the payload and weight of the rope is not balanced, the maximum unbalanced load occurs when the loaded conveyance is at the bottom of the shaft.

Split Differential Diameter Drum

A third, though uncommon, type of single-drum hoist is the split differential diameter drum. In this arrangement, each of the drum compartments is of a different diameter. This type of hoist is used with a conveyance and counterweight in balance or with a skip and cage in balance. If, for example, the counterweight rope is wound on the smaller-diameter drum, it moves less than the main conveyance, and rope adjustment problems are reduced.

Double-Drum Hoist—One Drum Clutched

Although more expensive than a single-drum hoist, the double-drum hoist with one drum clutched has certain advantages. With this type of hoist, it is possible to make quick adjustments to the ropes due to initial stretch. As a service hoist with cage and counterweight, this type of hoist can serve several levels efficiently. As a production hoist with two skips, the ropes can be adjusted to maintain balanced hoisting at any level in a multilevel operation.

Double-Drum Hoist—Both Drums Clutched

The double-drum hoist with both drums clutched has the added feature of allowing hoisting to continue in one compartment should something happen to the other compartment. This is an excellent feature if there is only one hoist available. This type of hoist is also favored during shaft-sinking operations.

Multiple-Rope Hoist—Blair Type

With this type of hoist, each conveyance is suspended from two hoist ropes that are each coiled onto the same drum. The advantage of this is that by doubling the number of ropes per conveyance, the conveyance payload can be increased. This type of hoist was developed in South Africa for deep mines, typically more than 1,800 m (5,900 ft). Another advantage of this arrangement is its ability to dispense with safety dogs on the cage (which are only required for single-rope hoists).

Two such hoists are now operating in Canada, and several more are scheduled to be installed in the near future.

Bicylindrical Conical Drum Hoists

This type of hoist is no longer manufactured, but there are still a few in operation in North America.

The drums on these hoists, both single- and double-drum configurations, are made in two steps with a conical section in between.

The hoists were developed before multilayer winding was practical. Prior to multilayer winding, drum diameters simply increased to match depth. This practice leads to very large diameters (10 m [33 ft] or more), resulting in very high starting torque requirements. By beginning the acceleration on a small diameter, the high starting torque requirement could be avoided.

Friction Hoists

Figure 12.9-2 shows the two possible arrangements of friction hoists. The Koepe or friction hoist was developed by Frederick Koepe in 1877. It consists of a wheel with grooved liner or liners made from a friction material to resist slippage. The hoist rope is not attached or stored on the wheel. In early installations, the hoist was mounted on the ground, and a single rope was wound around the drum and over the head sheaves to the two conveyances in a balanced arrangement. In addition, a tail rope of the same weight per unit length as the headrope was suspended in the shaft below each conveyance. Thus the only out-of-balance load was simply the payload. Friction hoists can be either tower mounted or ground mounted.

Tower Mounted

The main reason for selecting tower mounting is the reduction in cost of the structure, because the rope loads are confined internally. This arrangement also provides a very small footprint that allows the structure to be supported by the headframe's collar concrete in the slip-formed design or by localized piled foundations in the structural-steel design of the headframe.

Because the Koepe wheel diameter is generally larger than the conveyance compartment centers, deflection sheaves

must also be installed in the headframe below the hoist to move the ropes over to match these centers.

Tower mounting is also preferred in cold climates because the conveyance ropes are isolated from the weather.

Ground Mounted

A headframe for a ground-mounted friction hoist must be designed to resist the overturning loads produced by many headropes. These buildings are generally of a structural steel design and require the use of a pair of cluster sheaves to locate the rope centers over the conveyance compartments. Because they must support the entire suspended rope load, rather than simply deflecting the ropes by 10° to 15°, the cluster sheaves are much more robust and are, therefore, significantly more costly than the deflection sheaves used in tower-mounted applications.

Comparison of Friction and Drum Hoists

A friction hoist system differs from a drum hoist system in performance as well as components. Therefore, when deciding which type of hoist to use, it is necessary to compare the two complete systems rather than the two hoists alone. In addition to comparing the total capital costs of the hoist, headframe, ropes, conveyances, and shaft, it is necessary to consider operating costs, maintenance costs, reliability, power supply system, local custom, and individual preference.

The following general statements help distinguish between these two hoisting systems:

- Double-drum hoists are the preferred hoist for shaft sinking.
- Double-drum hoists are the best choice for hoisting in two compartments from several levels.
- Drum-type hoists are best suited for high payloads from shallow depths.
- The limitation on a drum hoist employing a single rope is the ultimate strength of the rope, because large ropes are difficult to manufacture and handle.
- The depth capacity of drum hoists can be extended by using two ropes per conveyance (Blair-type hoist), and with this arrangement, Blair hoists can be used for depths exceeding those of either single-rope drum hoists or friction hoists.
- Friction hoists with multiple ropes can carry a higher payload and have a higher output in tons per hour than drum hoists within a range of depths from 460 to 1,520 m (1,500 to 5,000 ft).
- Friction hoist mechanical operation is very simple, has a low rotational inertia, and is less costly than a drum hoist.
- Friction hoists have a lower peak power demand than drum hoists with the same output.
- The friction hoist can operate on a relatively light power supply.
- Rope maintenance is more intensive and difficult for friction hoists.

Hoist Components

The major components that make up a hoist are the drum or wheel, bearings, gearing, brakes, clutch motor, power conversion, and controls.

Drum

The drum of a drum hoist must be designed to store the amount of rope required for the shaft depth and accommodate the stresses caused by the rope tension loads. The prediction of these rope loads is well documented in the literature.

Although originally provided with no machined grooves (i.e., they were smooth), drums today are generally supplied with parallel grooving, which includes a half-pitch crossover twice per revolution. This grooving pattern was developed by LeBus International, Longview, Texas, to achieve stable spooling in multilayer winding. Drums can also be supplied grooved in a helical pattern, which is a continuous spiral from one end of the drum to the other. This pattern is limited to three layers of rope, because beyond this number of layers, the rope-winding pattern becomes unpredictable. LeBus International's grooved drums, in contrast, have been used to wind as many as 15 layers of rope without a problem.

Rope resonance must be considered in the selection of the grooving pattern. This is discussed in a later section of this chapter.

Wheel

The wheel of a friction hoist is not subjected to crushing forces. As a result, the drums are much lighter and are made wide enough to accommodate the rope-end attachment dimensions, as well as the space for the deflection sheaves.

The linings for the rope treads on Koepe hoists were originally made of wood or leather, which were then replaced by modern plastic.

Bearings

As shown in Figures 12.9-3 and 12.9-4, the hoist drum or wheel is supported on a shaft that rides in two or more bearings. Bearings provide the mechanism that supports the shaft loads, and bearings allow it to rotate at the same time with very little friction.

There are two types of bearings: sleeve bearings, which use a film of oil to keep the shaft out of contact with the fixed part of the bearing, and roller bearings. Sleeve bearings are being supplanted by spherical roller bearings that have the following advantages:

- Low coefficient of friction
- Economy of space
- Simplicity of lubrication
- Practical elimination of wear due to roller point contact
- Maintenance of accurate alignment
- Consistency in design and manufacture

The main disadvantages of the latter are the fact that they are not split, which complicates their replacement, and long order times are involved when bearings larger than about 500 mm (19.7 in.) in diameter are required.

Gearing

Hoists can be driven either directly by large-diameter, relatively low-speed AC or DC motors (90 rpm or less) or through a gear-reduction system by small-diameter, high-speed (400 to 1,800 rpm) motors. With the change in power conversion to variable-frequency drives, the motors have altered to AC machines operating in the 900-to-1,800-rpm range.

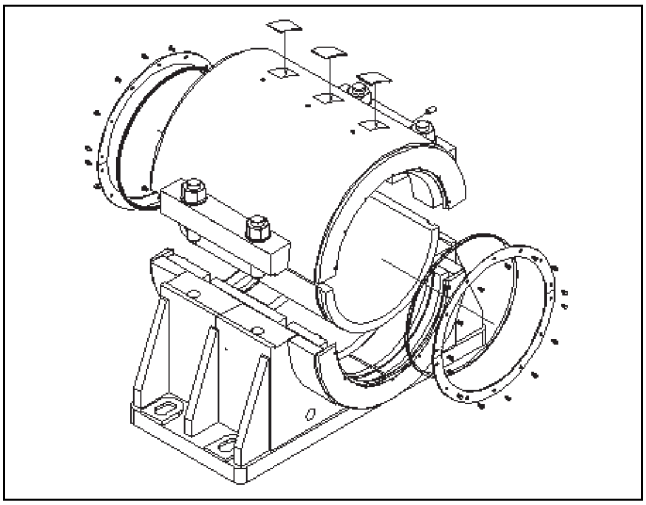

Figure 12.9-3 Sleeve bearing

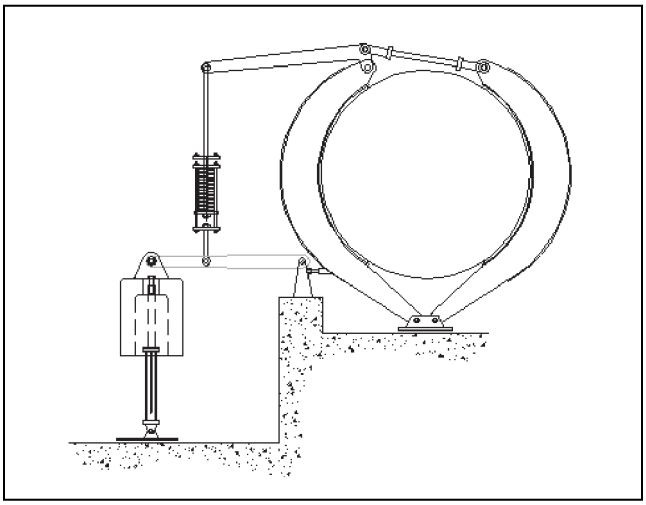

Figure 12.9-5 Jaw braking system

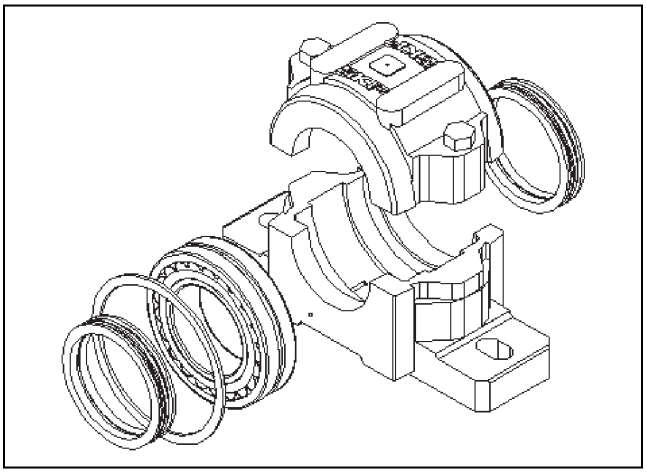

Figure 12.9-4 Spherical roller bearing

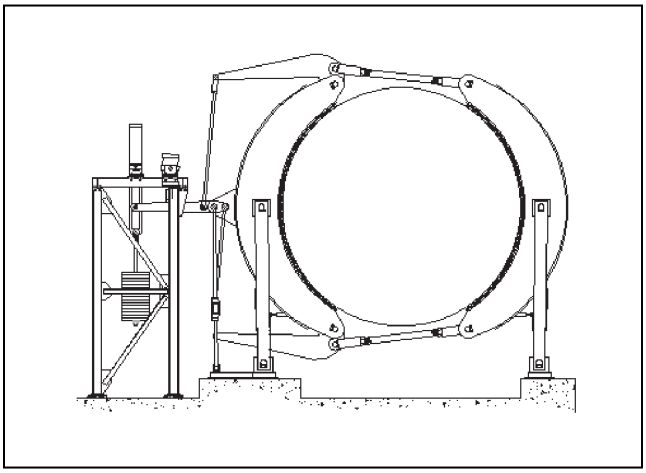

Figure 12.9-6 Parallel motion braking system

Gear reduction was commonly a single-stage system that incorporated a large gear fixed to the drum shaft and driven by one or more pinion gears. This cannot be used practically for the sealed, self-lubricating, multistage reducers now for high-speed AC motors. Reducers are now fully enclosed, multistage, and equipped with oil coolers as well as bearing vibration-monitoring systems. These utilize flexible couplings between the motors and high-speed input shafts as well as between the low-speed output shaft and the hoist drum shaft.

Brakes

A hoist must be equipped with a mechanical braking system to decelerate, stop, and hold the load. Although the electrical motor, drive, and controls can initially decelerate and stop the hoist, this equipment cannot hold the load because of thermal limitations inherent in the drive. Electrical systems also require a source of energy to function. For these reasons, hoists must be provided with mechanical braking systems that ultimately rely on either gravity or spring force to operate.

Drum brakes and disc brakes are the two main types of braking systems. Until the mid-1990s, drum hoists were exclusively equipped with drum brakes in jaw or parallel motion configuration, mainly because they were part of the hoist speed-control system rather than solely for holding or emergency braking functions. Most new hoists, both drum and friction, are equipped with disc brakes.

Figures 12.9-5, 12.9-6, and 12.9-7 illustrate the designs of jaw, parallel motion, and disc braking systems, respectively. Brake control systems are now required to control deceleration rates to very high accuracy to protect passengers from injury, limit the dynamic stresses that arise in the hoisting ropes during emergency stops, and prevent rope slip on Koepe hoists. This level of accuracy is readily achievable with the higher operating pressures and lower inertias associated with disc brakes.

In addition to accurate control of deceleration rates, braking systems must be capable of dissipating the energy absorbed during emergency stops. Disc brakes have lower mass than drum brakes and run at higher surface pressures. Therefore, they tend to heat up more quickly. By manufacturing brake discs in several segments and bolting the segments to the hoist drum or wheel, a disc brake can be designed to expand freely under thermal load and, therefore, avoid distortion or failure.

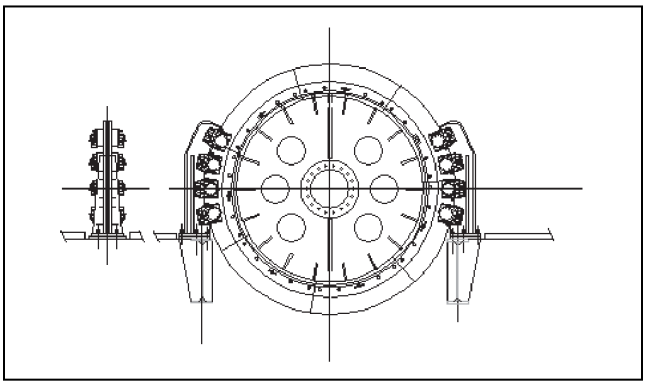

Figure 12.9-7 Disc braking system on a Koepe hoist

Clutch

Double-drum hoists used for unbalanced hoisting, such as when sinking or when operating from several levels, must have at least one of the drums clutch-connected to the drum shaft. This assembly consists of a clutched or floating drum that is supported on the shaft through a sleeve bushing and a clutch arm, which is used to transfer the torque to the drum. The clutch arm consists of a spider or gear that slides axially along the shaft supported by a hub driven by keys or splines or driven by a hexagonal section of the shaft. The drum also incorporates a clutch ring, which has teeth matching the clutch arm on its entire periphery, bolted to the side of the drum. As the spider moves axially, these two sets of teeth engage or disengage. The tooth pitch determines how accurately the rope lengths on each drum can be matched. Driving torque is then transmitted from the clutch spider to the drum through the bolts used to attach the clutch ring to the drum.

As the drum must be prevented from rotating when it is unclutched, it is necessary that the clutch's operating mechanism and the brake holding the drum be interlocked both electrically and mechanically.

Drive Motor and Power Conversion

Hoists have used energy sources such as steam, compressed air, and internal combustion engines to drive them. These have largely been replaced with electrical power.

Electrical drives for hoists originally employed AC wound-rotor induction motors using variable resistance in the secondary for speed control. These systems were then supplanted by DC machines that utilized motor-generator sets to provide DC power. The motor-generator sets were replaced by so-called static drives in the late 1960s. The name *static drive* referred to the fact that the power was converted from AC to DC using thyristors, which are made from silicon wafers and involve no moving parts. The DC technology began to disappear in the late 1980s when it was replaced with AC technology that utilized synchronous motors and variable-frequency sources called cycloconverters. The variable-frequency sources have now been replaced with pulse width-modulated, digitally controlled equipment that utilize transistors (injection-enhanced gate resistors or isolated gate bipolar transistors) for power conversion. The AC motors are now a mixture of synchronous and squirrel-cage designs, with the squirrel-cage design being the preferred option because of its simplicity and ruggedness.

This new generation of variable-frequency static drives also provides AC power with low harmonic content and ensures operation at unity power factor. These drives consist of two inverters back to back. The first converts line frequency AC to DC; the second, DC to variable frequency AC.

Hoist Control Systems

The hoist control system consists of two components: active and passive. The active component starts and stops the hoist, controls its speed throughout the hoisting cycle, and displays the state of the hoist to the operator. The passive component monitors the speed and position of the hoist itself as well as the state of its subsystems, such as the brakes, hydraulic power units, motor ventilation, and similar auxiliary equipment. The passive component also signals the active component when the system is operating outside of its normal range and thereby initiates a stoppage of the system until the fault that raised the alarm is cleared.

All of the required functions are now fulfilled by digital devices call programmable logic controllers. These devices utilize redundancy to a large degree to ensure that they are reliable.

The operator's interface has also evolved to what is called a human–machine interface, which is a graphical display provided on a computer monitor.

HOIST SELECTION

The capacity of a hoist depends on the drum or wheel dimensions, number and size of ropes, speed, and horsepower.

The mechanical components, such as drum, shaft, bearings, gearing, and brakes, are svized to match the rope loading; the electrical components are sized to match the torque required to handle the loads and the speed at which the hoist will run.

The rope is selected to handle the required payload while operating at a reasonable or legislated safety factor.

Selection Procedure for Production Drum Hoists

Sizing the hoist runs through an iterative process, which requires the following initial information:

- Hoisting depth
- Required annual production
- Hours available for hoisting

The process of selection is as follows:

1. Using the depth, calculate the hoisting cycle time. The cycle time will depend on the maximum speed, acceleration and deceleration rates, creep speeds and distances (arriving at and departing the loading pocket and dump), and the loading/dumping time when the hoist is stopped.
2. Varying these items will enable the designer to optimize the selection. Good guidelines are
   - a maximum speed of 5 m/s (1,000 fpm) per 300 m (1,000 ft) of depth up to a maximum of 20 m/s (4,200 fpm);
   - acceleration and deceleration times of 15 seconds;
   - a creep speed of 1.5 m/s and a creep time of 5 seconds; and
   - load and dump times of 10 to 15 seconds, depending on density of the load.
3. Use the cycle time to calculate the cycles per hour.

4. Use the required annual production and available hoisting times per year to calculate the skip payload.
5. Use the skip payload and a reasonable skip tare mass based on 70% of the skip payload to determine the total attached load.
6. Multiply the attached load by 8.5 to determine the required rope strength.
7. Select a rope with this strength.
8. Check that the rope strength also meets the required safety factor (typically 5 but may also have a factor that is depth dependent) when the rope weight is added.
9. Determine the drum diameter based on 80:1 drum-to-rope diameter (this ratio depends on the rope size).
10. Estimate the motor power using kW = (payload × speed)/102, where the payload is measured in kilograms and the speed is measured in meters per second.
11. Estimate the inertia of the rotating parts based on historical data.
12. Carry out a duty cycle calculation to verify the required motor power.

A typical double-drum production hoist cycle, starting with empty skips and loading pocket, no power on the hoist motors, and with the hoist brakes applied, is as follows:

1. Open the loading pocket door and load the empty skip.
2. Close the loading pocket door.
3. Apply power to the hoist.
4. When power is established (torque proving), release the brakes.
5. Accelerate to creep speed, about 1 m/s, and creep away from the end zones, about 2 m (6 ft), to clear dump scrolls.
6. Accelerate to full speed in 15 to 20 seconds.
7. Run at full speed.
8. Decelerate to creep speed in 15 to 20 seconds.
9. Enter dump scrolls at creep speed, about 0.75 m/s (150 fpm), and creep through dump scrolls until the full skip is in fully dumped position or empty skip is in position at the loading pocket.
10. Stop the hoist.
11. Repeat the cycle.

It is good practice to stop the cycle when the empty skip stops at the loading pocket rather than the full skip arriving at the dump point. Headframes are designed to allow for rope stretch and rope length mismatch, which means that the full skip can stop anywhere in about a 1- to 2-m (3- to 6-ft) zone when it is dumping. This is not possible at the loading pocket, because the headrope will stretch when the skip is being loaded and the loading window in the skip is limited in height.

Selection Procedure Drum Hoist for Service

The selection procedure for a service hoist is much simpler than a production hoist because service hoists are sized to handle a maximum payload at a speed that is largely independent of depth. In this case, the following guidelines apply:

- The maximum speed is 8 m/s (1,500 fpm).
- The acceleration and deceleration times are 20 seconds.
- The creep speed is 1.5 m/s (300 fpm), and the creep time is 10 seconds.
- The waiting time is 30 seconds.

The rope size is determined as before, except the cage weight is generally 50% of the payload.

When using a counterweight, it should be sized as the cage mass plus one-half the cage payload, which ensures that the maximum average unbalance for the hoisting cycle will never exceed one-half the payload.

Selection Procedure for Koepe Hoists

The selection procedure for a Koepe hoist is identical to that of a drum hoist, except that the number of ropes must be defined. A good starting point is to use four ropes, as this provides a reasonable limit on complexity while minimizing the size of the ropes.

One item that is different is the mass of the conveyances. As the ratio between the tension in the ropes on the loaded side of the wheel and the tension in the ropes on the empty side of the wheel must be kept below about 1.5, the conveyances must be heavy. A good guideline is to have the conveyance weight equal to the payload and then increase it until the ratio is 1.5 or less.

Koepe hoists often run on rope guides, so provision must be made in the hoisting cycle to slow the conveyance down as it enters the ends of travel where it is guided by fixed guides. These guides are required to keep the conveyances' lateral motion in check when it is traveling in the narrow confines of the headframe and shaft bottom. The guides are tapered to allow for the uncertainty in the conveyance position and are often called "spear" guides as a result.

The conveyance speed when entering these guides is usually kept below 3 m/s (600 fpm), but it can be as high as 6 m/s (1,200 fpm) if the system is properly designed.

The production hoisting cycle for the Koepe hoist is identical to the drum hoist, except for a situation when the skips are running on rope guides. This means that a high creep speed section will occur as the skip slows down to enter the spear guides and then runs in them until it reaches the dump point at which time it will decelerate to a low creep speed.

In addition to determining the hoist's capacity, consideration of the following items is critical for achieving efficient and trouble-free operation of friction hoists: T_1/T_2 ratio, rope tread, deflection sheaves, differential rope loads, and tail ropes.

T_1/T_2 Ratio

The T_1/T_2 ratio is the ratio of the static rope tensions on each side of the drum, where T_1 is the weight of loaded conveyance plus weight of ropes, and T_2 is the weight of unloaded conveyance plus weight of ropes. The maximum recommended value for a particular installation is a function of the coefficient of friction of the tread material, the acceleration and deceleration required, and the angle of lap of the rope on the drum. A typical maximum static value of T_1/T_2 is 1.5. It is also necessary to consider the dynamic loads that occur when the hoist is accelerating and decelerating, both under the normal and braking conditions. Because acceleration will decrease the rope load and deceleration will decrease it, T_1/T_2 can become too high, causing the rope to slip on the drum. When this happens, the coefficient of friction drops and control is lost. There will also be tread damage due to friction temperature rise and abrasion.

The maximum coefficient of friction that should be used when calculating the allowable T_1/T_2 ratio is 0.25. This number is achievable even with wet ropes, as long as they are not overlubricated.

The tension increase during acceleration is given by the factor $(1 + a/g)$; the tension decrease during deceleration is

give by the factor $(1 - a/g)$. Here, a is the acceleration/deceleration and g is the acceleration due to gravity (9.81 m/s^2 [32.17 ft/s^2]). Thus, the dynamic tension ratio is the static tension ratio $T_1/T_2 \times (1 + a/g)/(1 - a/g)$.

The amount of unbalance that the friction can support is given by

$$T_1/T_2 = e^{(\mu \times \theta)}$$

where

e = base of the natural logarithm (2.713)
μ = coefficient of friction
θ = angle of wrap measured in radians (typically π or 3.14 radians, equivalent to 180°)

As an example of the effect of dynamic variation in the rope tension on the margin to rope slip, assume that the actual static tension ratio is 1.5 and that the system has been designed with an angle of wrap of 180°. A coefficient of friction of 0.25 will produce an allowable static tension ratio, T_1/T_2, equal to 2.2, well above the actual static T_1/T_2 of 1.5.

If the hoist is subjected to a deceleration rate of 3 m/s^2, the dynamic T_1/T_2 increases as follows by the factor $(1 + 3/9.81)/(1 - 3/9.81) = 1.88$, giving a dynamic T_1/T_2 of $1.5 \times 1.88 = 2.82$. This is greater than 2.2, indicating that the ropes will slip if the coefficient of friction is only 0.25.

This example shows why braking systems for Koepe hoists must be carefully designed.

Rope Tread

Selection of an appropriate tread material for the drum rope grooves and tread pressure is important. As the rope passes over the drum, the load and thus the strain in the rope changes. This change in strain tends to cause the rope to creep (as opposed to slip) on the drum. A resilient tread material such as polyurethane tends to flow with the change in strain and reduce creep.

Typically, the average tread pressures (i.e., the sum of the rope tensions/projected rope area on the drum) of 2,069 kPa (300 psi) with lock coil ropes, 1,724 kPa (250 psi) with flattened strand ropes, and 1,379 kPa (200 psi) with round strand ropes on plastic treads will give good life.

More recently, nonrotating flattened strand ropes have replaced lock coil ropes in North America. To compensate for the greater tendency of these ropes to wear the tread liners, the liners have been replaced with harder plastics. Although these materials lack the resilience of polyurethane, good rope life can still be obtained provided the hoisting plant is properly designed in the first place. This is explained in greater detail in the sections that follow.

Deflection Sheaves

Deflection sheaves are used when the pitch circle diameter of the friction hoist pulley wheel (sitting above the shaft) is greater than the center-to-center distance of the compartments. In addition to positioning the hoisting ropes, the use of deflection sheaves has the advantage of increasing the angle of contact of the ropes on the wheel, permitting a higher T_1/T_2 ratio before slippage will occur.

However, deflection sheaves have the disadvantage of requiring additional torque during the hoisting cycle, increasing the height of the headframe and putting reverse bending into the ropes, which can reduce their life.

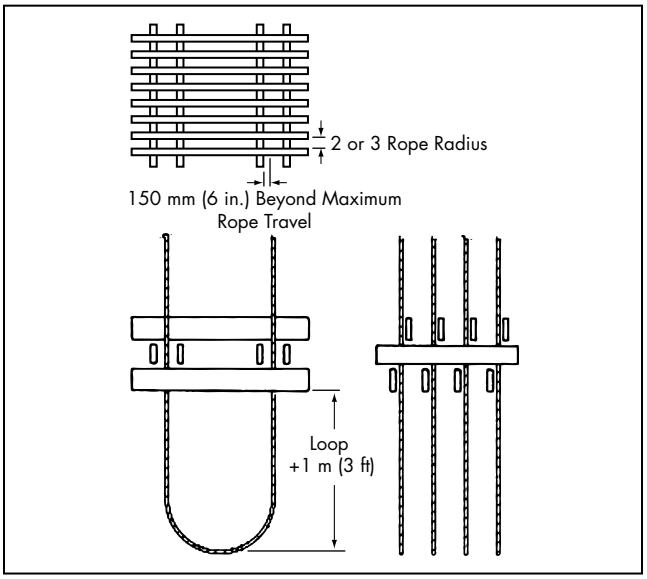

Figure 12.9-8 Tail loop divider

Differential Rope Loads

A great concern with multirope friction hoists is the equalization of loads between the ropes. The two most common causes of differential loading are a difference in rope length or in circumferential lengths of each rope groove on the wheel.

Analysis of this problem and procedures to identify and correct the effects are well covered in the technical literature. In the initial design stage, it is important that steps be taken to reduce its effects. Because there are no hard and fast rules, the following guidelines have been developed in the industry.

The ratio of rope lengths (skip at loading pocket to hoist wheel)/(skip at dump to hoist wheel) should be greater than 50. The total number of revolutions of the drum per trip should be less than 80.

The number of ropes should be kept to a minimum. There will be less difficulty maintaining equal tension on a four-rope hoist than on a six-rope hoist. In addition, a larger wheel will be required for a four-rope drum having fewer revolutions per trip, lower rope bending stresses, and lower sensitivity to tension variations. This requirement may conflict with rope size choice, however.

Rope attachments should have both fine and coarse length adjustment. Rope attachments that incorporate a hydraulic cylinder to balance the loads equally should always be used.

Tail Rope Loop Dividers

To avoid mishap and possible mechanical damage through entanglement, the balance rope loop area should be well controlled in the sump. One method is by constructing a loop divider. The balance ropes should be restricted quite closely in the direction of their lateral movement.

Early contact with the dividers between individual ropes will provide good control in the sump area and also assist in ensuring that adequate stability through the shaft is maintained. Longitudinal movement, on the other hand, should not be overly restricted. The dividers should be designed to avoid trapping any material from spillage. Some operators have found that a wire rope equipped with numerous ultra-high molecular

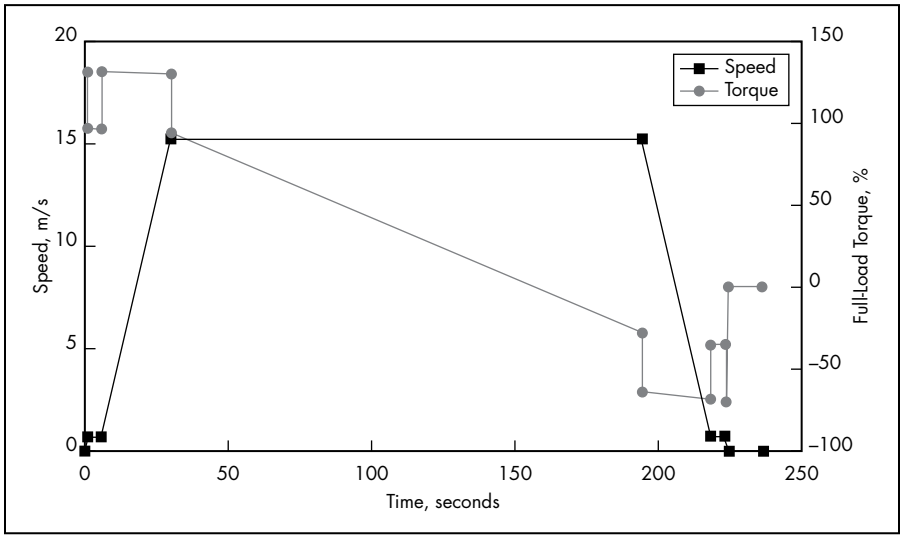

Figure 12.9-9 Double-drum hoist duty cycle

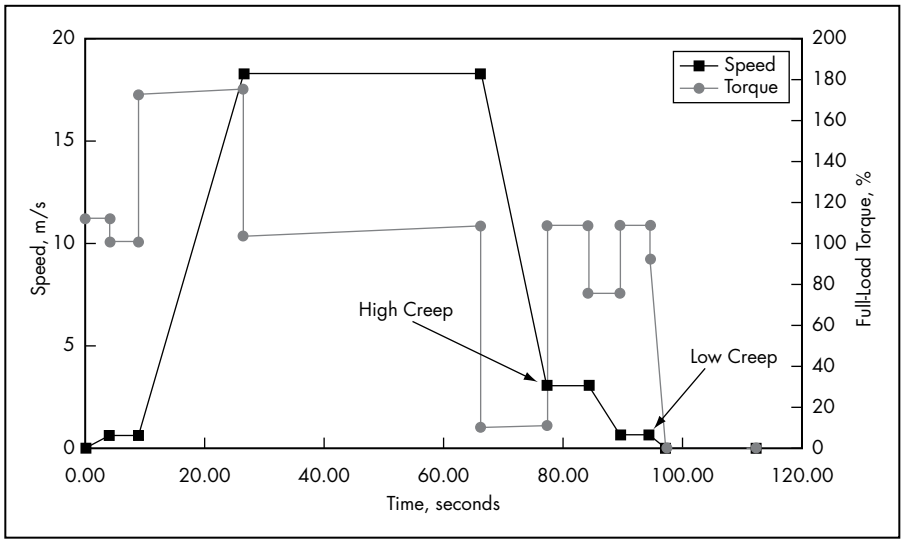

Figure 12.9-10 Koepe hoist duty cycle

weight polyethylene rollers, about 150 mm (6 in.) in diameter and placed in the configuration shown in Figure 12.9-8, has proven to be most successful in this connection. The elevation of the loop divider for good results is one loop diameter plus approximately 1 m (3 ft) above the bottom of the loop. Some operators have placed such dividers at several elevations in the sump area to ensure good contact over the height of the tail loop.

DUTY CYCLES

A duty cycle is a determination of the root mean square (RMS) thermal and torque load on the electrical equipment. The calculations assume that motor current is directly proportional to motor torque.

Duty cycles are usually carried out assuming the motor is force-ventilated. If the machine is self-ventilated, then factors have to be applied to account for the amount of time the motor spends accelerating and decelerating and at rest. These factors differ for AC and DC machines because of the differences in their construction.

The heating effect on each segment of the duty cycle is calculated using

$$\text{heat generated} \sim \text{torque}^2 \times \text{time}$$

The rate of cooling on each segment of the duty cycle is calculated using

$$\text{equivalent cooling time} = \text{cooling factor} \times \text{actual time}$$

The thermal load over the whole duty cycle is the square root of the sum of each segment, that is

$$\text{RMS torque} = \sqrt{\frac{\sum \text{torque}^2 \times \text{time}}{\sum \text{cooling time}}}$$

These results are reasonably accurate for force-ventilated motors but can be misleadingly low for modern self-ventilated machines.

A typical speed-and-torque-versus-time chart corresponding to a duty cycle for a double-drum hoist is shown in Figure 12.9-9 and for a Koepe hoist in Figure 12.9-10.

The drum hoist usually has a significant regenerative portion in its cycle because the large unbalance caused by the rope changes from a positive load to a negative one when the conveyance passes the shaft midpoint. Because Koepe hoists utilize balance ropes, this reversal of load is absent from the cycle.

HOIST UTILIZATION

The previous section outlined the procedure for sizing the hoisting system based on the production or service duty required. Inherent in this procedure is a step for determining how much production time is available each year.

Many mines have multipurpose shafts, that is, the shaft will provide both production and service capacity for the mine. Production and service can proceed at the same time if the shaft is equipped with both a service and a production hoist, as long as the compartments are physically separated by brattice or the personnel are not transported in the shaft while it is in production. It is also possible to use the same hoist for both production and service duty, but this requires a much higher degree of planning and leaves little room for any hiccups in the mining process.

Table 12.9-1 demonstrates the daily examination and testing required on a hoist in North America. In addition to examination and testing, time must also be allotted for maintenance of the hoists, conveyances, shaft, and shaft furnishings. The amount of time required will depend somewhat on the shaft configuration and hoist type, but all of the items listed in Table 12.9-2 are required to some degree.

Experience has shown that the average time available for production hoisting can vary from 12 to 20 hours per day when spread out on an annual basis. For most mines, the production time available will be between 16 and 18 hours per day.

The total hoisting time will also depend on the shift system in practice at the mine. Although most production hoists are automatic, they may have to be shut down during shift change if proper isolation between the cage hoist and production hoist is unavailable or if there is only one combined production/service hoist. Bearing all of this information in mind will permit the mine operator to determine how many hours of actual hoisting is available on an annual basis. Most hoisting plants today will achieve about 95% availability, as long as time has been allotted for their proper maintenance.

Table 12.9-1 Daily hoist examination and testing required in North America

Procedure	Time, minutes
Run through shaft	5
Test overwind and underwind protection	10
Test brakes (dynamic drag)	10
Verify safety devices	20
Examine head- and tail ropes	30
Examine rope attachments	15
Examine hoist and deflection sheaves	10
Total	100

Table 12.9-2 Annual shaft maintenance summary for a shaft with two hoists

Activity	Hours per Activity	Annual Total, hours
Daily hoist examination and testing*	1.5	433.5
Daily rope examination	4	1,196
Weekly hoist, rope, and conveyance examination*	8	208
Weekly shaft equipment and guide examination*	4	208

Monthly shaft equipment repairs†	8	96
Annual rope electromagnetic testing (4 ropes)	32	32
Annual hoist testing	16	16
Annual brake testing	8	8
Biannual rope change	48	24
Total	—	2,317.5
Annual hoisting time with 1-week shutdown	357×24	8,568
Available hoisting time	8,568–1,121.5	6,250.5
Average per day	7446.5/357	17.51
Shaft availability	—	73%

*Will require one crew per hoist.
†May be done on special shutdown.

CONVEYANCES

The transportation of ore, waste, personnel, and material requires the use of a conveyance. Conveyances for handling ore and waste are termed *skips*; those used to carry personnel and material are termed *cages*.

Skips

The skipping cycles discussed above have implicit assumptions as to what type of skip is being used. There are three main types of skips in use today: the overturning (Kimberley), the swing-out body, and the fixed body, as shown in Figures 12.9-11, 12.9-12, and 12.9-13, respectively.

Overturning Skip

The overturning or Kimberley skip consists of a bail frame, a shaft to support the skip, and the skip body itself. The skip body rests on the shaft. The skip is dumped through the action of a bull wheel mounted on each side (at the top) of the skip body. Each bull wheel engages a scroll, causing the skip body to rotate around the shaft as the skip is being hoisted through the dump. The design of the tipping path is complex because the payload is being discharged as it moves along the path. The horizontal and vertical forces that need to be considered in designing the scrolls and their support steel are dependent on the speed at which the skip enters the dump, the inertia of the skip plus payload, the acceleration the skip produced by the curvature of the dumps scrolls, and the gravity forces.

The advantages of Kimberley skips are that there is less shaft spillage when handling fine or wet material and that they can handle larger pieces for a fixed cross-sectional area. The disadvantages are that the capacity is limited because of the height-to-width ratio; the payload ratio is usually lower, particularly with sticky material that tends to build up in the bottom; they generally impose higher stresses on the headframe and bins; and they require more headframe height to dump.

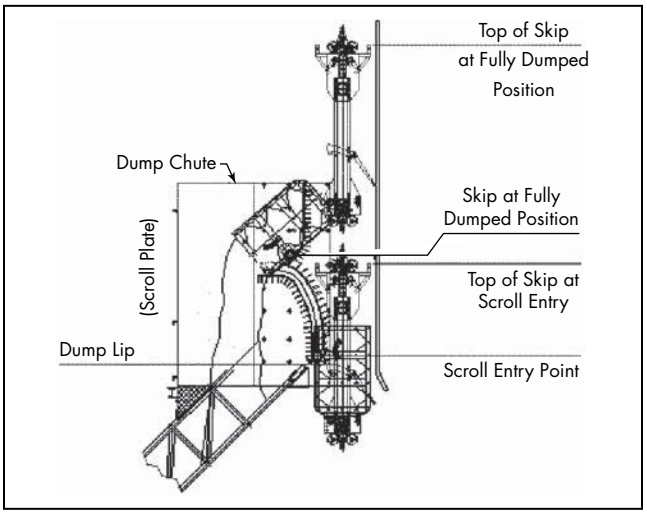

Figure 12.9-11 Overturning (Kimberley) skip

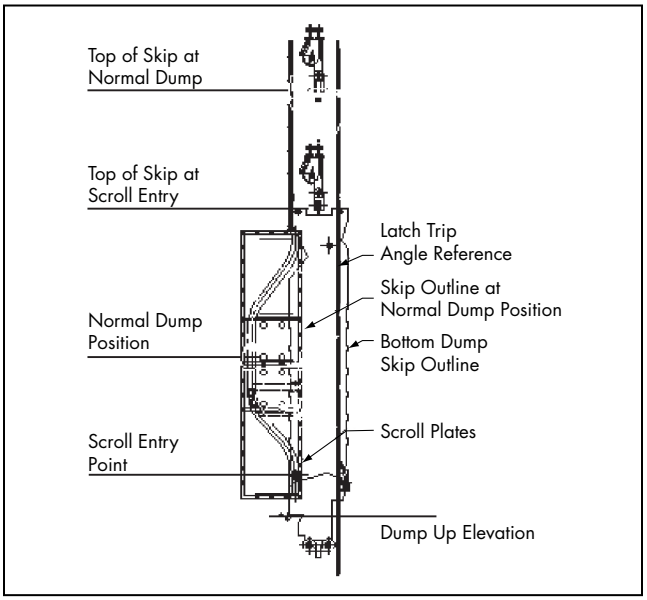

Figure 12.9-12 Bottom-dump skip (the most popular type of swing-out-body skip)

Swing-Out-Body Skip

The swing-out-body skip also consists of a bail frame, a shaft, and the skip body. In this case, the skip body is suspended from the shaft and the skip is dumped by means of rollers mounted on each side (at the bottom) of the body. The rollers engage a scroll and cause the body to pivot away from the bail into the dump. At the same time, a discharge door, which forms the bottom of the skip, opens and the material is discharged. The skip can be dumped by using either a mechanical operator or scroll or by using a hydraulic operator that pulls the skip body out of the bail. These options are illustrated in Figures 12.9-14 and 12.9-15.

For bottom-dumping skips in general, the cross-sectional area is partially determined by the size of the material to be handled. The door opening is sized to be at least three times the dimensions of the largest piece to be handled to prevent possible bridging.

The advantages of swing-out-body skips are that they have a more favorable payload ratio than the overturning type, the tipping path is less complex than for the overturning skips, the dumping distance in the headframe is less than for the overturning type, and they can be built to handle much larger payloads because dumping does not involve lifting the entire mass of the skip body and its payload. The main disadvantage is that muck buildup at the hinge point in the door can prevent the door from closing and thereby place large forces on the headframe scroll or skip body during the closing cycle. In addition, with wet material, there could be spillage or dribble from the door lip; and the bottom door mechanism is more complex than in the fixed-body type.

Fixed-Body Skip

In fixed-body skips, the body of the skip remains fixed and does not move out of the confines of the skip compartment during dumping. Instead, a door at the bottom of the body swings open to form a chute and allows the material to discharge into the dump bin. This type of skip may or may not have a bail.

There are several types of fixed-body skips. The most common are the Rolachute, Arc-Gate, and Sala-type skips. The difference among these types is the mechanism involved with the opening and closing of the door. In the Rolachute skip, the door is held closed by means of a door latch. When the skip enters the headframe, a latch track releases the latch, allowing the door to open and the material to discharge. With the Arc-Gate skip, a roller is mounted on each side of the door. When the skip enters the dump area, the roller engages a scroll, causing the door to swing open. In the Sala-type skip, the door is operated by means of air cylinders mounted on the skip body. Compressed air to operate the cylinders is provided through a yoke that is permanently mounted in the headframe and picked up by the skip as it enters the dump. The Sala design, with its onboard air cylinders, adds additional complications brought about by the requirement to interface with an external source of air.

The cross-sectional area of fixed-body skips is determined by the size of the material to be handled. Because fixed-body skips can be built without a bail, the cross-sectional area of the skip can be increased by 10% to 15% when compared to skips with a bail for the same sized compartment.

The advantages of fixed-body skips are as follows:

- The skip can load and dump through the guides.
- The skip has no bail, thus allowing a larger cross-sectional area to be used for the skip body (this can reduce the overall length of the skip for a given capacity).
- The only moving part is the door that forms its own dump chute.
- The skip requires less travel distance to open the door (none at all with the Sala-type skip).
- This type of skip places less stress on the headframe, skip body, and ropes during the dumping operation.

Both the Arc-Gate and Sala types have the added advantage that no part of the skip, particularly the dump door, protrudes beyond the skip body, thereby avoiding any possibility of hanging up or impacting shaft furnishings should the door fail to close completely.

The disadvantages of this type of skip are as follows:

- Problems can occur with sticky muck, as there is no shaking action when dumping.

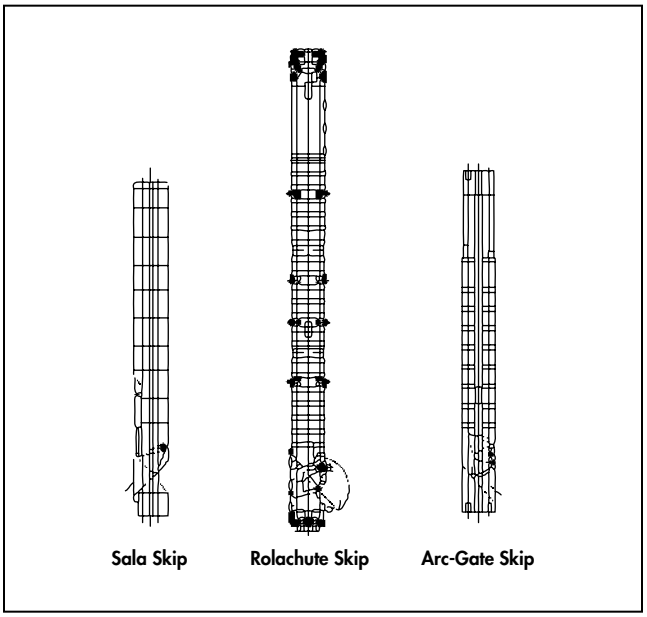

Figure 12.9-13 Fixed-body skips

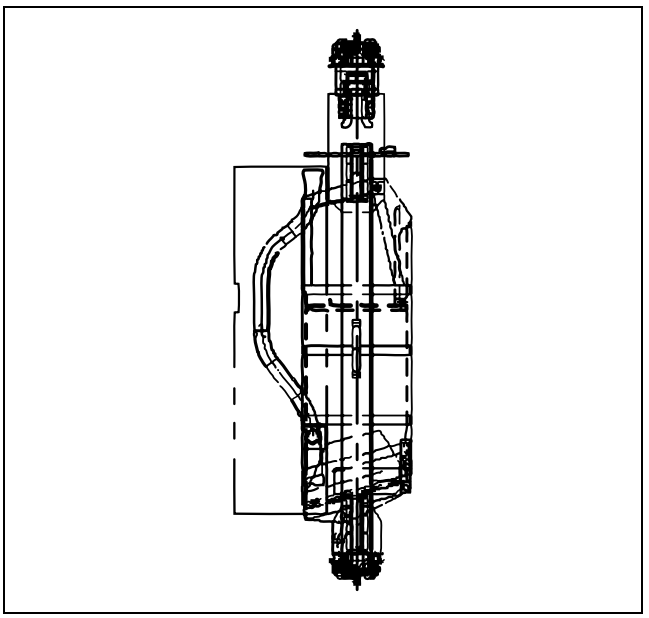

Figure 12.9-14 Dump with mechanical scrolls

- The body necks down at the transition to the dump portion of the assembly, and this can cause hang-ups.
- The entire skip must be removed for replacement of wear plates, not simply the body.
- There is always some dribble into the shaft because the chute does not extend beyond the projection of the skip's body (except with the Rolachute design).

Skip Design Considerations

When selecting a particular skip, the components to be considered during the evaluation process include design methods, body, doors, crosshead, bail, guide rollers, and guide shoes.

Design Methods

Skip components may be designed based on experience and practice or through analytical methods that define the loading being placed on the various components of the skip. The types of loading to be considered are dynamic loading (caused by filling, hoisting, and dumping the skip) and static loading. Factors of safety are usually specified by legislation.

Body

The skip body is designed as a rectangular box with stiffeners. The type of material, its thickness, and the stiffener size and spacing are the variables to be examined. Particular attention must be given to the area on the backside of the skip that receives impact and abrasion from loading.

Skip bodies are usually lined with abrasion-resistant material to increase overall life. Two types of steel and elastomers have been used for skip liners. Abrasion-resistant steels are members of the high-strength, low-alloy family of steels. Manganese steels are used because they have the ability to work-harden during service. Elastomers have the advantage of reduced weight, less ore sticking and buildup, corrosion resistance, and ease of handling during replacement.

The use of aluminum is also increasing, particularly in drum hoist applications. Such skips have a lower mass and allow a higher payload to be hoisted.

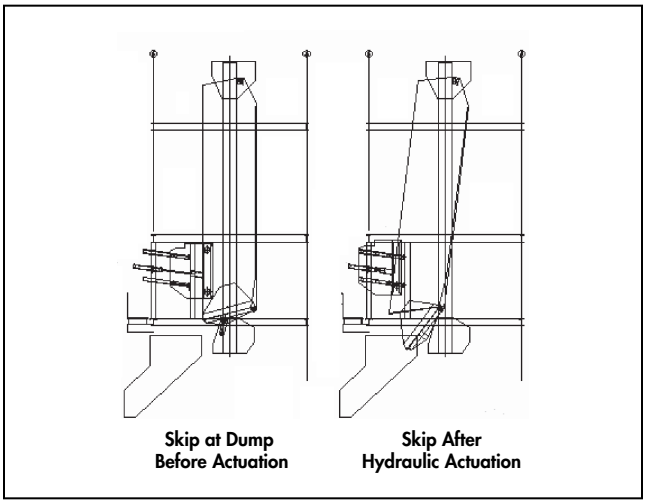

Figure 12.9-15 Hydraulic dump before and after actuation

The impact areas are often lined with heavy rubber materials that were originally designed for use inside of rotating grinding mills. These liners are quite thick, typically 75 mm (3 in.), so they must be accounted for when estimating the live volume of the skip.

Doors

Both swing-out-body and fixed-body skips have doors at the bottom of the skip. Doors must be designed to withstand the impact of large pieces falling on the floor during loading, the static loading of a full skip, and abrasion during unloading.

With swing-out-body skips, the door is hinged at the back, and several problems are associated with leakage paths between the door and the body. These door leakage problems may be solved through the use of rubber sheets, flexible materials, or special modification of plates at the door. Fixed-body skips generally have fewer problems with leakage or door

closure. Problems may occur with both types when they are loaded on the side opposite the dump site. In this case, a vertical stop may be placed for the dump roller to react against. Doors are made and lined with the same material as used in the body.

Crosshead

The crosshead fastens the bail to the rope. It must be designed to take all the skip loads, including acceleration, impact, and service factors. The location of the crosshead above the skip is particularly important during loading. It should not interfere with the flow of muck from the loading pocket. The rope stretch in deep mines can be several feet and must be considered.

Bail

During hoisting, the bail supports the body pivot, prevents the body from moving, and supports the door. At the dump, the bail is subjected to horizontal loading and supports the door. It is thus subjected to both bending and axial loading.

Guide Rollers

The purpose of guide rollers is to keep the guide shoe off the guides. This in turn results in a smoother ride, reducing dynamic loading between the skip, guide, and buntons when traveling.

When selecting guide rollers, there is usually a conflict between a large-diameter tire, adequate shaft clearance, and the cross section of the skip. Left unresolved, the final design usually results in a small-diameter tire. Such tires need frequent replacement. Tire sizes range from 150 to 350 mm (6 to 14 in.) in diameter. Tires are rated on a load-speed basis. High-speed hoists require special guide rollers that are typically made from wire-reinforced rubber. Guide rollers should be part of an assembly comprising springs and shock absorbers in order to work effectively. Systems in which the guide roller is simply fixed to a bracket bolted to the skip are of little use.

Guide Shoes

Guide shoes are used on vertical conveyances to keep the main structure from being worn away by the guides. They are considered as expendable items to be replaced when they are too worn for further use. Clearance between the guide and guide shoe varies from 6 to 12 mm (0.25 to 0.5 in.). Guide shoes can be made from many materials, such as cast iron, mild steel, hardened steel, abrasion-resistant steel, brass, and bronze. The amount of wear to be expected is directly proportional to the load on the guide shoe and inversely proportional to the hardness of the material.

Cages

Cages are used primarily to move personnel and materials entering into and exiting from the mine. In some instances, cages are used to hoist cars loaded with ore and waste. The design and construction of cages are similar to those used for skips.

A cage is merely an enclosed box opened by a door or doors and suspended from a hoisting rope. The dimensions and capacity of the cage are determined by the quantity, volume, weight, and dimensions of the materials and items to be transported.

Cages are much lighter in construction than skips because they are not exposed to the impact loading and abrasion produced when loading and dumping the mine's ore and waste.

Counterweights

In some balanced hoisting systems, a counterweight may be used with either a cage or skip. Because counterweights serve no functional purpose other than to provide for balanced hoisting, their dimensions are quite variable. They are usually designed to fit the space available.

One configuration that has been used for a counterweight consists of a cylinder running in a steel pipe. These systems, although apparently simple, have been found to be hard to maintain because inspection of the pipe is very difficult and correct alignment of the pipes is complicated to determine and monitor.

When used in conjunction with skips on a Koepe hoist, counterweights allow the system to operate from several loading levels, which is not possible with a balanced skipping configuration.

Safety Devices

In North America, cages must be equipped with safety devices that are designed to prevent the cage from falling down the shaft in the event of rope breakage or serious overwind. Different types of safety devices are used for drum hoists and friction hoists.

Drum Hoists

With drum hoists, both excessive overwind and rope breakage can occur. Of these two types of accidents, rope breakage is considered the most serious, and provisions to bring the conveyance to a safe stop in the event of a rope break is required by legislation.

The most common safety device used is the safety dog. A pair of dogs is installed at the top of the conveyance, one pair for each guide. During normal operation, the tension in the hoisting rope keeps the dogs open. Should the rope break, or become slack, a large spring and a series of levers cause the dogs to bite into the guide and stop the conveyance from descending. The dogs dig into the guide to produce a retarding force.

Although dogs are available for use on both wooden and steel guides, only one design, the so-called Wabi single-tooth dog (Wabi Iron and Steel Corp.), which operates on wooden guides, has been demonstrated to produce consistent and acceptable deceleration rates. The dogs used on steel guides are prone to self-energizing, which results in extremely high deceleration rates causing serious injury to personnel riding in the cage.

Friction Hoists

In multiple-rope friction hoist installations, the probability of all hoisting ropes breaking is small. Therefore, overtravel is considered to be more serious, and provisions to bring the conveyance to a safe stop in the event of overtravel are required.

The most common device used is an arrestor gear, consisting of steel frames supported in the hoisting compartment and transported by the conveyance as it travels through the arrestor zone. These devices are located in the headframe and at the shaft bottom. They rely on friction or mechanical deformation of steel to decelerate the hoist.

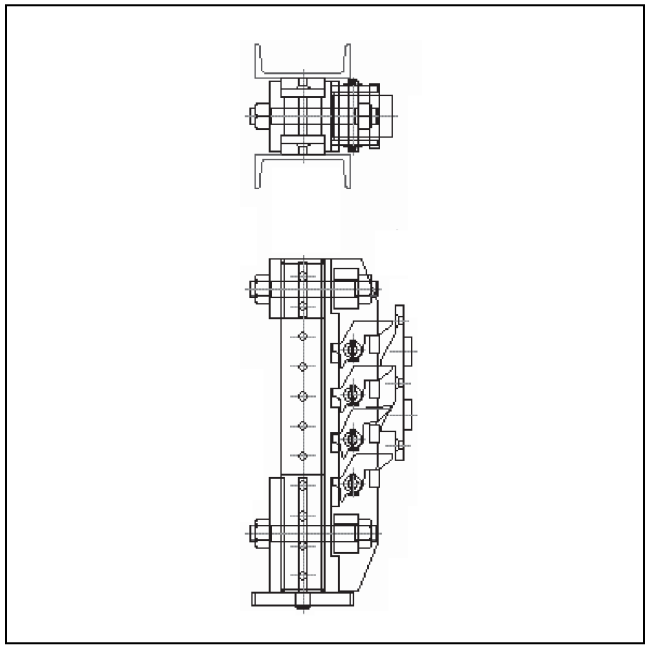

Figure 12.9-16 Catch-gear rack and catch plate

These devices are designed to arrest an upcoming skip at a g-force of 0.9 g's (8.8 m/s^2 or 29 ft/s^2). This level of deceleration ensures that personnel on board will not "float" and thereby injure themselves and ensures that the balance ropes will not overtake the cage, fall back, and likely fail.

In addition to the arrestor gear, the headframe is also equipped with fallback protection. This can be as simple as tapered wooden guides that will jamb the conveyance and hold it until personnel can be evacuated or, more typically, by sets of ratchets that consist of a series of teeth on pivots. This arrangement allows the cage to move up the shaft but prevents it from reversing. Figure 12.9-16 is an illustration of this mechanism.

Loading Pockets

At the loading pocket, ore and waste are transferred from the mine to the skip. The equipment and systems installed can vary from simple manually operated to complex and automated. Two basic types of loading systems are available. These involve measurement by weight or by volume.

The criteria to be considered in the design of all systems include response time, loading time, accuracy of measuring devices, operating and maintenance costs, and amount of spillage.

Although details can vary, each system has the following common elements: a pocket chute with control gates, a measuring pocket, and a skip feed chute with a control gate.

Pocket chutes are generally fabricated from steel with liners. They have an angle of inclination of 45° to 55°. Chute gates can be pneumatically or hydraulically controlled and may be guillotine, ball-and-chain, or undercutting radial arc types.

Skip Loading

Skips are loaded directly from the orepass and are loaded using a measuring flask or a conveyor.

Direct Loading from the Orepass

This method is only used in small operations, typically less than 4 t (4.4 st). The orepass terminates close to the shaft and is equipped with a heavy chain gate, which is raised to allow the ore or waste to fill the skip via a chute. In double-drum installations, the chute will include some kind of diverter mechanism to select between the two skips, as shown in Figure 12.9-17.

Loading via a Measuring Flask

This is the most common arrangement with the flask or flasks installed in a cutout adjacent to the shaft and being fed via a conveyor or sometimes a pan feeder. The flasks, sized to match the skip volume, are filled from the top and are equipped with a door and chute to control and direct the discharge of material into the skip. Loading the flasks is typically controlled by load cells supporting the flask with a volume override. When the material is of a consistent density, such as crushed salt or potash, the systems are often controlled by volume only. The material flows into the flask until the flask is full. At this point, an undercutting arc gate will close the bottom of the storage bin that feeds the flasks. The loading flask is furnished with pneumatically or hydraulically controlled gates. The bottom of the flask is usually inclined at an angle of 60° or greater to ensure rapid loading and complete clean out. Examples of these systems are shown in Figure 12.9-18. With balanced skip hoisting, two loading flasks are provided, one for each skip.

Loading via Conveyor

One of the problems associated with the previously mentioned systems is the difficulty in controlling the loading rate. After the gate is raised to allow the material to flow, there is very little that can be done to regulate the flow, and, as a result, the entire load drops into the skip. This can produce very high dynamic loads on the ropes that support the skip. These loads will reduce the life of the ropes.

To overcome this problem, skips can be fed directly from a conveying system, which can be programmed to fill the skips at a constant rate over a period of 10 to 20 seconds. The conveyors can be equipped with load cells to measure the load accurately. Figure 12.9-19 shows a layout of such a system.

Skip Feed Chute

A feed chute is required to direct the material from the measuring pocket or conveyor to the skip. The angle of inclination of the feed chute is usually 60° or greater.

The clearance between the chute and the skip is approximately 75 mm (3 in.). It has been suggested that the ratio of the chute discharge width to the skip width should not exceed 0.7 for skips up to 1.5 m (5 ft) wide and 0.8 for skips up to 1.8 m (5.9 ft) wide. To reduce spillage, the sides of the chute must be narrower than the opening in the side of the skip body.

Automatic Loading

Automatic loading of skips is used to improve the efficiency of hoisting systems and to reduce labor requirements. Efficiency is improved by ensuring that each skip receives the required load without overloading or underfilling. Labor is reduced when automatic loading is used in conjunction with automatic hoisting. So that automatic loading can be accomplished, a minimum of three control systems must be included. There must be a means of measuring the weight and/or volume of

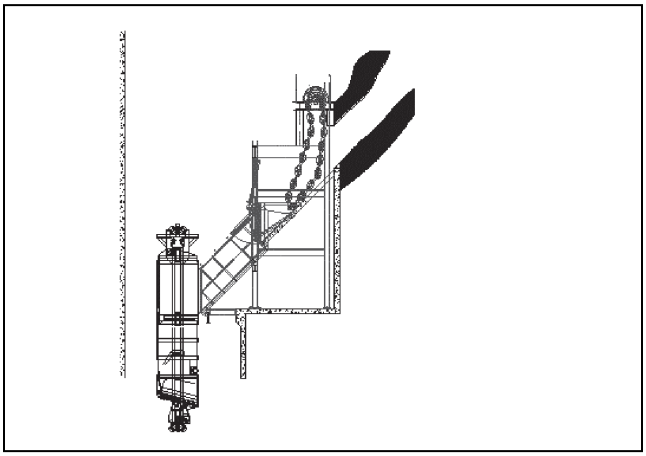

Figure 12.9-17 Chain-gate-controlled skip loading from orepass

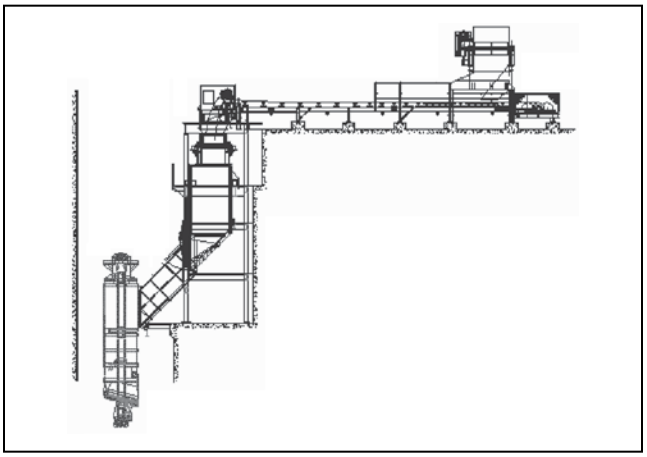

Figure 12.9-18 Skip loading with measured flask

material in the measuring pocket, a means of opening and closing feed chutes to fill and empty the measuring pocket, and a logic system to ensure that the above operations are carried out in the correct sequence to prevent such system failures as double loading and dumping into an empty shaft. With automatic hoisting, the logic system extends to the operation of the hoist.

Spill Pockets

Despite the precautions taken to prevent spillage during the loading and dumping of the skips, a certain amount is inevitable below the loading pocket. This spillage may be confined to the hoisting compartment by lining these compartments down to a spill pocket. According to data available from a number of mines in South Africa, the amount of spillage, expressed as a percentage of tons hoisted, varies from 1.5% to 5%. The larger amounts of spillage are associated with manually operated systems handling uncrushed material.

Two methods of handling spillage in modern hoisting systems are commonly used. One method consists of installing deflectors in the shaft below the underwind position of the skip. These deflectors direct spillage into a small flask similar to the loading pocket. The spillage pockets are then cleaned as required. With drum hoisting, this system can be used at any elevation in the shaft. With a friction hoist, the spillage pocket must be located below the tail rope loops, and a second conveyance, such as the cage, must be used to handle spillage. The second method of handling spillage consists of developing a ramp from the lowest horizon in the mine to the shaft bottom. In this system, any spillage falls directly to the shaft bottom, where it can be mucked out. Regardless of the system used, particular care is required with friction hoist systems to ensure that the tail ropes do not become entangled or affected by the buildup of spill in the shaft and to ensure that the guide rope tensioning weights do not end up resting on the accumulated spill. Most mines today provide ramps to the shaft sump for cleaning the spill.

ROPES

The basic purpose of the hoisting rope is to connect the conveyance to the hoist. It is selected primarily based on safety, compatibility, life, and costs. Safety requirements when hoisting personnel, or where persons may be endangered by hoists and their appurtenances, are usually determined by legislation.

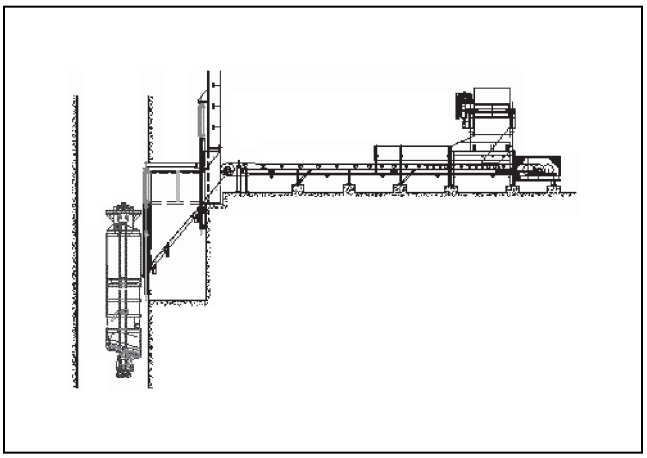

Figure 12.9-19 Skip loading with conveyor and chute

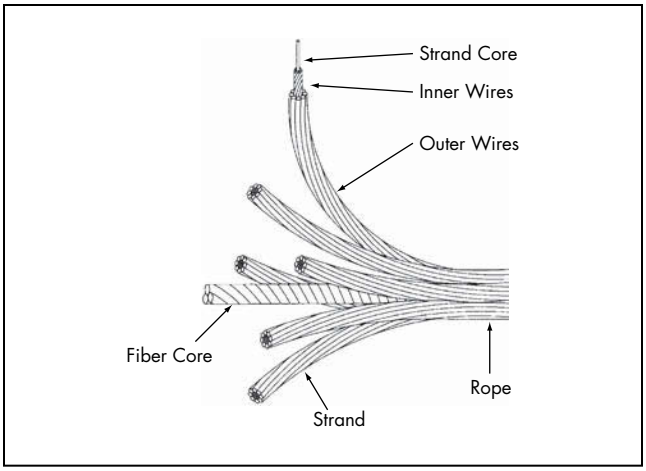
The life of a rope is usually expressed as the number of trips it will make; it is affected by rope construction, hoist and sheave dimensions, type of loading, shaft atmosphere, and maintenance. Costs of initial purchase, maintenance, and rope replacement, including lost production, are normally considered. In addition to hoisting ropes, the hoisting systems designer must be concerned with balance ropes (for friction hoist application), guide ropes, rubbing ropes, and rope attachments.



The types of rope construction commonly used for various hoisting applications are as follows.

Drum hoist ropes

- Production duty: Lang lay flattened strand 6 × 30 fiber, or wire metal or plastic core
- Shaft sinking duty: Multistrand, nonspin, 34 × 7, wire metal core

Friction hoist ropes

- Head ropes:
  - Full locked coil
  - Multistrand, nonspin, plastic cushion, 29 × 7, plastic core
  - Round strand, regular lay, plastic core

Source: Anon. 1980.
Figure 12.9-20 Exploded view of a rope

- Balance ropes: Multistrand, nonspin, 34 × 7, plastic core
- Guide and rubbing ropes: Half-lock coil, wire metal core

In this section, a general description of the various types of ropes, plus the factors to be considered to ensure correct application and selection, is presented.

Rope Construction

In the construction of most wire ropes, a number of individual wires are wound around a core to form a strand. The strands are then wound around a core to form the rope. Figure 12.9-20 is an exploded view of a rope showing its components.

Some ropes are constructed without strands by winding consecutive layers of wire around the inner layers. The factors to be considered in rope construction are the wire, strands, cores, and lay. By varying these factors, ropes with different characteristics can be constructed.

Hoist Ropes

The four types of ropes generally considered for hoisting applications are round strand, regular lay; flattened strand, Lang lay; multiple strand, nonspin; and locked coil. Typical properties for these types of rope are given in Table 12.9-3.

Round Strand, Regular Lay Ropes

The wires in these ropes are laid up (i.e., twisted together) to forms strands in the opposite sense to which the strands are laid up to form the rope. The wires on the outside surface lie approximately parallel to the axis of the rope.

Under tension, the wires tend to untwist in one direction and the strands tend to untwist in the other direction. With careful design, the rope will show little tendency to twist when loaded.

Flattened Strand, Lang Lay Ropes

The strands in these ropes are formed around a triangular core and have the wires laid up to form strands in the same sense as the strands are laid up to form the rope. The wires on the outer surfaces of the strands lie at approximately 45° to the axis of the rope. This construction was developed specifically for multilayer winding on hoist drums.

When compared to a round strand, regular lay rope, the flattened strand, Lang lay rope

- Is more flexible because the wires lie parallel to the rope near the rope center, not on the surface;
- Has wires at the outer surface of the rope that are less subject to "plucking" by adjacent turns as the rope coils on the drum; and
- Is designed so that contact loads at the surface of the rope and between strands are distributed over many wires, thereby reducing internal nicking of wires.

One disadvantage of a Lang lay rope is that it tends to untwist when loaded. The two types of lay ropes are illustrated in Figure 12.9-21.

Multiple Strand, Nonspin Ropes

These ropes were developed to overcome the torsion forces developed by Lang lay ropes. They are more susceptible to the crushing forces associated with multilayer winding on a drum and have a lower strength/weight ratio than Lang lay flattened-strand ropes.

This type of rope is used on drum hoists for shaft sinking, where the required service life is relatively short and the conveyances run on rope guides and, thus, low-torque ropes are required. More recently, their design has evolved to include plastic cushioning between layers to reduce internal nicking. The resulting ropes are used as head ropes and balance ropes on Koepe hoists.

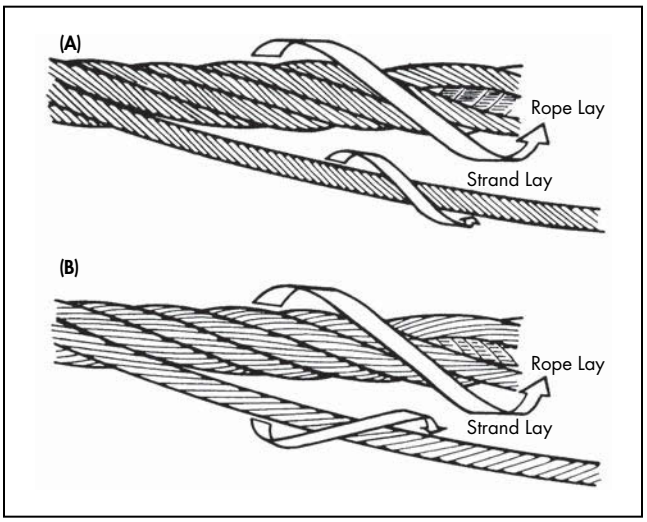
Full Locked Coil Ropes

This type of rope is completely different from both round and flattened strand rope. The center or core of the locked coil rope consists of a concentrically laid strand of round wires. Around this core lies one or more layers of X-shaped cross-sectional wires, the outer layer always being Z-shaped and interlocking. The lay of the various layers can be arranged so that the rope does not have a tendency to untwist when loaded. In addition, the structure is compact and stable and better able to withstand crushing stresses than any other rope, and the line contact seals between the wires in the outer layer keeps lubricant in and corrosive environment out.

On the debit side, the specially shaped outer wires cannot be made as strong as round wires, and the rope is less flexible than stranded rope. Larger sheaves and drums are required for ropes of equivalent strength.

The main use of these ropes is on Koepe hoists running on rope guides in deep mines. Figure 12.9-22 shows the cross section of a full locked coil rope.

Rope Selection



For the initial selection, the following four requirements should be considered: strength, resistance to fatigue failure, abrasion resistance, and resistance to crushing or distortion. The choice should be made after correctly estimating the relative importance of each of the above requirements. Naturally, strength is the overriding concern.

Rope Selection for Drum Hoists

This segment discusses the selection of the size of rope to meet operating conditions for drum hoists used in vertical and slope applications. In the United States, the Code of Federal Regulations (CFR), CFR Title 30, Part 56, specifies minimum requirements for the following items that are relevant to drum hoisting: factor of safety, ratio of drum/sheave diameter to rope diameter, and fleet angles.

Table 12.9-3 Typical properties of rope types

Rope Type	Characteristics and Applications	Comparative Strengths, kN (for 38-mm diameter)	Unit Mass, kg/m
Round strand, regular lay	Used on sinking and Koepe hoists	980	6.1
	Tend to nick in multilayer applications		
	Available from wires up to 1,960 MPa (284,000 psi)		
Flattened strand, Lang lay	Used on drum hoists and shallow Koepe hoists		
	Best for multilayer applications	1.135	5.9
	Very high strength, easy to perform nondestuctive testing		
	High torque under load		
	Available from wires up to 2,000 MPa (290,000 psi)		
Multiple strand, nonspin	Used on sinking and Koepe hoists	1.000	5.7
	Low torque, internal nicking unless plastic fillers incorporated into the design, low elastic modulus, and high initial stretch		
	More difficult to perform nondestuctive testing		
	Available from wires up to 1,960 MPa (284,000 psi)		
Locked coil	Used on drum and Koepe hoists	1.400	8.4
	Near-zero torque, lower unit strength, high elastic modulus		
	Available from wires up to 1,570 MPa (228,000 psi)

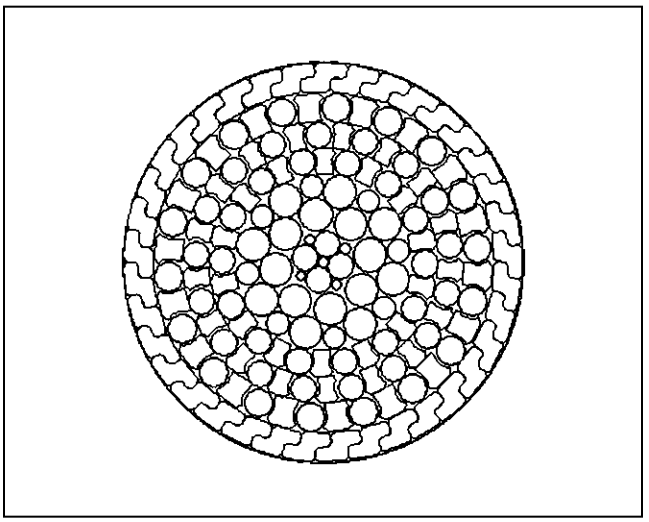

Figure 12.9-22 Cross section of full locked coil rope

Factor of safety. Mandatory requirements by the Mine Safety and Health Administration (MSHA) are covered in CFR Title 30, Parts 55 and 56, and Section 57.19-21 for metal and nonmetal underground mines and underground coal mines, which require the following minimum rope strengths, where L is the maximum suspended rope length in meters:

- For rope lengths less than 914 m (3,000 ft): minimum strength = static load × (7.0 – 0.0033*L)
- For rope lengths in excess of 914 m (3,000 ft): minimum strength = static load × 4.0

Drum/sheave diameter. Mandatory requirements for drum and sheave diameters have now been removed from the regulations, but insofar as the old regulations are still common practice in the United States, as well as Canada and Europe, they are repeated here.

Drum and sheave tread diameters should be

- Not less than 60 times the hoist rope diameter for slope or inclined shaft applications,
- Not less than 80 times the hoist rope diameter if the hoist ropes are 25 mm (1 in.) in diameter or greater or not less than 60 times the hoist rope diameter if the hoist ropes are less than 25 mm (1 in.) in diameter for vertical shaft applications, and
- Not less than 100 times the hoist rope diameter for locked coil ropes.

Fleet angles. The fleet angle refers to the angle made by the headrope between the drum and sheave. If this angle lies outside of fairly small limits, the rope will tend to either pile up at the drum flange or jump several pitches when it starts to return across the drum. Practice has found that the fleet angle

should be between 0.5° and 1.5° for ungrooved drums but can be between 0.25° and 2.0° with drums grooved in the parallel, so-called LeBus pattern.

South African Code of Practice

The most recent codes of practice relating to the selection of headropes as well as assessment of rope condition are those produced by the South African Bureau of Standards (SABS). These are called SANS 10293 (1996) and SANS 10294 (2000) and are worth obtaining to better understand all facets of mine hoisting ropes.

Rope Selection for Koepe Hoists

A friction hoist differs from a drum hoist in that the rope is not wound on and off the drum but passes around the hoist drum, with the friction between the rope and drum providing the force necessary to move the rope. Friction hoists may be mounted in the headframe tower directly over the shaft, or they may be mounted in a hoist house at ground level. The friction hoist drum is often referred to as a wheel.

Regulations and other calculations and considerations involved in rope selection for friction hoists are discussed here.

Factor of safety. Mandatory requirements by MSHA are covered in CFR Title 30, Parts 55 and 56, and Section 57.19-21 for metal and nonmetal underground mines and underground coal mines, which require the following minimum rope strengths, where L is the maximum suspended rope length in meters:

- For headropes with lengths less than 914 m (3,000 ft): minimum strength = static load $\times$ (7.0 – 0.00164*L)
- For headropes with lengths in excess of 914 m (3,000 ft): minimum strength = static load $\times$ 5.0
- Balance or tail ropes = 7.0 on weight of rope (static load)
- Guide or rubbing ropes = 5.0 on weight of rope (static load)

Bending ratio. The required bending ratios are the same as for drum hoists when stranded construction ropes are use. The bending ratio for locked coil ropes must, however, be larger because these ropes are much stiffer in bending than stranded ropes.

Wire Rope Industries of Canada recommends the following minimum bending ratios for locked coil ropes, although all such specifications have been removed from CFR requirements:

- Less than 25 mm (1.0 in.) 100:1
- 25 to 32 mm (1.0 to 1.25 in.) 100:1
- 38 mm (1.5 in.) 110:1
- 51 mm (2.0 in.) 120:1
- Greater than 51 mm (2.0 in.) 130:1

Rope Types

Lang lay ropes work satisfactorily in installations where the hoisting distance is less than 750 m (2,500 ft); at greater depths, the spin upsets the rope structure, resulting in misplaced strands, broken wires, and so forth.

Ropes of nonrotating design, such as multistrand, nonspin, or full lock coil, should be used if the hoisting depth is greater than 750 m (2,500 ft).

Tail Rope Orientation

Any object falling down a mine shaft is affected by the angular velocity of the earth and will move toward the east wall. A tail rope behaves in a similar way. If the shaft compartments are arranged in an east–west direction, the tail rope loops will open and close freely. However, if the compartments are north and south, the ropes could foul the separators at the shaft bottom. Because tail ropes are required for friction hoist installations, the orientation of compartments should be considered. The above described action results from a physical principle known as the Coriolis effect and is a function of the hoist speed and the longitude of the mine.

Tail Rope Loop Diameter

When the tail rope hangs in a shaft beneath a pair of conveyances, there is a curved segment at the shaft bottom which is called the tail loop. The diameter of this loop is determined by the spacing of the conveyances. The rope, however, will twist if the conveyance spacing is less than the natural loop diameter of the rope. This natural loop depends on the rope construction and will vary between 30 and 60 times the rope diameter. The stiffer the rope construction, the bigger the loop.

Guide and Rubbing Ropes

Ropes used as guides and rubbing ropes should be of half-locked coil construction. These ropes are manufactured with a core of concentrically laid round wires covered with one or two layers of shaped wires. The outer layer of locked coil construction is always composed of interlocking wires of Z shape.

Some of the advantages of half-locked coil ropes as guides and rubbing ropes are as follows: their smooth surface reduces friction, they have a greater degree of rigidity, and they use wires with large cross sections on their outer layer. This is critical because one broken wire on the outer layer is cause for the rope to be replaced. A broken wire will catch in the guide rope bushing on the skip, which could lead to a major mishap.

Rope Sag

A rope between a ground-mounted hoist and a head sheave sags and takes the form of a catenary. With a heavy rope and a light load, the sag can be significant and cause problems with the rope impacting the sheave deck or the hoist building front wall, if not considered.

The shape of the catenary is given by

$$y = 2*H/q*\sinh(\bar{r} + a)*\sinh(\bar{r})$$

where

y = vertical coordinate along caternary
H = horizontal tension in the cable
q = unit mass of the catenary
$\sinh$ = hyperbolic sine function
$\bar{r}$ = horizontal coordinate along the catenary
a = horizontal spacing of catenary end points

Inclined (Slope) Haulage

The selection of ropes for an inclined shaft differs little from selection for a vertical shaft. The three major differences are calculation of rope tension, sizing of sheaves, and abrasive wear.

Calculation of Rope Tension

The tension in the rope is the sum of the gravitational, frictional, and acceleration forces. The gravitational force is the sum of the weights of the car or cars, payload, and the rope multiplied by the sine of the angle of the incline. The friction force is commonly taken as 2.5% of the weight of the car and payload plus 10% of the rope load.

Sizing of Sheaves

Because of the space restrictions underground and the need for portability, deflection sheaves are commonly smaller than used elsewhere for hoisting ropes. Minimum drum diameter to rope diameter D/d ratios are presented in Table 12.9-4.

Abrasive Wear

Abrasive wear is more likely to be a problem in a slope than in a vertical shaft, and this potential problem should be addressed in rope selection. One approach is to select ropes with thicker wires, such as 6×7. Some designers increase the factor of safety to allow more wear on the rope before it needs to be replaced.

Rope Operating Practices

The correct wire rope properly installed on well-designed equipment maintained in good working condition provides the foundation for satisfactory rope performance. To attain and sustain the required rope performance, it will be necessary that the rope be properly operated and adequately maintained. Well-developed rope-operating practices should consider the following: rope storage, rope installation, rope changing procedures, rope cuts, lubrication, and inspection procedures.

Rope Storage

Whether the rope must be stored temporarily or indefinitely, it should be indoors, where it can be shielded from weather, corrosive fumes, and excessive heat that might dry the lubricant or fiber core. The rope reels must be turned 180° every 4 months so that lubricants do not settle to the lowest point, thereby allowing unprotected steel to rust.

Rope Installation and Handling

Ropes should be wound onto the drum under load. The direction of coiling should be determined by the accepted rule-of-thumb method, as shown in any rope handbook. Before cutting, the rope supplier or a technical handbook detailing correct cutting procedures should be consulted. This typically requires seizing of the rope on both sides of the cut with hose clamps and cutting the rope with a grinding disc.

Drum Hoist Rope Changing Procedures

Rope changing procedures for drum hoists are relatively easy and are described in rope handbooks. Precautions must be taken, however, to ensure that adequate tensions are applied to provide correct spooling during installation and to pretension the dead turns. Pretensioning the dead turns is particularly important in multilayer winding. Failure to adequately pretension will lead to loose dead turns and catastrophic rope wear.

Adequate pretensioning can be provided by using a special rope-tensioning winch or by doubling down the headrope using a loaded skip.

Table 12.9-4 Minimum D/d ratios for sizing of sheaves

Rope Construction	Minimum D/d
6×26	30
6×31	26
6×36	23
6×41	20
8×36	18

Friction Hoist Rope Changing Procedures

There are several options for changing head and balance ropes on a Koepe hoist. Procedures involve careful planning and special equipment. These procedures are beyond the scope of this document.

Rope Cuts

The end of the rope adjacent to the conveyance suffers premature strength reduction as a result of corrosion and local bending. These ends must be cut off at regular intervals.

In multilayer winders, wear occurs on those areas of the rope that meet at the crossovers, that is, the region of the drum where the rope changes layer. These locations need to be moved regularly (every 3 or 4 months) to avoid premature retirement of the rope.

Lubrication

Atmospheric moisture, shaft water, and chemical fumes are a few of the agents that will cause corrosion. This frequently leads to wire breakage and to the premature removal of mine hoist ropes. In mines with very wet and corrosive shafts, it is distinctly advantageous to apply a lubricant that will penetrate the interior of the rope and that contains a corrosion inhibitor. These must be applied during fabrication of the rope. It is impossible to apply lubricants that can penetrate the rope strands after the ropes are manufactured. Ropes made with fiber cores soaked in lubricants will extend rope life in wet shafts.

Inspection Procedures

To achieve optimum rope performance, an inspection procedure that requires findings to be recorded, fully diagnosed, and translated into appropriate action should be instituted.

The presence of the foregoing not only allows the operator to estimate the remaining safe working life of the rope but can also pinpoint the source causing such damage to the rope.

Ropes should be visually examined daily and tested regularly using electromagnetic devices to detect loss of cross section and broken wires. When the rope's strength is determined to have been reduced below 90% of the original value, the rope must be replaced. Other retirement criteria also exist and are stipulated in CFR Title 30, Section 57.19024.

Rope Attachments

Wire rope end attachments are as important as the rope to which they are fastened. Therefore, the selection of the correct type of attachments should be based on an understanding of how they affect ultimate rope serviceability and efficiency.

Forming a loop in the rope or attaching a fitting to the rope are the only ways of attaching something to a wire rope.

Loops are made either by splicing the rope to itself or by the use of clamps or wedges. Fittings secured directly to wire rope can be applied by cold forming (snagging) of the metal in the fittings, either by pouring a liquid material, such as molten zinc, or by a wedging arrangement. In this section, some of the most commonly used attachments are described and are shown in Figure 12.9-23.

Factor of Safety

The factor of safety for rope attachments is not specifically covered in CFR Title 30, Part 57. However, it is considered good engineering practice to design the rope attachments to be stronger than the rope, that is, the rope will fail before the attachments. British codes require a factor of safety equal to 10 based on static loads.

Cappels

Cappels are rope fittings attached directly to the rope. These types of fittings consist of a pair of wedges grooved to suit the particular rope diameter and interlocked to ensure complementary movement. A number of bands driven over the diverging exterior surfaces of the cappel limbs provide the initial compressive force to ensure that the wedges grip the rope. The limbs' internal surfaces have been machined to fit the external surfaces of the wedges. A safety block is fastened on the end of the rope, protruding beyond the bottom of the wedges. Several types of cappels are used for hoist ropes, including the wedge and loop.

Thimbles

In North America, many mine hoist ropes on drum hoists are terminated with a wire rope thimble and U-bolt cable clamps. With this type of attachment, a loop is formed in the rope and the thimble placed within this loop. The free end of rope is then clamped to the long end to secure the thimble.

Thimbles are made of cast steel, whereas clamps, shackles, and pins are made of 1.5% manganese steel.

Thimble Cappels

These attachments represent a significant improvement over the basic thimble without the complication of installing bands to secure the wedges. These devices are self-locking, using the force on the rope to drive a wedge into a housing that incorporates an extension with a pin to connect the cappel to the conveyance drawbar.

Swivels

When winding with balance ropes, the lay length tends to shorten as each conveyance in turn approaches the bottom landing. It is for this reason that swivels are provided to allow the ropes to spin and regain their normal length. Shaft conditions and loadings influence the type of swivel used.

Attachment Maintenance and Inspection

If thimbles and clips are to be used, then the manufacturers' recommendations for the correct number of clips, amount of turnback, clip positions, and correct torques should be followed closely. If a wedge-type connection is being applied, then care should be taken to properly clean the rope surface. Frequent applications of cement dust and subsequent steel brushing will remove all the surface lubricant.

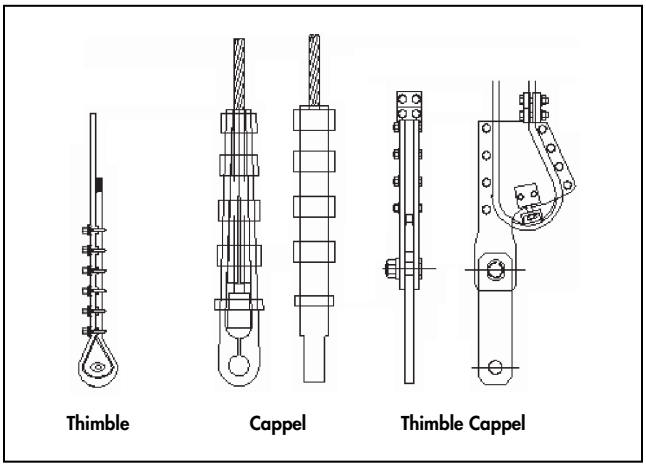

Figure 12.9-23 Rope attachments

In some jurisdictions, statutory mining regulations require that all types of attachments be inspected both visually and nondestructively on a regular basis. In other parts of the world, removal criteria for attachments have been established.

SHAFT AND GUIDE SYSTEMS

A shaft is a vertical or inclined primary opening in rock that provides access to and serves various levels of a mine. Primary openings are those that are considered to be permanent and require a high degree of safety. Chapter 12.4 discusses design and construction details.

Shaft Design Procedure

A suggested procedure for the design of shafts follows. It is important that the steps be followed in the given sequence. The process is iterative and involves working through the process several times before an optimum design is achieved. The shaft design procedure involves the following steps:

1. Define the purpose of the shaft.
2. Identify the location and determine the inclination.
3. Determine the number of hoists required.
4. Determine the size of the conveyances and compartments.
5. Determine the arrangement of the compartments.
6. Determine the exterior shape.
7. Design the interior members (guides, buntons, etc.).
8. Design the shaft lining.
9. Check the ventilation characteristics.
10. Determine the ground stabilization and temporary ground support.
11. Determine the shaft collaring method.
12. Determine the shaft sinking method.
13. Evaluate and modify this procedure by repeating these steps.

Purpose of Shaft

One of the first items to be examined when designing a shaft is to identify its intended purpose. Shafts usually fall into one of the following categories: production (ore and waste handling), service (personnel and materials handling), ventilation (upcast or downcast), exploration (for defining mineral deposits), and combinations of the above.

Location

Generally, the location of a new shaft at the mine site is determined after establishing the following:

- Mine surface layout
- Location, dip, and extent of the ore body
- Number of working levels to be considered
- Location of ore and waste handling facilities
- Water collection sump requirements
- Safety and stability of the shaft pillar
- Future planned expansion of the shaft

The bottom of the shaft, where possible, must also be in a stable formation, and it should be able to facilitate any future deepening. The location of the shaft must also avoid adverse surface features and should satisfy surface layout plus logistics of surface and underground ore and waste handling facilities.

Inclination

The dip of the ore body is the main factor involved in deciding to sink either a vertical or inclined shaft. A secondary factor is the relative ground strength and geologic formations to be encountered by the proposed shaft.

The main advantages associated with vertical shafts are that hoisting speeds are greater, shaft maintenance costs are lower, sinking can be carried out faster, and sinking can be achieved in almost any type of ground.

Inclined shafts (slopes) are generally associated with inclined (dipping) ore bodies, where the length of crosscutting to reach the ore body from a vertical shaft becomes longer with the increase in depth of the shaft. They have the advantage of minimizing development to reach the ore from the shaft and are frequently used in coal mines.

Number of Hoists

The number of hoists (and conveyances) required to meet hoisting demands has a major impact in the design of a shaft. The number of hoists will be determined using the procedures described previously.

Compartment Size

The cross-sectional area of a particular compartment (horizontal area) is dependent on its use. To determine the most appropriate size, it is necessary to list the items to be transported in the compartment, determine their approximate dimensions and weight, indicate their direction of flow, and indicate their approximate quantities. Another important factor to be considered is the size of the shaft-sinking bucket. After having determined the size of compartments for cage, counterweight, and skips, the remaining area is then divided to accommodate ventilation, manway, and pipe facilities.

Size of Skip Compartment

The skip capacity is determined by such variables as the hoisting capacity, material density, lump size, and vertical height available in the headframe. Generally speaking, the skip dimensions and cross-sectional area are determined by the skip supplier. The amount of clearance between the skips and shaft equipment is typically 300 mm (12 in.) for rope-guided skips and 75 mm (3 in.) for skips on fixed guides.

Size of Cage Compartment

Cages are generally used to transport personnel and materials. The following clause of CFR Title 30 (Section 57.19-66 Mandatory) applies in the United States: "In shafts inclined over 45°…each person shall be provided a minimum of 0.14 m^2 (1.5 ft^2) of floor space."

The cage capacity is determined by the cage supplier based on a knowledge of the following factors: the amounts of material to be transported, the dimensions and weights of the major pieces of equipment to be lowered and raised, the number of personnel to be lowered and raised per shift, and the type of conveyance preferred (i.e., single deck, double deck, combination skip/cage, etc.)

After establishing the cross-sectional area for the cage, the cage compartment is sized the same way as the skip compartment to provide similar clearances.

Size of Manway Compartment

From CFR Title 30 (Section 57.11-37 Mandatory): "Ladder ways constructed after November 15, 1979, shall have a minimum unobstructed cross-sectional opening of 610 × 610 mm (24 × 24 in.) measured from the face of the ladder."

From CFR Title 30 (Section 57.11-41 Mandatory): "Fixed ladders with an inclination of more than 70° from the horizontal shall be offset with substantial landings at least every 9.1 m (30 ft) or have landing gates at least every 9.1 m (30 ft)."

In addition to these mandates, it is necessary to provide adequate clearance at the landing platform to allow a person to move from one ladder to the next offset ladder. Generally, an additional floor area of 914 × 610 mm (36 × 24 in.) is provided.

Size of Counterweight Compartment

The counterweight compartment can be of any size or shape as long as it provides sufficient space and clearance for the safe passage of the counterweight with the same clearances as for skips and cages.

Size of Service Compartment

There are no hard and fast design rules for sizing the service compartment except that the cross-sectional area of the compartment should be adequate to provide the following: separate locations for communications (signaling) and power lines; space for locating air, water, pump, and backfill lines; clearance for pipe fittings; and space for pipe column brackets. The compartment must also be accessible from a shaft conveyance, preferably a cage, to allow maintenance of the services in the compartment.

Compartment Arrangement

The arrangement of the compartments in relationship to one another depends on the surface layout, the underground layout, and the type and size of hoist to be used. Because these design details are not known precisely during the initial design stages, one must first make a "best estimate" and be prepared to change the arrangement as the final design evolves.

On surface, the orientation of the compartments in relation to the hoist and headframe is of major importance. Good rope practice for drum hoists requires that the location of the hoist in relation to the shaft and headframe be in line to provide acceptable rope fleet angles.

For friction hoists, the center-to-center distance on the compartments is a major consideration for determining the size

of the drum, the necessity for deflection sheaves, and the type of rope construction for the tail ropes.

Exterior Shape

The exterior shape of a shaft is established by considering ground-stability factors. A circular shape provides better resistance to deformation by lateral pressure. In fair to competent formations, an opening excavated in this form is generally self-supporting. In weak formations, the circular shape is adaptable to a variety of lining materials: concrete, steel segments, or cast-in-place concrete. Competent formations can be excavated to a rectangular shape and be generally self-supporting. An elliptical shape offers better support than a rectangular shape but not as good as a circular one. The geotechnical considerations leading to the selection of an exterior shape are beyond the scope of this discussion, but their importance in the overall design process cannot be overstated (see Chapter 12.4). Also shafts may have different exterior shapes at different depths, reflecting the different strata encountered.

Interior Members

Guides and buntons are the main vertical and horizontal structural elements in a mine shaft conveyance system. The primary function of these members is to facilitate running of the shaft's conveyances. Their characteristics influence not only speed of operation and amount of maintenance required, but also production and ventilation costs. Therefore, the choice of sets and guides is of great importance to achieving operational cost savings. To minimize construction costs and the time to install guides, bunton spacing is maximized. The current trend is to install buntons at 5-m (16.4-ft) spacing. This results in flexible guides and requires more sophisticated designs and simulation of the conveyance motion to avoid so-called conveyance slamming events, which can lead to destruction of the guides and conveyances.

Shaft Guides

Shaft guides are used in vertical shafts to keep the skips, cages, and counterweights in proper shaft position. The two types of guides in use are fixed guides (wood, rail, and structural steel), and rope guides.

Wooden guides. Wooden guides are supported by the horizontal sets installed in the shaft. They are favored where conveyances require safety devices. This is because the decelerating characteristics of safety dogs on wood are more reliable than on steel or rail. When hoisting on wooden guides, a speed of 11 m/s (36 fps) with a medium-sized skip is the practical upper limit. To achieve speed of this order with large conveyances and longer guides, it is necessary to install wooden guides supported by structural steel backers. These backers, typically wide-flange structural steel, are bolted between the steel buntons, and the wooden guides are then bolted to them. This arrangement avoids the problems associated with fastening wood guides directly to wood or steel buntons. Wooden guides are subject to changes in dimensions due to changes in moisture content. They are also subject to wear to a greater extent than steel guides. Wooden guides generally are not used in shafts where fire hazards exist, such as in coal mines.

Until recently, the wood used for these guides was either British Columbian fir or Australian Karri wood. Both of these products are now in scarce supply. Wooden guides are now available in composite wood materials, akin to plywood. The only disadvantage of the composite guide is its tendency to swell when wet; therefore, it is not suitable for wet shafts.

Rail guides. Rail guides are common in inclined shafts. These guides vary in size, with the larger rails giving a wider bearing surface for the wheel. The steel rail provides a harder surface but presents a smaller wear area; this creates more wear and maintenance on conveyance guide shoes and wheels. They have also been used to guide conveyances (usually in shafts equipped with Koepe hoists) in vertical shafts but suffer from their higher lateral flexibility, which leads to excessive motion of the conveyance as it moves in the shaft.

Steel guides. Structural steel tube sections have virtually replaced wood as the material of choice for guides in production shafts, where higher speeds and heavy loads require a fairly rigid and stable section. With steel guides, the conveyances are usually equipped with adequately sized guide roller assemblies to minimize wear between the guides and shoes on the conveyance. When hoisting on steel guides, a speed of 18 m/s (3,500 fpm) is a practical upper limit.

Rope guides. Rope guides are also used for guiding conveyances in vertical shafts. These are generally used with multirope hoisting systems where the effect of hoist-rope torque is minimal or nonexistent. Half-locked coil ropes are used for this service. Rope guides do not require any intermediate support, thereby eliminating the steel sets required for fixed guides. Because rope guides are not able to withstand the horizontal forces of loading and unloading, the conveyance must be supported by other means in these areas. Fixed guides are used at the extremes of travel, and a retractable guiding system can be considered at intermediate levels. There are several schemes by which rope guides are suspended and tensioned, and the selection of any one of these will depend on the particular installation. These methods will be reviewed in a later section.

Because rope guides eliminate the need for horizontal buntons, the ability of the shaft to handle airflow is enhanced. In a large shaft, with multiple conveyances traveling at the same time, the aerodynamic effects can cause unexpected rope deflections. These effects should be studied during the design stage. Because rope guides are the smoothest of all guides, hoisting speeds up to 20 m/s (3,900 fpm) are feasible. Discussion of the detail design of rope-guided systems is provided in a following section.

Shaft Buntons

Shaft buntons are horizontal members used to divide the shaft into compartments. They also support and carry the shaft guides, pipes, and cables. Buntons can be of any cross-sectional shape and can be installed in a shaft at any spacing. However, the correct design and layout of buntons and their installation at a suitable spacing minimizes the air resistance of shafts and, hence, reduces ventilation operating costs. Steel buntons are available with aerodynamic cross sections that minimize the resistance to airflow.

Guide and Bunton Structural Design

The design of guides and buntons has progressed to the point where their design is no longer empirical. The design requires the use of computer-based simulation of the motion of a

conveyance as it moves up the shaft. This allows the designer to optimize the design and reduce the amount of steel that is required for this equipment.

In addition to using simulation software, the designer can also use guidelines detailed in SABS 0208-4 (2001) to provide a check on a proposed design before submitting it to the rigor (and expense) of a computer simulation.

Guide Alignment

One of the required inputs to either the guideline or computer simulation is the degree of alignment expected for the installation. This means how far off of plumb, or straight line, one expects, or allows, the guides to be.

A practical limitation for this has been found to be ±3 mm (±0.125 in.) over 5 m (16 ft). To verify that this has been achieved, it is necessary to either install two plumb lines for each guide the entire length of the shaft or to utilize sophisticated instrumentation developed in South Africa for this purpose. This latter option is a more reliable method, as it does not rely on measurement and recording by individuals with its inherent inaccuracy.

Guide Rope Design

Guide ropes are common in high-speed shafts operating large conveyances from a single horizon. This situation is common in North America in coal, potash, trona, and salt mines.

It is first of all necessary to calculate what resistance to lateral motion the guide ropes provide. The lateral restoring force produced by a guide rope is termed its *stiffness*. This term refers to the force produced by moving the guide rope laterally in the shaft as opposed to bending the rope in an arc.

Calculation of this stiffness in kilograms is depicted in Figure 12.9-24. As this figure shows, the restoring force at any point along the guide rope is simply a function of the tension in the guide rope at that point and the distance the force is from the end of the rope.

The more difficult problem comes in calculating what forces arise as the conveyance moves up or down the shaft. These forces can be put into one of the following categories:

- The Coriolis force, which is the result of the conveyance moving radially through the earth
- Impulsive forces from the buffeting produced as conveyances pass at mid-shaft or cross a ventilation opening
- Steady aerodynamic forces caused by the shape of the conveyance
- A twisting moment arising from the head- and tail ropes

Coriolis force. When a body descends in a shaft, it moves toward the east wall; when it ascends, it moves toward the west wall. This motion is a result of the different circumferential velocities that exist between points along any radius of a rotating sphere. The *apparent* lateral acceleration of the object, as it moves at a constant speed in the radial direction, results in a force on any structure, such as a guide rope, trying to restrain it. This force is called the Coriolis force and is proportional to twice the product of the object's radial and angular velocities. The force is required to increase or decrease the object's lateral velocity to match that of the guide rope, and all other matter at the same radial location. The magnitude of the Coriolis force is given by

$$F = 2\,\Omega\,V$$

where

Ω = rotational speed of the object about the earth's axis
V = radial speed of the object in the shaft

Aerodynamic and buffeting forces. Conveyances will experience short-term impulsive forces called buffeting forces when they pass one another as well as steady aerodynamic forces as they travel the entire length of the shaft. The buffeting forces have been found to be inconsequential and do not need to be considered when designing a shaft. The aerodynamic forces that arise as conveyances move through a shaft are, however, very significant and need to be determined. They arise because the flow of the air around the conveyance is asymmetrical and will cause lift to occur. The lift generally acts toward the closest walls because the air velocity is higher in the reduced space between the conveyance and shaft wall. It is difficult to determine the lift coefficient. Some recent research has provided a means for calculating this coefficient and has thereby enabled the designer to determine reasonable estimates for the level of force that a conveyance might encounter. More accurate determination of the lift coefficient requires the use of computational flow dynamics to model the flow around the conveyance in the shaft or scale-model wind-tunnel testing of the shaft.

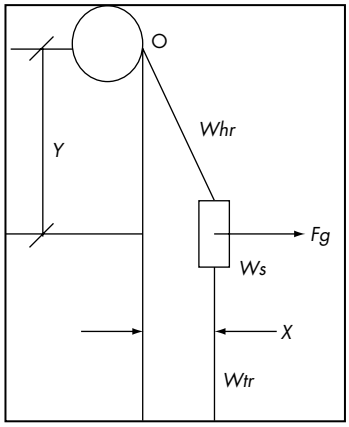
The force on the conveyance is calculated from

$$F = \tfrac{1}{2}\, C_L \rho V_r^2 A_c$$

where

C_L = lift coefficient
ρ = air density
V_r = relative velocity of the conveyance and ventilating air
A_c = the area of the skip facing the section of shaft wall

Forces are typically in the range of 100 to 500 N (20 to 100 lb).



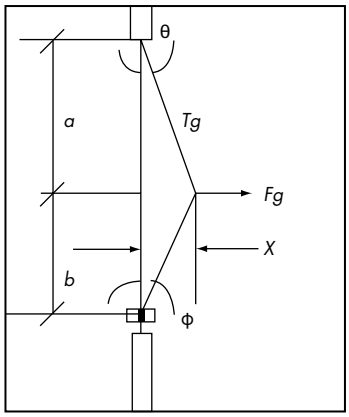
Rope Torque

Both headropes and tail ropes induce torque and, therefore, twisting of the conveyance because of the natural tendency of a rope to untwist when under tension. The data provided above shows that headropes are available with very low torque constants. The ropes used for balance, or tail ropes, are typically designed to minimize the torque that arises as load is applied to them. This minimum is still significant and is the reason why the ropes are attached to the bottom of the conveyance using swivels. This arrangement reduces the torque to a function of the friction in the swivels. The swivels are basically a rolling contact bearing that has a static friction, or stiction, of about 1.5 to 2 times the rolling friction. Based on the data provided by the manufacturer of the swivels, each tail rope will typically produce a torque of the order of 50 N·m (40 lb-ft). This will be developed when about 250 m (800 ft) of tail rope is suspended below the skip.

Guide Rope Location

Figure 12.9-25 illustrates the two most common arrangements of guide ropes. Option A has all four guide ropes along one side of the conveyance, while Option B has one rope at each of the four corners of the conveyance.

Although both options offer the same resistance to lateral motion, Option B provides significantly better resistance to



Skip and Ropes

Moments about O:
$Fg \times Y = (Whr/2 + Ws + Wtr) \times X$

Spring rate of Skip and Ropes:
$Ksr = Fg/X = (Whr + Ws + Wtr)/Y$

where
- Fg = Force in Horizontal Direction
- Whr = Weight of Headrope
- Ws = Weight of Skip
- Wtr = Weight of Tail Rope
- X = Displacement of Skip
- Y = Location in Shaft
- Ksr = Spring Rate due to Skip and Rope Masses

Guide Ropes and Tensioning Weights

- Gw = Guide Rope Weight/Unit Length
- Tw = Tensioning Weight Mass
- Tg = Guide Rope Tension at Skip
- Fg = Applied Force on Guide Rope
- θ = Guide Rope Angle at Top
- ϕ = Guide Rope Angle at Bottom
- a = Location of Skip from Top
- b = Location of Skip from Bottom
- Kg = Spring Rate due to Guide Ropes
- $Tg = Tw + b \times Gw$

  and
- $Fg = Tg \times (Sin(\theta) + Sin(\phi))$
  $= Tg \times (X/a + X/b)$
  $= Tg \times (X(a + b)/a \times b$

  hence,
- $Kg = Fg /X = Tg \times (a + b)/a \times b$

Figure 12.9-24 Guide rope stiffness calculation

twist. In fact, Option A will cause twist for any force that acts in a direction parallel to the plane of the guide ropes.

Guide Rope Tensioning

To keep conveyance motion to a minimum, guide ropes should be tensioned to the maximum amount permitted by local regulations. This typically permits operation with a minimum safety factor of 5.

Tensioning of ropes is possible by the following two means: hanging heavy weights (called cheese weights) from the bottom of ropes, and anchoring the bottom of the rope to a beam in the shaft and tensioning the rope in the headframe using either large springs or hydraulic cylinders. The use of hydraulic cylinders simplifies rope changing and reduces the need for shaft excavation. The most reliable method is still the use of tensioning weights, because this approach automatically compensates for rope stretch and temperature fluctuations.

If cheese weights are used, it is necessary to clean out the shaft bottom on a regular basis, or the weights will become buried in spill and drop their tensioning force.

Shaft Lining

Shaft lining may be comprised of shotcrete, cast-in-place concrete, or steel and cast-iron tubbing. When a lining is required, the selection depends on a number of design considerations that relate to the strata being excavated. For further discussion, see Chapter 12.4.

Shotcrete

Sprayed concrete, 150 mm (6 in.) or more in thickness, may be used to control immediate raveling and weathering of the shaft walls. To date, shotcrete has not been used extensively to provide long-term support nor has it been used as the only means of lining in shafts.

Concrete

The use of concrete for permanent support is common in most new shafts. Shafts may be fully lined or partially lined with "concrete rings" with areas of open ground between the rings. Common spacing used for ringed shafts is 1.2-m- (4-ft-) high concrete rings with a 1.2-m (4-ft) open area between, resulting in a 2.4-m (8-ft) set interval. Concrete is generally placed with a minimum thickness of 300 mm (12 in.), but this will increase with depth for linings designed to withstand the hydraulic head encountered in formations that include aquifers.

Steel or Cast-Iron Tubbing

Although the use of concrete as a lining material is becoming more common, there are certain geologic conditions where steel or cast-iron tubbing is a more appropriate

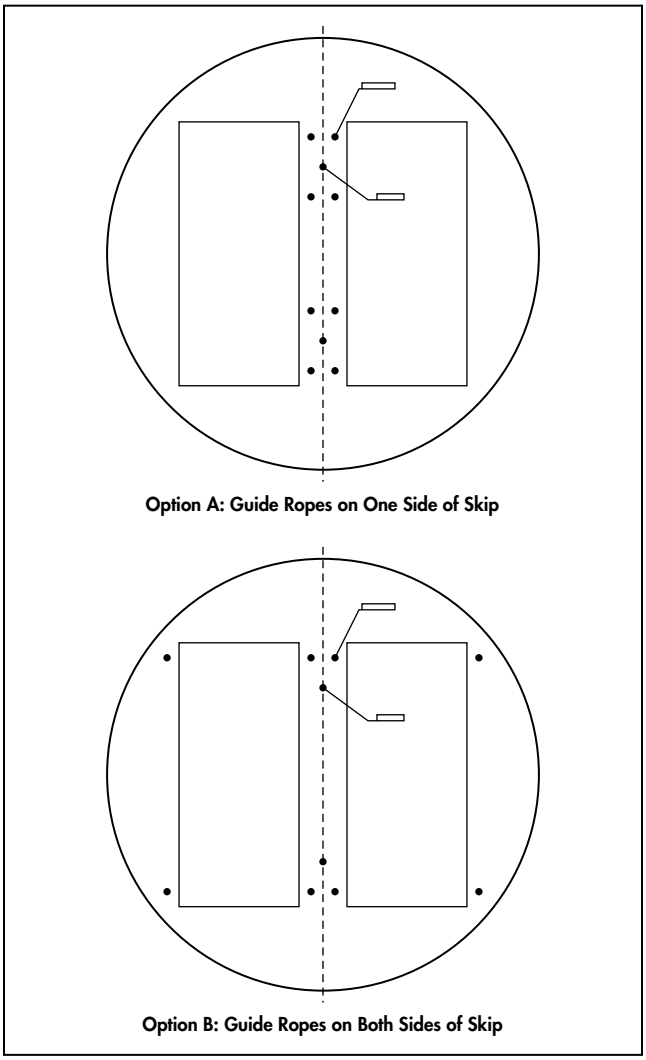


Figure 12.9-25 Guide rope locations for Options A and B

material. Concrete is suitable when water pressures are less than 1,700 kPa (250 psi) and when the stress field is uniform and compressive in nature. Steel is more suitable for a completely watertight lining and is capable of withstanding tensile stresses. These stresses could arise if the shaft is subjected to bending loads caused by subsidence or buckling loads caused by a nonuniform horizontal stress field.

Steel lining can be butt-welded to make it permanently watertight, and this has a higher buckling safety factor than tubbing. Steel is particularly useful as a lining for shafts sunk by drilling methods. Cast-iron tubbing consists of several segments bolted to form a ring and requires a lead gasket to be placed between segments. This type of tubbing is much stronger than the steel liner and is typically used to provide support when crossing aquifers are encountered at considerable depth and, hence, high pressure.

Design Considerations for Shaft Lining

The design requirements for lining a structure are governed by the required duty of the shaft and environmental conditions in which it is constructed. Careful consideration of the following points should be made in the design of structural lining: the precise behavior of the rock mass in situ, the self-supporting action of the rock itself, the effect of separation of the lining due to certain vertical and horizontal movements of the surrounding rock formation, the construction of watertight linings, and the economics of the lining structure.

The design of steel or cast-iron linings is a much more complex process, because the buckling characteristics of an elastically embedded hollow cylinder with external pressure must be evaluated.

Ventilation Characteristics

The shaft is generally the largest single contributor to total mine air resistance when it is equipped with rigid guides for hoisting purposes. The resistance consists of the following two components: frictional resistance caused by viscous drag in the thin air layer at the shaft walls and the periphery of the vertical elements (guides, pipes, cables, ropes, etc.) of the shaft; and shock resistance due to the transverse sets (buntons and dividers) completely immersed in the air stream, thereby obstructing the flow and recurring at intervals throughout the shaft.

These transverse elements create turbulence in the airstream with a corresponding loss of flow energy. The turbulent waves below buntons and conveyances often contribute much more to the total shaft resistance than the skin friction of the shaft walls. The forces caused by the buntons are parallel to the airstream and are proportional to velocity pressure, frontal area, surface texture, and shape. Because the frontal area of all the buntons in a shaft is likely to be more than the frontal area of the cages and skips, the aerodynamic design of the bunton is of importance in the design of a mine shaft.

A reduction in shaft resistance can be achieved through improving the aerodynamic effect of horizontal obstructions such as buntons, minimizing the frontal area of the set members, and increasing the spacing between the horizontal obstructions. Practical experience has indicated that there is little ventilation advantage to be gained from spacing greater than 5 m (16 ft).

A general treatment of mine ventilation is offered in Chapter 15.3.

HEADFRAME

The basic purpose of a headframe installed over a shaft is to support the sheave wheel over which a hoisting rope passes for raising or lowering conveyances or, in the case of a tower-mounted Koepe hoist, to support the hoist and all of its suspended loads. The construction of a headframe is also necessary to allow dumping of hoisted materials aboveground. Structurally, there are two types of headframes: steel headframes, which are typical for drum hoists, and slipformed concrete headframe structures, which are typical for tower-mounted Koepe hoists. These designs are shown in Figures 12.9-26 and 12.9-27, respectively.

Construction Materials

Headframes may be constructed of timber, steel, or concrete. Modern trends in high-capacity hoisting have necessitated the construction of very large headframes, which effectively preclude the use of timber as a construction material.

Steel Versus Concrete

Both concrete and steel can produce economically viable, structurally compatible, and visually appealing headframes

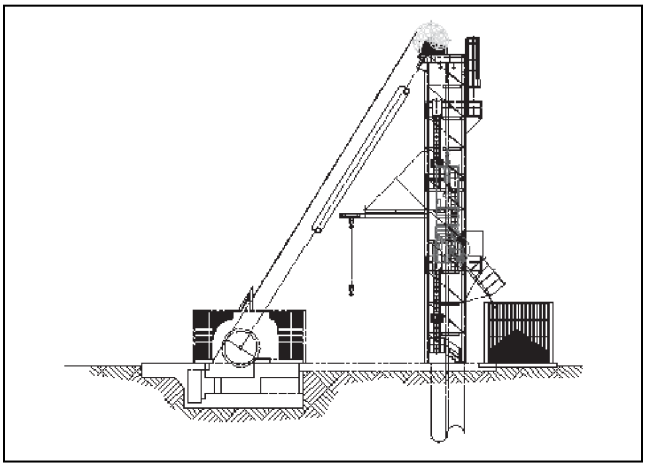

Figure 12.9-26 Steel headframe

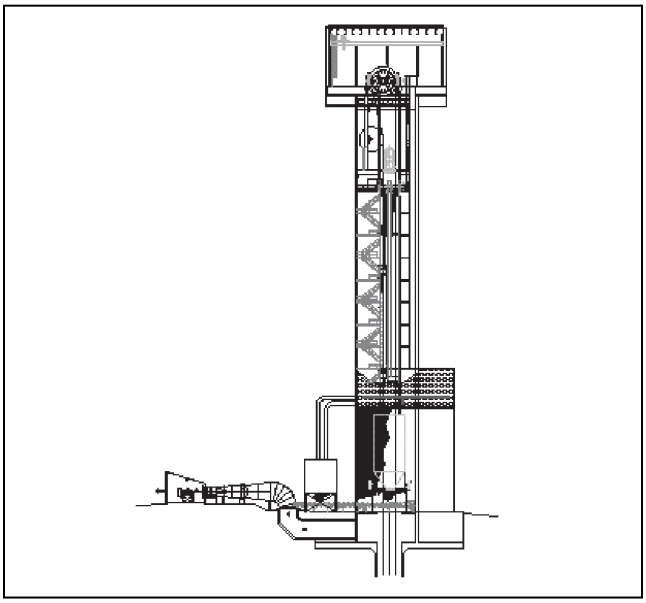

Figure 12.9-27 Concrete headframe

for any new development. The advantages of concrete structures include the following:

- Effective use can be made of space within the structure for tower-mounted friction hoists.
- When used in conjunction with ground-mounted drum hoists, the hoist may be located at any position around the headframe.
- Maintenance costs are low.
- A high damping effect of the massive concrete structure occurs on shock and vibration.
- The collar layout and the interconnection with service buildings is simple.
- Future expansion is possible.
- The structure is durable and resistant to corrosion.

The disadvantages of concrete structures include the following:

- Erecting in remote areas is difficult.
- Supporting the structures in poor ground is difficult.
- Concrete offers no salvage value.

For steel structures, advantages include the following:

- Foundation loads are lighter.
- They are adaptable to minor changes.
- They offer no salvage value.
- Capital-cost saving in remote areas is possible.
- The structure can be prefabricated into transportable lengths for on site assembly.
- Construction is speedy.

The main disadvantage of steel is that it is prone to corrosion and, thus, is not suitable as a production headframe for corrosive ore (e.g., salt and sulfides) unless the steel is treated and regularly maintained.

Design Considerations

A successful headframe design must be based on an overall integrated hoisting system design, which involves a critical examination of the impact of at least the following items: loads, foundation, mine services, sinking provisions, equipment monitoring facilities, conveyance and rope handling, heating and ventilation, and others such as local mining regulations.

Loads

All headframes should be designed to withstand a combination of loads, comprised of the following:

- Dead load consisting of the weight of the headframe, sheave wheels, ore bins, and contents
- Live load from hoisting at maximum capacity
- Breaking loads of the ropes when the conveyance is stopped by the crash beams or if it is jammed in the shaft (breaking stresses introduced by an overwind are usually transferred to the structural system, often through an arrestor gear, and thus the supporting structure must be critically analyzed with a thorough understanding of the arrestor mechanism)
- Wind load, the intensity of which depends on the location, height, and shape of the structure
- Snow load
- Temperature and seismic stresses, taken from published data relating to the geographic area of the shaft location

Foundation

The foundation should be capable of withstanding and absorbing stresses imposed by the structure and associated loads. Foundation design in areas where the ground must be frozen by artificial means before the shaft is sunk require much more consideration than normal because the ground will heave when the freeze is removed, which can lead to tilting of the headframe.

Mine Services

The design of the headframe must suit surface layouts for providing the essential mine services. When possible, it should be located close to the shaft collar house, waiting area, lamproom, first-aid room, hoist house, maintenance shop, changing house, and administrative offices. The type and design of the headframe must also take into account the shaft's internal arrangement, position of the hoist with respect to the shaft, and the position of the sheave steel.

Facilities for the following key concerns must be considered and adequately developed during the conceptual design stage:

- Arrangement of skip dumping area in relation to ore and waste storage and handling facilities
- Clearance required for installation, maintenance, and removal of conveyances
- Lifting equipment required for maintenance of conveyances
- Access required for maintenance of conveyances, dump areas, and so forth

In the case of headframes for drum hoists, provision must be made for

- Lifting equipment and access for maintenance of sheaves;
- Access and anchorage facility to support the ends of hoist ropes when doubling down for pretensioning drum end coils, and
- Subcollar loading access for double-deck cages.

The design of headframes for friction hoists should address the following:

- Supporting facility at predetermined elevations for hoist or balance ropes and conveyances or counterweights during installation and changes
- Clearance for installation of conveyance arrestor gear
- Provisions for handling shaft ventilation air and for sealing machinery rooms
- Arrangement of power conversion equipment adjacent to hoist motors to minimize runs of heavy bus bars
- Lifting equipment access during changing of headropes and tail ropes
- Support, accommodation, inspection, removal, and replacement facilities for rope guides where used
- Ventilation to specific machines and areas
- Controlling moisture, dust, and temperature where required
- Accommodation of sinking arrangements
- Accommodation of all services for air, water, communications, and power lines to the shaft and to the headframe-mounted equipment
- The accommodation of stairwells and elevators
- Lighting and lightning protection

Sinking Provisions

After the decision has been made to sink a shaft, considerations should be given to the type of surface sinking plant (such as headframe and hoist) that is to be used for shaft sinking. In particular, it should be determined whether the sinking plant is to be temporary or is to make use of the permanent headframe and/or hoist.

Temporary headframe. Sometimes a temporary headframe is used during shaft sinking by the contractor. These headframes are generally made in modular form from structural steel. Headframes of this type are portable and can be reused many times.

Design criteria for a temporary sinking headframe are the same as for a permanent headframe. Its height depends on the method of rock disposal and size of bucket. The sinking headframe should embody features for dumping buckets or skips, for protecting personnel on the surface and in the shaft from falling pieces of rock while dumping, and for minimizing the work of top personnel in dumping buckets and removing broken rock. The design of temporary headframe structures should accommodate an adequately sized storage bin and should provide sufficient clearance for a rock disposal vehicle.

Permanent headframe. Current trends favor installation of a permanent headframe for the sinking operation, as it tends to be more economical and time saving. The permanent main skeleton can be designed to facilitate erection and installation of the sinking sheaves at a suitable elevation. The structure can then be finished and equipped during the shaft sinking operation. The use of the permanent structure as a sinking headframe can make the permanent hoisting facilities available at an earlier date following completion of the shaft-sinking program.

Equipment Monitoring Facilities

Two main hoisting incidents, which can be detrimental to personnel and equipment and require monitoring, are overtravel at the shaft extremities (i.e., sump, headframe) and overspeed during the duty cycle. To protect against these incidents, it is mandatory that monitoring and safety devices be installed in the headframe.

Operation of all hoists is monitored by digital equipment designed for this purpose and often termed *safety controllers*. These are driven by the hoist drums and they check hoisting speed, overtravel at each end of the wind, and deceleration in the end zones. In addition to these dynamic checks, track limit switches must be incorporated to protect against a safety monitor losing its synchronism with the hoist. The function of track limit switches is to provide independent overtravel protection in the headframe.

Ultimate protection against overwind is provided for all Koepe hoists by conveyance arrestors. These are installed at the ends of travel in each hoisting compartment. The headframe arrestors are designed to retard an ascending conveyance from the speed of a person riding at a rate of 0.9 *g*'s. Arrestors are also installed at the shaft bottom and are designed to retard a full descending conveyance at a rate of at 1 *g* or higher. It is not practical to install arrestors in the headframe to stop a hoist from full speed. For example, a hoist traveling at 18 m/s (3,600 fpm) would require a stopping distance of 18.5 m (60 ft) when decelerating at 0.9 *g*'s. This amount of overtravel provision would be very expensive to provide and would still not guarantee absolute protection because a runaway hoist can easily reach speeds in excess of 50 m/s (10,000 fpm).

Where applicable, the headframe should accommodate installations of a crash beam and catch gear. With drum winders, the crash beam is located below the sheaves in the headframe. In the event of an excessive overwind, it stops the conveyance from traveling beyond this point and is designed to withstand the breaking strength of the headrope. Should a conveyance on a Koepe hoist be involved in an overwind situation in which the hoist ropes break, the conveyance and tail ropes will fall down the shaft, causing damage. To prevent this, fallback protection should be provided in the headframe to "catch" the conveyance.

Conveyance and Rope Handling

In the design and layout of a headframe, provisions must be made for the handling and changing of conveyances, hoisting ropes, and rope guides (if applicable). Friction hoisting often requires the use of very large skips and cages. Because of their size, the service and handling of these conveyances, and the tying off of the headropes and tail ropes associated with them, considerable problems can arise. In the friction hoist headframe, these can be facilitated through the installation of an adequately sized overhead traveling crane. More

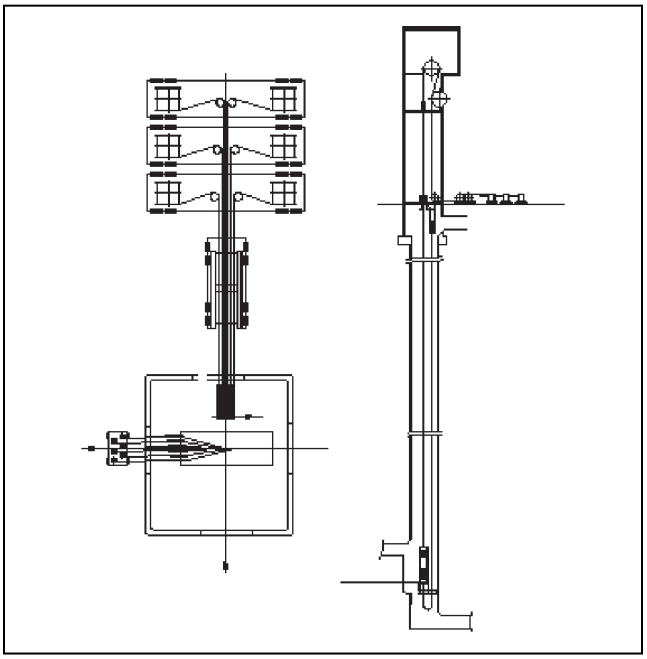

Figure 12.9-28 Multirope changing reeving diagram

recently, special equipment has been designed to permit the removal or installation of all of the headropes at the same time. The process requires a special winch that is designed to pull all of the headropes at once and transfer them on or off of numerous rope-holding winches. A reeving diagram for this arrangement is shown in Figure 12.9-28. In the drum hoist headframe, handling and changing of conveyances and ropes are relatively easy and are usually achieved through the use of mobile cranes, rope blocks, and tugger hoists.

Heating and Ventilation

In warm climates, the headframe may be left open. In colder climates, however, it is necessary to design the headframe as an enclosed structure with adequate provisions for a heating system. In tower-mounted friction hoist systems, with all of the hoists, motors, controls, and so forth enclosed in the headframe, it is necessary to provide a ventilation system to supply filtered air for both cooling and heating.

Some headframes located over downcast shafts are pressurized and must be equipped with air locks to isolate the movement of personnel and equipment into and out of the collar house.

Mining Regulations

Mining operations, including the design and construction of the headframe and shaft facilities, are subject to local, state, and federal regulations that relate to, among other things, safety of permanent structures and environmental protection. These regulations affect the design and construction of mine facilities.

Height

Because of increasing public awareness of the aesthetic impact of industrial development, the height of the headframe should be considered. This is especially true for locations in flat terrain where any large structure can be seen for long distances. The height of a headframe is generally based on the storage bin capacity requirements for ore and waste, the clearance required for the loading facility under the storage bin, the requirement that the resultant force from headframe loadings falls within the backleg post, and the need for providing minimum clearance for conveyance overtravel beyond its normal travel to the head sheaves. Of the above, the determination of the minimum clearance for overrun distance is the principal design consideration. The determination of the minimum clearances required in headframes is described in the following paragraphs.

Operating Allowance

An operating allowance is required to allow for variations in repeatability of the final stop position of the conveyance in the headframe. In multilevel hoisting with drum hoists, this tolerance compensates for permanent rope stretch, differences in drum and rope diameter, and clutching accuracy. In the case of Koepe hoists, the allowance compensates for creep during resynchronization and also allows a reasonable gap for rope adjustment due to permanent rope stretch.

Rope Stretch Allowance

This is included to avoid contact with the track limit switch or encroaching on the safety controller's overwind protection limit when empty conveyances are hoisted.

Stopping Allowance

A stopping allowance is needed to ensure that clearance remains between the top of the conveyance and the first obstruction in the headframe should the conveyance exceed its normal operating limits and require the use of emergency braking to stop.

Rope Tension Equalization

The ropes on a Koepe hoist operate at slightly different diameters because of uneven wear of the rope treads. To minimize the effects of this variation, it is recommended that the ratio of the maximum to minimum suspended rope length should not be more than 50.

Spacing of Koepe Wheel and Deflection Sheave

When a headrope is bent in an arc, the wires that make it up move relative to one another to accommodate the different lengths at the outer and inner radii of the surface of the rope. When the rope straightens again, the wires do not assume their original positions immediately, primarily because there is friction between them. The headrope passing over the hoist wheel is bent one way, straightens when it leaves the wheel, and then bends the other way when it passes over the deflection sheave. If the time taken to pass from the wheel to the sheave is less that 0.5 seconds, the wires will not have time to realign between these reverse bends and will eventually produce distortion and premature failure of the rope. Allowance for this spacing must be made when laying out the headframe.

Rope Harmonics and Vibrations

Vibrations in hoist ropes can be observed as "yo-yo-ing" at the collar, and, in the case of drum hoists, as the rope whips between the hoist and the head sheave. The causes of these vibrations are jerking operations, such as uneven braking, and the horizontal and vertical movement of the rope at the crossover points on the drum. These vibrations cannot be avoided and normally do not cause problems. However, there have

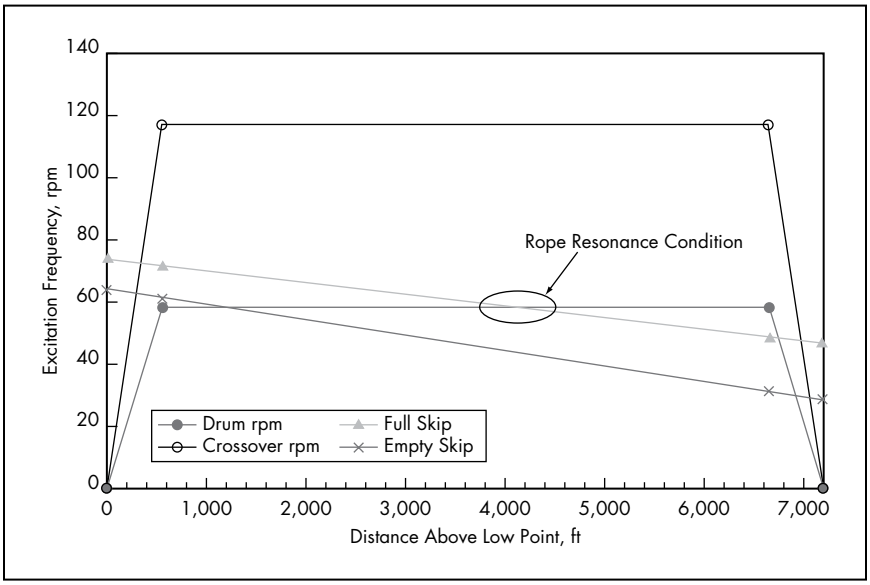

Figure 12.9-29 Rope resonance plot

been cases where the frequency of the crossover motion is a harmonic of the natural frequency of the flight rope (i.e., the length of rope between the drum and head sheave), and severe and dangerous whipping has occurred. Such a situation is most likely with a long, flat span of rope between the hoist and head sheave.

The hoist designer should analyze the harmonic behaviors of the ropes and try to select the type of drum grooving that will avoid harmonic vibrations. This selection requires two calculations. The first calculation determines the natural frequency of the flight rope (which varies with rope tension and therefore decreases linearly as the conveyance ascends the shaft). The second calculation determines the frequency spectrum excited by the crossover spacing. If the excitation spectrum includes harmonics that match the natural frequency of the flight rope, alternative crossover geometries will have to be considered. If suitable alternatives are not found, the hoist speed will have to be altered or idler towers will have to be added between the drum and the head sheave.

A typical plot of excitation frequency and flight rope natural frequency is illustrated in Figure 12.9-29. This plot illustrates that a rope resonance condition would exist if the rope crossover occurred once per revolution but not if it occurred twice per revolution with the crossovers spaced 180° apart.

Calculations for Minimum Clearance

The following details show how the required clearances are to be calculated.

Elastic Rope Stretch for Skip

The headropes stretch when a skip is loaded. This stretch is locked into the rope as it coils on the drum when the loaded skip is raised and is relieved as it uncoils when the empty skip is lowered. The drum will, therefore, make more revolutions when raising a full skip than an empty one. Because the skip distance is measured by revolution of the drum, the hoisting cycle is only accurate for a loaded skip. The headframe will usually be fitted with a "clutching-mark" magnet switch located at a distance above the "skip-at-dump" magnet switch equal to the elastic rope stretch. The stretch (S) can be calculated from

$$S = P*L/(A*E)$$

where

P = payload
L = rope length from the drum to the skip at the loading pocket
A = rope area based on its nominal diameter
E = rope elastic modulus in tension

A good guideline for elastic rope stretch is 300 mm (1 ft) per 300 m (1,000 ft) of shaft depth.

Clutching Accuracy

A clutch includes a ring with a finite number of teeth. The clutching accuracy is, therefore, limited to plus or minus the tooth pitch. The ability for the operator to compensate can be determined from

$$C = \pm\pi*D/(2*N)$$

where

C = clutching accuracy that can be achieved
D = pitch circle diameter of the headrope
N = number of teeth in the clutch ring

Unequal Drum and Rope Diameters

Inequalities in drum or rope diameters between two drums of the same hoist will be amplified by the number of revolutions the hoist makes as it travels up the shaft. This difference is given by

$$\Delta T = \pi*N*(\Delta Dd + 1.7*\Delta Rd)$$

where

ΔT = difference in travel
N = number of revolutions of the hoist
ΔDd = difference in drum diameters
ΔRd = difference in rope diameters

Unequal Rope Lengths

If the ropes on two drums of a hoist are not exactly the same and the drums wind more than one layer of rope, then the drum with the longer rope will operate at a larger average diameter. As a result, this drum will take fewer revolutions to raise a skip than the drum with less rope. This difference is proportional to the number of extra turns times the constant π.

For example, consider the case where the rope and drum diameters are equal but there is one more turn on one drum than the other. Assume also that there are four layers of rope, the PCD of the first layer is d = 4,653 mm, and the PCD of the fourth layer is D = 4,915 mm. One drum has 6 turns on the first layers when the skip is at the loading pocket and 18 turns on the fourth layer when the skip is at the dump, and the other drum has 7 turns on the first layer when the skip is at the dump and 19 turns on the fourth layer when the skip is at the dump.

$$\text{difference in rope lengths} = \pi * d = \pi * 4.653 = 14.6 \text{ m}$$

$$\text{difference in skip travel} = \pi * (D - d) = \pi * (4.915 - 4.653) = 0.8 \text{ m}$$

As these calculations demonstrate, when one rope is damaged and needs to be shortened, the same length must be cut off the other rope.

Stopping Distance

If a conveyance travels beyond the track limit switch (which must be checked at least daily) it will initiate an emergency stop using the brakes to stop and hold the hoist. The allowance to be made for the conveyance overtravel during this event is given by

$$S = 2 * V^2/(2 * D)$$

where

S = stopping distance
V = hoisting speed permitted by the safety controller in the end zone (typically 0.5 m/s or 100 fpm)
D = deceleration rate achieved by the braking system

The factor 2 is included in the equation to account for the dead time of the brakes.

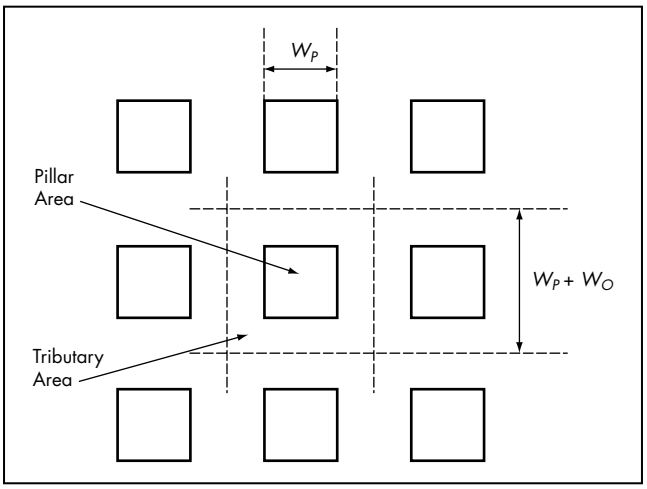
PART 13

Underground Extraction



CHAPTER 13.1

Room-and-Pillar Mining in Hard Rock

Richard L. Bullock

Room-and-pillar (R&P) mining is a mining method whereby a series of rooms (horizontal openings) is extracted, leaving pillars of ore, rock, or coal in place between the rooms. Figure 13.1-1 shows a plan view of an ideal R&P mine. The square blocks are pillars; the spaces between the pillars are rooms. In hard rock, pillars are usually much smaller horizontally than rooms. In soft rock and coal mines, they are usually much larger.

The R&P method has been used widely and often—for example, in lead/zinc/copper ore bodies of mines in southeast Missouri (United States) for 150 years; in mines in Charcas (Mexico) for more than 100 years; in copper mines in Poland for nearly 50 years; and in underground rock quarries and salt mines worldwide for more than 100 years. The proliferation of this method for such a long period of time suggests that it is low cost, versatile, and safe.

Source: Zipf 2001.

Figure 13.1-1 Plan view of a room-and-pillar mine

ORE-BODY CHARACTERISTICS OF R&P MINING

The R&P method is normally employed on fairly flat seams or ore bodies, but may in some cases be used in seams that angle up to 45°. Ideally, the ore body or seam to be mined should be very large laterally and fairly uniform in thickness. However, many R&P mines in hard-rock ores have nonuniform ore horizons. For example, in some of the R&P mines in the Old Lead Belt of Missouri, the ore horizon varies in thickness from 3 to 91 m (10 to 300 ft). In the Viburnum Trend mines of Missouri, ore varies in thickness from 3.5 to 30 m (12 to 100 ft).

The strength of both the back/roof and the ore are important. Obviously, roof strength must be sufficient to stand open for the width of the room when the room is opened. Similarly, ore strength determines the size of the pillar required to support the open span of the back. Thus pillar size is not fixed but rather is determined by the sum of (1) stress in the pillar due to the weight of the overburden above the opening, (2) additional stress in the pillar due to removal of the ore that originally supported the current back, and (3) tectonic stress-related forces that may still remain in the rock. The ore in the pillar must be strong enough to compensate for these collective stresses.

Farmer (1992) and Zipf (2001) described the design of stope pillars and barrier pillars normally used for a new R&P mine in a new mining district. The caveat "new mine in a new district" is important, since, in opening a mine in an already-mined district, decisions regarding pillar size and room size for a given stope depth and ore strength have already been made. Yet it is nevertheless important to understand how to design stope (panel) pillars and barrier pillars for a new mine.

TRADITIONAL STRENGTH-BASED PILLAR DESIGN METHODS

This section is adapted from Zipf (2001). Significant research has been done on pillar design for both R&P and longwall mining. Many ground-control and pillar-design experts have contributed (e.g., Holland 1964; Salamon and Munro 1967; Hardy and Agapito 1977; Mark 1999). Their studies include verification of pillar-design formulas and formula constants by statistical verification with a large database of both failed and nonfailed coal mine incidents from Australia and South Africa (Galvin et al. 1999; Gale and Hebblewhite 2005). However, with the exception of the work of Hardy and Agapito, these studies

Richard L. Bullock, Professor Emeritus, Mining & Nuclear Engineering, Missouri University of Science & Technology, Rolla, Missouri, USA

concern coal, and there has been no similar verification for hard rock or even other softer minerals such as trona, salt, oil shales, or borates. The purpose of the following discussion is to extend this work to the design of pillars for all minerals, not just coal.

R&P mines may cover only a hundred square meters and contain just a few pillars, as is typical for small zinc deposits. Or they may cover many square kilometers, as is typical for coal, trona, and limestone mines. In an R&P mine, large arrays of pillars are typically grouped into panels, which in turn are surrounded by barrier pillars. The small pillars within a panel are sometimes called panel pillars. In developing layouts, the mining engineer must develop appropriate dimensions for room spans, panel pillar widths, panel sizes, and barrier pillar widths. Developing these dimensions requires evaluation of not just pillar strength but also the consequences of pillar failure, which can happen anywhere in the layout at any time.

Traditional strength-based pillar design requires estimates of pillar stress and pillar strength. The safety factor for the pillar is then calculated by dividing pillar strength by pillar stress. What constitutes an acceptable safety factor depends on the tolerable risk of failure. Safety factors of 2 are typical for pillars in main development headings or panels during advance mining. Safety factors of 1.1 to 1.3 are typical for panel pillars after retreat mining. Safety factors much less than 1.0 are possible for panels where pillar failure is the eventual intent.

Pillar Stress

All equations in this section can be dimensioned as preferred by the user, as long as dimensions are consistent with the equation constants.

According to traditional R&P design methods, in-situ vertical stress is (Farmer 1992)

$$\sigma_s = \lambda z \tag{13.1-1}$$

where
λ = unit weight of rock
z = depth of mining horizon

The tributary area method then provides a first-order estimate of the average pillar stress. For the square R&P system shown in Figure 13.1-1, the average pillar stress is

$$\sigma_{pa} = \sigma_z \left(\frac{W_p + W_o}{W_p} \right)^2 \tag{13.1-2}$$

where
W_p = pillar width
W_o = opening width

For rectangular or irregular-shaped pillars, where R is the extraction ratio, the average pillar stress is

$$\sigma_{pa} = \sigma_z \left(\frac{1}{1-R} \right) \tag{13.1-3}$$

$$R = \frac{A_M}{A_T} = \frac{A_T - A_P}{A_T} \tag{13.1-4}$$

where
A_M = area extracted (i.e., total room area)
A_T = total area of the ore body
A_P = pillar area

The tributary area method assumes that the mined area is extensive and all pillars have the same dimensions. It also ignores the deformation properties of the surrounding rock mass relative to the pillar rock. However, pillar stress is generally higher at the center than at the edge of a panel. Coates (1981) partially solved this problem by developing the following relation for average pillar stress that accounts for the width and number of pillars across a panel and the relative mechanical properties of the pillar and rock mass:

$$\sigma_{pa} = \sigma_z \left\{ \frac{\left[2R - K_0 \frac{H}{L} \frac{(1-2\upsilon_{rm})}{(1-\upsilon_{rm})} - \frac{\nu_p}{(1-\upsilon_p)} K_0 \frac{H}{L} \frac{E_{rm}}{E_p} \right]}{\frac{H}{L} \frac{E_{rm}}{E_p} + 2(1-R)\left(1 + \frac{1}{N}\right) + 2\frac{RB}{L} \frac{(1-2\upsilon_{rm})}{(1-\upsilon_p)}} \right\} \tag{13.1-5}$$

where
K_0 = ratio of horizontal to vertical stress
H = mining height
L = lateral extent of the mined area
E, υ = elastic constants
rm = rock mass
p = pillar mass
B = individual opening width
N = number of pillars across the panel

Although this equation is based on two-dimensional elasticity theory and therefore applies only to long, narrow rib pillars, it illustrates the behavior of average pillar stress. As the E_{rm}/E_p ratio increases, average pillar stress decreases due to the bridging effect of the stiff rock mass. Similarly, as panel width L decreases and the H/L ratio increases, the average pillar stress decreases.

As with the tributary area method, the solution offered by Equation 13.1-5 gives only average pillar stress for all panel pillars and does not give changes in pillar stress across the panel. Boundary-element method programs such as ExamineTAB (Zipf 2001), MUL SIM/NL (Zipf 1992a, 1992b), or LAMODEL (Heasley 1997, 1998) are needed to calculate changes in pillar stress across a panel or within a pillar.

Pillar Strength

Over the past several decades, a large amount of rock mechanics literature has addressed pillar strength in both coal and metal/nonmetal mines (Obert and Duvall 1967; Hoek and Brown 1980; Bieniawski 1992; Brady and Brown 1993). Much of this work is empirical and addresses two issues: (1) the size effect, whereby rock strength decreases as specimen size increases; and (2) the shape effect, whereby rock strength decreases as the width-to-height ratio decreases. Using energy considerations, Farmer (1985) developed theoretical expressions relating strength to size. When failure occurs in a brittle manner, as it does in most rocks, strain energy within the specimen transforms to fracture surface energy, which is constant for a particular rock. Based on energy conservation,

$$SED * V = FE * A \tag{13.1-6}$$

where
SED = strain-energy density
V = volume
FE = fracture-surface energy, which is a material constant
A = fracture surface area

Table 13.1-1 Values for constants in empirical pillar-strength formulas

Source: Zipf 2001.
*a and b are dimensionless.
†Use with English units only.
‡Use with metric units only.

Rearranging gives

$$SED * \frac{V}{A} = SED * L = FE = \text{constant} \tag{13.1-7}$$

where L is the characteristic dimension or length of the rock specimen.

Assuming that laboratory-scale failure is mechanistically similar to full-scale pillar failure, then

$$SED_S * L_S = SED_P * L_P \tag{13.1-8}$$

where

S = subscript denoting laboratory-scale specimen
P = subscript denoting full-scale pillar

Since strain-energy density at failure is proportional to the square of stress at failure,

$$\sigma_S^2 * L_S = \sigma_P^2 * L_P \tag{13.1-9}$$

or

$$\frac{\sigma_P}{\sigma_S} = \left(\frac{L_S}{L_P}\right)^{1/2} = \left(\frac{V_S}{V_P}\right)^{1/6} = \left(\frac{V_S}{V_P}\right)^{0.1\,7} \tag{13.1-10}$$

where

σ_P = strength of the full-scale pillar
σ_S = strength of the laboratory specimen
V = volume, which is proportional to L^3

This theoretical relationship accounts for the size effect in observed rock strengths. The following empirical strength formula, proposed by Hardy and Agapito (1977) for oil shale pillars, follows this general theoretical form and provides some experimental confirmation. It also includes an additional term for pillar shape.

$$\frac{\sigma_P}{\sigma_S} = \left(\frac{V_S}{V_P}\right)^{0.118}\left[\frac{W_P}{H_P}\frac{H_S}{W_S}\right]^{0.833} \tag{13.1-11}$$

where

W_P = width of pillar
H_P = height of pillar
H_S = height of specimen
W_S = width of specimen

Classic empirical pillar-strength formulas usually follow one of two general forms:

$$\sigma_P = \sigma_{S'}\left(a + b\frac{W}{H}\right) \tag{13.1-12}$$

$$\sigma_P = K\frac{W^{\alpha}}{H^{\beta}} \tag{13.1-13}$$

where

σ_S = strength of a cubical pillar ($W/H = 1$) at or above the critical size
K = constant characteristic of the pillar rock
a, b, α, β = constants that account for the shape factor

Formulas by Obert and Duvall (1967) and Bieniawski (1968) follow the first form; formulas by Salamon and Munro (1967) and Holland (1964) follow the second. In these forms, the size effect is accounted for directly by the unit pillar strength σ_S or the rock constant K. The constants a, b, α, and β, which account for the shape factor, show reasonable agreement, as shown Table 13.1-1.

Several methods exist for estimating σ_S and K in Equations 13.1-12 and 13.1-13, respectively. One is to consider the strength of a cubical pillar ($W/H = 1$) at or above the critical size, where critical size is the size beyond which rock mass strength remains relatively constant. For coal pillars, the critical size is widely recognized to be about 0.9 m (36 in.). For coal mines in the United States, the recommended strength value for a cube of coal this size is σ_S = 6.2 MPa (900 psi) (Mark and Chase 1997). This unit strength for a full-scale cube of coal can then be adjusted for shape effects using the Mark–Bieniawski relation (Mark 1999):

$$\sigma_P = \sigma_{S'}\left(0.64 + 0.54\frac{W}{H} - 0.18\frac{W^2}{HL}\right) \tag{13.1-14}$$

which reduces to the original Bieniawski relation when pillar width W equals pillar length L.

If laboratory-scale strength data (σ_S) is available, the full-scale strength of a cube of rock mass (σ_S), from Equation 13.1-10, is

$$\sigma_{S'} = \sigma_S\left(\frac{V_S}{V_{S'}}\right)^{0.17} \tag{13.1-15}$$

This unit strength for a full-scale cube of the rock mass can then be adjusted for the shape effect using the Obert–Duvall relation:

$$\sigma_P = \sigma_{S'}\left(0.78 + 0.22\frac{W}{H}\right) \quad (13.1\text{-}16)$$

Finally, the Hoek–Brown failure criterion can also provide an estimate of the strength for a full-scale cube of the rock mass. For most rock masses with good to reasonable quality,

$$\sigma_1' = \sigma_3' + \sigma_c\left(m_b\frac{\sigma_3'}{\sigma_c} + s\right)^a \quad (13.1\text{-}17)$$

where

m_b, s, a = constants that depend on the rock mass quality
σ = uniaxial compressive strength of the intact rock pieces (equivalent to σ_S)
σ_1' = axial principal stress
s_3' = confining principal stress

The constants m_b and s are estimated using a rock-mass classification index called GSI, or Geological Strength Index, which is equivalent to Bieniawski's rock mass rating (RMR) system, assuming a dry rock mass. For a complete discussion of the Hoek–Brown failure criterion for rock masses, see Hoek et al. (1995).

Barrier Pillar Design

The previous formulas for pillar stress and pillar strength apply mainly to pillars within a large array, or so-called panel pillars. The barrier pillars surrounding this array of panel pillars also require sizing. The tributary area method can provide a conservative estimate of barrier pillar stress, if we assume that the panel pillars have all failed or are all mined and therefore carry no overburden stress. Alternatively, numerical methods such as MULSIM/NL or LAMODEL can estimate barrier pillar loads without need for conservative assumptions inherent to the tributary area method.

The empirical pillar strength formulas shown earlier apply to pillars with width-to-height ratio $W/H < 5$. For barrier pillars and other pillars in coal mines with $W/H > 5$, Salamon's "squat" pillar formula applies:

$$\sigma_P = \sigma_{S'}\left(\frac{5^b}{V_P^a}\right)\left(\frac{b}{e}\left(\left(\frac{W/H}{5}\right)^e - 1\right) + 1\right) \quad (13.1\text{-}18)$$

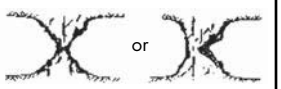
where

$b = 0.5933$
$a = 0.0667$
$e = 2.5$

For hard-rock and other noncoal mines, an equivalent squat pillar formula does not exist. It is necessary to extrapolate the Obert–Duvall relation to high W/H ratios or use numerical methods and the Hoek–Brown failure criterion to estimate the required barrier pillar size.

Koehler and Tadolini (1995) reviewed no fewer than 10 empirical and observational approaches to barrier pillar design in coal mines. Most approaches calculate minimum barrier pillar width as a function of depth, and some include seam thickness. Coal strength is generally neglected. Equivalent empirical approaches to estimate barrier pillar size in noncoal mines do not appear to exist.

Summary of Traditional Strength-Based Pillar Design Methods



For R&P coal mining, the Analysis of Retreat Mining Pillar Stability (ARMPS) method and program developed by Mark and Chase (1997) applies. This method incorporates the tributary area method and empirical strength formulas for sizing coal pillars during advance and retreat mining, and includes adjustments to pillar stress for factors such as side-loading from previously mined panels. It can also determine barrier pillar size. Again, an equivalent program does not appear to exist for noncoal R&P mining, but the ARMPS method should apply with suitable adjustments to the input parameters.

With traditional strength-based pillar design methods, the mining engineer can determine panel pillar size and barrier pillar size, but not panel dimensions. Operational considerations such as equipment and productivity determine the panel width and usually set it as large as possible. Based on strength considerations alone, a narrow panel requires a narrow barrier pillar and a wide panel requires a wide barrier pillar, and rock mechanics factors do not affect the panel-width determination. Maximum panel width can be determined by the size of air blast that an operation can withstand, but this is not a rock mechanics factor. Other rock mechanics considerations are needed to determine maximum panel width as well as panel pillar and barrier pillar sizes.

Typical R&P Sizes for Metal Mines

Within the bounds of roof and pillar safety, larger rooms enable use of larger equipment and increase the productivity of the stoping operation. Case studies completed many years ago showed that the average productivity of three mines with average room size of 41 m^2 (440 ft^2) was 21.7 t, or metric tons (23.9 st, or short tons) per worker-shift; in contrast, the average productivity of three mines with average room size of 158 m^2 (1,700 ft^2) was 71.5 t (78.8 st) per employee shift (Bullock 1998a). While safety should never be compromised, larger rooms are more productive, providing that they do not get too high to safely maintain the back and the loose rock on high pillars and ribs. Many limestone producers typically have rooms 12.2 m (40 ft) high in a single pass.

Examples of typical R&P mines with very high rock-quality designations (RQD = >85) are the mines of the Viburnum Trend (Carmack et al. 2001). Room widths are held to 11 m (36 ft), but are typically 9.8 m (32 ft); final heights after multiple passes are preferred to be <15 m (50 ft). Roof bolting is done typically in every intersection and elsewhere as needed. Historically, pillar sizes were 8.5 × 8.5 m (28 × 28 ft) on 20-m (60-ft) centers; then panel pillar sizes of 11.6 × 23 m (38 × 76 ft) were adopted for wider areas of mining where pillar extraction is planned upon retreat from the area. Relative pillar strengths in the mines are monitored using a rating system of 1 to 6, where 1 denotes no visual stress and 6 denotes pillar failure (Figure 13.1-2). This classification system is important not only for pillar recovery but also for pillar maintenance. Pillars whose rating reaches 3 must be reinforced with grouted rebar bolts to halt further deterioration if they are to maintain their integrity for a long period. The rock strength of samples in this area depends considerably on mineral content, but varies from ~70 to 200 MPa (10,000 to 30,000 psi). A similar but less defined and seemingly more conservative pillar rating system was developed by Westmin Resources Ltd. (Lunder and Pakalnis 1997).

Pillar Rating	Pillar Condition	Appearance
1	No indication of stress-induced fracturing. Intact pillars.	
2	Spalling on pillar corners; minor spalling of pillar walls. Fractures oriented subparallel in walls and are short relative to pillar height.	
3	Increased corner spalling. Fractures on pillar walls more numerous and continuous. Fractures oriented subparallel to pillar walls and lengths are less than pillar height.	
4	Continuous, subparallel, open fractures along pillar walls. Early development of diagonal fractures (start of hourglassing). Fracture lengths are greater than half of pillar height.	
5	Continuous, subparallel, open fractures along pillar walls. Well-developed diagonal fractures (classic hourglassing). Fracture lengths are greater than half the pillar height.	
6	Failed pillar, may have minimal residual load-carrying capacity and be providing local support to the stope back. Extreme hourglassed shape or major blocks have fallen out.

Figure 13.1-2 System for rating pillar strength

Some resources exist for which mineral continuity is so consistently inconsistent that no amount of surface prospecting can accurately identify ore continuity, and thus pillar and stope layouts cannot be preplanned. The Mississippi Valley type zinc deposits of central and east Tennessee (United States) are of this type. If this is the case and it is the first mine in a new mining district, an underground test mine is required so that better geotechnical information can be obtained on which to base plans for room widths and pillar widths and height, all of which greatly affect mine operating cost. Structural information can then be seen and accurately mapped, data needed to determine joint and fracture information can be accurately measured, in-situ stress measurements can be taken, and large core samples can be gathered for laboratory analysis.

ORIENTATION OF ROOMS AND PILLARS

Pillar orientation is affected by in-situ stress. The orientations of both rooms and pillars are affected by the extent of dip.

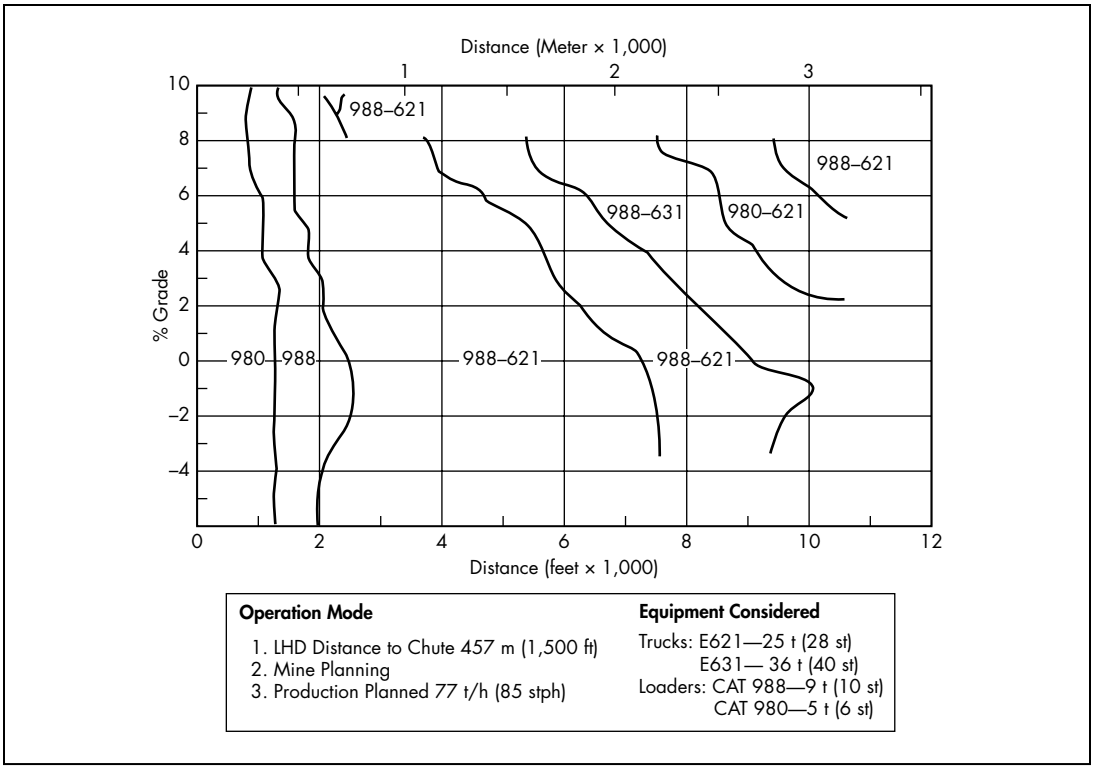
Pillar Orientation Due to In-Situ Stress

As in all mining methods, mining engineers who are planning R&P operations must be aware of probable in-situ stress within the rock before mining. Any significant horizontal stress in a particular direction must be taken into account by orienting the room advance and the direction of rectangular pillars to give the most support in the direction of stress. In the early phase of development, research should be done to determine the magnitude and direction of inherent stress. However, very shallow R&P operations may have very little horizontal stress, in which case the orientation of rectangular or barrier pillars is not a concern, particularly if a mine has been opened from a hillside with adits where nature could have relieved horizontal stresses eons ago.

In sharp contrast to this condition, some deep R&P mines have tremendous problems, not only with horizontal stress but also with rock that absorbs a large amount of energy and then fails violently. In such operations, not only is pillar orientation important, but the sequence of extraction and how it takes place is also important. Such an operation is documented as a case study by Korzeniowski and Stankiewicz (2001).

R&P Orientation Due to Dip

R&P mining is usually done on fairly flat strata but need not be limited to that. Shallow dips, of up to ~8%, have little effect on the layout of the R&P stope. If the mine is developed from a shaft, rooms should be laid out so that haulage of the load goes downgrade. If the mine is developed from an adit or decline, of course, this would not be the case. As to the orientation of rectangular pillars, it probably makes sense to orient the long side of the pillar in the direction of the dip.



Steep dips of 35% to 40% (~20°) are best mined in a series of parallel slices in steps, each following a level contour of the dipping ore body. As each round is blasted, much of the rock cascades down to the next level, where it can be loaded. This so-called cascade mining method was first reported for the Mufulira copper mine in Zambia (Anon. 1966). However, in this case the pillars were removed almost immediately in a second cycle of mining, leaving the hanging wall to cave as mining retreats along the strike.

Very steep dips of >20° do not allow operation of trackless equipment. Manufacturers have proposed back-mounted, cog-wheel-driven jumbos that can drill stope rounds under these conditions, but the ore so mined does not flow by gravity and must be removed by scraper, conditions being too steep for any other type of loading equipment. Thus many operators over the years have resorted to drilling with handheld jackleg drills and using rope scrapers (slushers) to move ore from steep slopes to the haulage equipment (Christiansen et al. 1959).

R&P MINE HAULAGE DEVELOPMENT

For hard-rock R&P mines, the production shaft is normally developed somewhere near the centroid of the ore body (unless the production opening is by adit or decline, or the ground will be allowed to cave). The objective of production development is to minimize the haul cost for the ore to the shaft. Rail haulage should be kept as straight as possible, with long-haul grades of <2%, although within the rooms themselves grades of up to 5% are permissible. In a trackless haulage operation, however, these numbers may differ and the following apply:

- Keep grades as low as possible and long hauls at <8.0%.
- Keep haul roads as straight as possible. Locate pillars in such a way that roads need not deviate around them. Lay out all main haul roads before mining, and lay pillars out from this plan.
- Keep haul roads in excellent condition. Use adequate crushed stone and keep them well graded and dry. Water

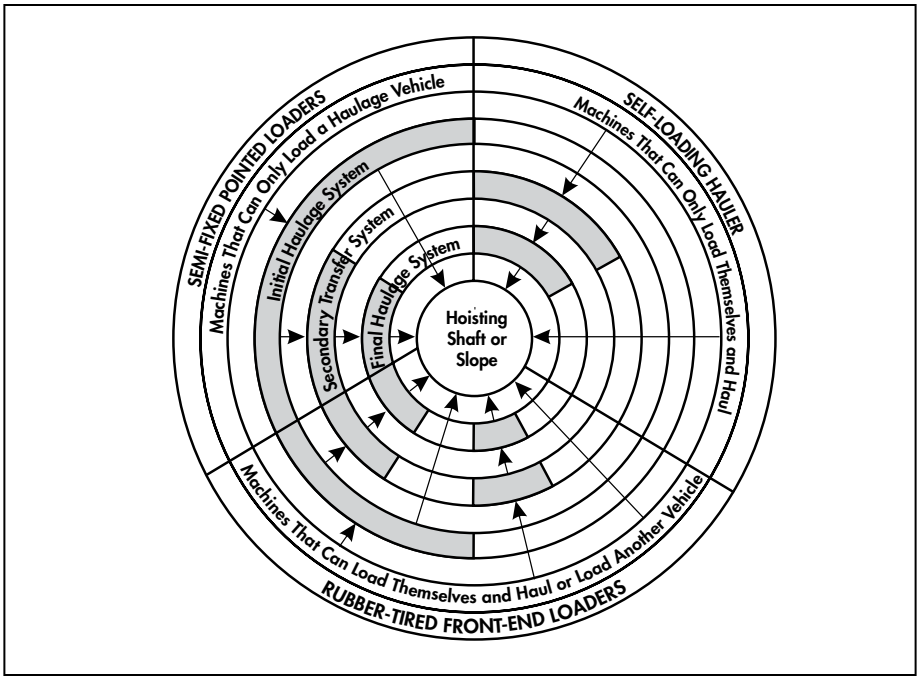
Figure 13.1-3 Equipment and operations planning from a materials-moving simulation program

not only causes potholes, but also lubricates rock to the point that it can cut tires.

In laying out a mine development plan, Spearing's rules of thumb should be kept in mind (Spearing 1995; Bullock and Hustrulid 2001):

- Keep intersections off of the main drift six widths apart.
- Avoid acute-angle turnouts that create sharp bullnose pillars.
- Separate near-parallel ramps and declines from the main drift by at least three times the diagonal width of the main drift.

In planning a trackless/rubber-tire haulage system for an R&P mine, consider the various methods of moving rock from the working face to the crushing/hoisting facility. The versatility and flexibility of modern hydraulic excavators and powerful rubber-tired equipment can make it difficult to choose the optimal method. The following guidelines can help:



1. When the mine starts operation from the bottom of a decline or shaft, the haul distance is short. Unless hauling is up a decline to the surface, a rubber-tired load-haul-dump (LHD) unit is probably optimal.
2. As the mine works out from the dump point, the LHD unit should eventually start loading a truck. Just one truck suffices as long as the loader can load the truck, then load itself and follow the truck to the dump point by the so-called load-and-follow (LAF) method.
3. As the distance between the mine and the dump point continues to increase, eventually the LHD unit should stay in the heading and load multiple trucks, enough to keep itself busy. At this point, the LHD unit is no longer optimal, and a front-end loader (FEL) may be required. As distance or haulage grade increases, larger trucks and FELs may be also required.

Examples exist (Bullock 1975) where true wheeled loaders have been successfully modified and adapted for both LHD and FEL operation, and perform efficiently at all three stages.

Figure 13.1-3 shows a graph generated by a materials-moving simulation program used in the late 1970s in the Viburnum Trend lead/zinc/copper mines. The program optimizes equipment selection based on least cost. At that time, the equipment manufacturer charged less capital cost per ton of capacity for the 25.4-t (28-st) truck than for the 36.2-t (40-st) truck. When it took this into account, the simulation found it cheaper to run a fleet of smaller trucks at the greater distance and grade. This is not the normal expected result, and thus the simulation proved its effectiveness.

If a mining zone has more than one level and the main haulage is on the bottom level, then various combinations of LHD units to the orepass or FELs with trucks hauling to the orepass are possible, and at the bottom of the orepass, automatic truck-loading feeders can transfer the ore to trucks or rail-mounted trains. If the upper ore body is small and an automatic ore chute cannot be justified, then the ore can be allowed to fall to the ground and an LHD unit or FEL can load it into another truck. Figure 13.1-4 shows all of the possibilities for moving material from an R&P face to the final ore pocket at the shaft. For a complete explanation of how to optimize these variable conditions, see Bullock 1975 or Bullock 1998b.

Clearly, then, in an expanding R&P mine, the optimal method or combination of methods for moving ore constantly changes. But for every condition and distance there

Source: Bullock and Hustrulid 2001.

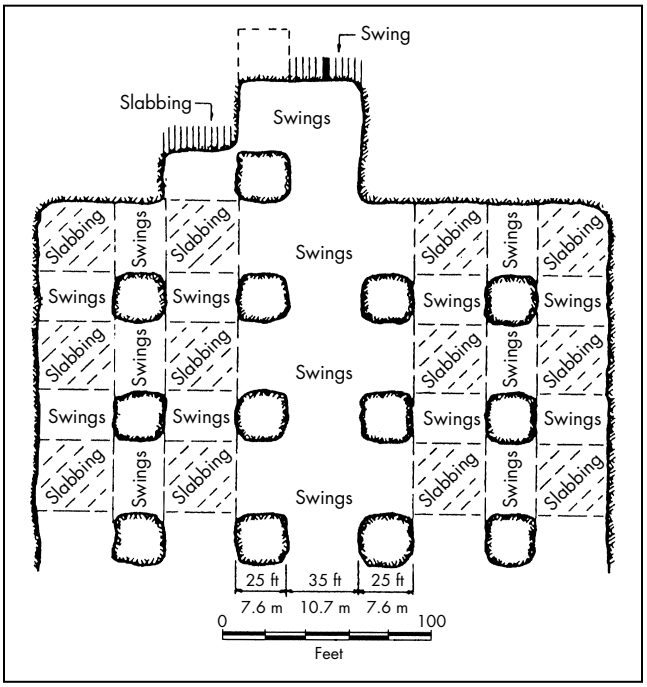
Figure 13.1-4 Multiple methods of moving ore from a stope face to a hoisting conveyance

is one optimal least-cost method, which can be determined by computer simulation of the underground mine environment (Bullock 1975; Gignac 1978).

Another R&P concept is worth noting. In some older Tennessee mines, the haulage ways along which ore is transported are somewhat narrow. As haul distance increased, it became desirable to use larger-haulage trucks, but such trucks could not be accommodated on the narrow haulage ways. To solve the problem, Savage Zinc, in their Gordonville mine, hooked side-dump, powered truck-trailers (built by Gulf Transport of Australia) together into a mini-truck train, thus increasing the payload per trip and optimizing production for load-haul conditions.

If a conveyor system of haulage is used for the main distance haulage, then the preceding advice for mine layout still applies to the general layout of the mine, except conveyance starts from the decline of the mine entrance where the main conveyor carries mine production to the surface. In these cases, a hard-rock mine usually has a semimoveable crusher or breaker underground before the feeder to the conveyor system. The system of haulage, either LHD unit or FEL/truck, hauls broken rock from the faces to the central receiving point at the crusher. The crusher then feeds the conveyor. The crusher must be moved periodically—about 6 to 12 months—depending on how fast mine production moves the faces away from the central hauling point.

At one time, rail haulage was the principal method of gathering ore from the faces to the production shafts. In the Old Lead Belt of Missouri, more than 556 km (300 mi) of interconnected railroad was used to bring ore into two main shafts from what was originally about 15 mines. Today in the United States, very few R&P metal mines use rail haulage, but many coal mines still do, and in other countries many metal mines still do as well.



SINGLE-PASS OR MULTIPLE-PASS EXTRACTION

Two approaches exist to mining ore body or valuable rock: (1) taking the entire ore-body thickness in a single pass or slice, or (2) removing the ore body by multiple passes or slices. The choice of approach of course is related to the overall thickness of the ore body to be extracted and to concerns for safety and efficiency.

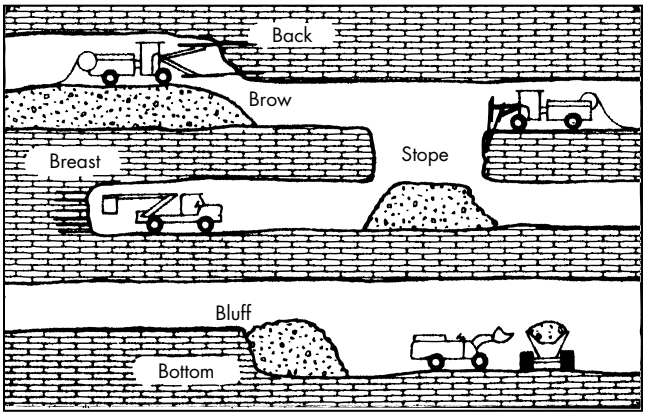
Normally, in mining bedded deposits for aggregate, the total thickness of the desired horizon is known and the decision concerning slice thickness can be made in advance. However, in metal ore deposits, particularly in Mississippi Valley or collapsed Breccia type deposits, most of the time the thickness of the total mining horizon is not known except where the formation has been penetrated by diamond drill holes and identified, although a few meters away from the hole the formation may very well be different. For both aggregate producer and metal-ore producer, the best approach is first to mine what is thought to be the top slice through the ore body. The thickness of this first mining step depends on the available equipment and on the height of ground that can be mined and maintained safely and efficiently. The advantage of first mining what is thought to be the top slice is that whatever back and rib/pillar scaling and reinforcement is required can be reached easily and safely, probably at distances not more than 6.1 m (20 ft). However, some aggregate producers mine 12.2 m (40 ft) or more in one pass by using high-mass jumbo and extendable-boom roof-scaling equipment.

R&P Rock Breaking for Single-Pass Stoping

In most hard-rock R&P mines, extraction is done by drilling and blasting the face. The initial pass of drilling and blasting is usually done by drilling either burn-cut or V-cut drill patterns. However, only about 40% of the rock should be broken with drilled swing patterns (rounds), breaking to only one free face.

Source: Bullock and Hustrulid 2001.

Figure 13.1-5 Optimizing the drilling and blasting of R&P stoping using 40% pattern swing drilling and 60% slabbing



The other 60% of the rock should be broken by slabbing—that is, by drilling holes parallel to the second free face as it is exposed (Figure 13.1-5), which minimizes the cost per ton of rock broken and maximizes productivity.

Particularly in the R&P mining of aggregates and metals, extraction is often done by mechanical means. In many trona and potash mines, and some salt mines, all extraction is done mechanically.

R&P Rock Breaking for Multiple-Pass Stoping

After the first pass is completed in a metal mine for a given stoping area, the back and floor should be sludge-sampled with either pneumatic or all-hydraulic drills. Some operations do this with a stope rock-breaking jumbo and some with an all-hydraulic jumbo designed for this role. The purpose of this sludge-sampling prospecting is to determine what ore remaining in the back and floor needs to be removed by additional slices. If ore is found in the back and floor, then the ore in the back should be removed first. After it is removed and additional back-prospecting reveals no more ore, the back should again be made secure and safe, and ore in the floor can be taken.

Methods of mining ore in the back vary depending on the thickness of the ore yet to be mined and the height of the original stope. If the original stope height was no more than 7.6 m (25 ft) and the back slice thickness was no more than ~2 m (7 ft), most extendable-boom jumbos can reach high enough to drill the brow with breast (horizontal) drilling. Drilling horizontal holes increases the chance of leaving a smooth back, which requires less maintenance than when holes break to the free face of the brow. This is especially true for smooth-wall blasting or flat-seam deposits. A jumbo feed should not be tilted up for drilling near-vertical holes and for drilling uppers

Source: Adapted from Bullock and Hustrulid 2001.

Figure 13.1-6 Various types of stoping action involved in R&P metal mines

to break a brow, particularly in bedded deposits that exist in so many R&P mines.

If ore thickness in the back is greater than the conditions cited previously or if room height is already at the maximum that can be safely maintained, then the back slice should be mined by first cutting a slot in the back at the edge of the entrance to the stope (Figure 13.1-6). This slot should be between the pillars and reach the height of the next slice or the top of the ore body. Care must be taken not to damage the rock that will form the top of the new pillars.

Smooth-wall blasting can be used to advantage in this area. A mine dozer (usually a small dozer of D-4 or D-6 size) begins by pushing rock up and making a roadway for the jumbo to travel on the top of the rock pile. If a dozer is unavailable, an FEL can also do a reasonable job of building the roadway. The jumbo then drills breast (horizontal) holes in the brow and follows the ore zone wherever it goes throughout the stoped area. Even if it goes into the solid beyond the original stoped area, this is not a problem, except that a loader now must load the ore as it is broken. About 75% of the ore must remain in the stope rock pile until back-mining is complete, which can be a disadvantage if the mine must produce immediately. When the top of the ore is finally reached, the back should be made safe since miners are still working close to the back. This type of mining has been practiced in the Tennessee zinc and Viburnum Trend lead/zinc districts. It is not uncommon for several passes of ore to be mined from broken rock piles. In these cases, either ore must be loaded from the bottom edges of the rock piles to make room for new broken rock or a loader must go up on the rock pile and load out the excess rock.

If after the first slice is taken through the stope it is then discovered that a thick, continuous ore zone lies above this first slice—a zone of perhaps 15 to 20 m (50 to 65 ft) or more—then an entirely different approach is required. It may be preferable to create a development ramp to what is now the top of the ore, mine the top slice from this new ramp, and then put through a slot raise from the bottom to the top level that can be slabbed out to make room for long-hole drilling and blasting the ore body down to the level below. Again, the pillars should be presplit or smooth-wall-blasted to protect them. If the eventual height of a pillar can be anticipated, the size of the pillar at its base should be determined taking this

additional height into account. If it is not taken into account and safety factors in the design are insufficient, then the pillars may need reinforcement with grouted rebar bolts to give them the required strength and stiffness.

When all back ore is removed from the stope and the final back is made completely secure, bottom ore can be removed from the floor. This is best done by first cutting a ditch or short decline in the floor, at the entrance to the stope, to the depth of the desired bluff or bench. Bluffs can be carried very thick and are limited only by the height required for the loading equipment to work safely. It is common practice to carry bluffs up to 9 m (30 ft) in the lead mines of the Viburnum Trend area using 7–11-t (8–12-st) loaders. Beyond this height, the safety of the loader operator may become an issue.

Bluffs at least 4 m (13 ft) thick are usually drilled and blasted with downholes by small-surface quarry-type drills. Bluffs of less than this thickness can be drilled out with face jumbos, drilling breasting, or horizontal holes (sometimes called lifters and splitters). These procedures can be repeated over and over until the bottom of the ore is reached.

When it is known beforehand that bluff mining will be done, for the initial pass the pillar width must be left large enough to accommodate considerable height should it be needed. If additional ore is not found, then the pillars can be slabbed down to smaller size. However, again the precaution: in both removal of back ore and taking up of the bottom, the pillars most be protected with presplitting or smooth-wall blasting. Pillar design is discussed in more detail in the following section; the point here is that, unless the original mine plan specifically allows for taking down the back and taking up the floor or specifies a very large safety factor in pillar design, the width-to-height ratio required for safe operation will be exceeded by multiple-pass mining. It cannot be overemphasized that everything must be done to protect pillar integrity during the first of what may become multiple passes. Unless caution during presplitting or smooth-wall blasting is observed, blasting fractures may extend into the pillar as far as 2 m (6.6 ft) or more. As more slices are removed, these fractures begin to open, reducing pillar size and subjecting the pillar to failure.

METHODS OF PILLAR EXTRACTION IN HARD-ROCK MINES

The mining engineer should anticipate some percentage of pillar removal beyond what is cited in the original mine plan and stope layouts. If future pillar extraction is planned—whether by partial slabbing, removal of a few high-grade pillars, or complete removal incorporating some system of backfilling—then what is left after the first pass greatly influences what can be done in the future. Too often, too much is extracted on the first pass, so that the entire area is weakened and must be reinforced just to keep the mine open, much less enabling the selective robbing of pillars.

The first and most important thing to do is to install a complete network of convergence stations throughout the affected area. Experience shows that regular monitoring of such a network over time can reveal what rate of back–floor convergence is acceptable and what rate will lead to massive failure. Convergence in some mines can be as high as 1.25 mm per month without the back breaking up and failing (Parker 1973). Convergence in other mines, such as those of the Old Lead Belt of Missouri and the Viburnum Trend, can be as low as 0.1 mm per month and still cause problems. However, the following are good general guidelines:

- Convergence of 0.0254 mm (0.001 in.) per month is not significant.
- Convergence of 0.0762 mm (0.003 in.) per month indicates a serious problem, but is controllable with immediate action.
- Convergence of 0.1778 mm (0.007 in.) per month indicates that acceleration is getting out of control and the area may be lost.

Several methods exist for pillar removal of R&P stoping:

- Slab some ore off of each pillar containing the high-grade portion of the ore during retreat from the area.
- Completely remove a few of the most valuable pillars, but leave enough pillars untouched to support the back.
- In narrow stopes, completely remove all pillars in a controlled retreat.
- Use massive backfill methods to remove some or all pillars.

Placing cemented rock fill around pillars, all the way to the back, to properly support the stope between the solid and the backfill creates a pressure arch over the intervening pillars, which can then be removed. Economics permitting, the area can be backfilled if necessary, and the pillars that were encapsulated or trapped in the original fill can be mined from a sublevel beneath the pillar by long-hole blasting of the pillar into the sublevel area. (Lane et al. 1999) The total backfill prevents any future subsidence.

All of the previous methods (except sublevel extraction) were used in the final mining of the Old Lead Belt of Missouri in its last 25 years, and much more intensely in its last 10 years. This R&P mining district was mined for 110 years before finally shutting down.

Sometimes when pillars are partially removed without proper planning, or when pillars that are too small are left after first-pass mining, the pillars begin to break up and serious convergence accelerates uncontrollably. One of two things must be done to save the area: (1) massive pillar reinforcement, if there is time before collapse; or (2) massive backfill in the entire area.

Among examples of massive pillar reinforcement, fully grouted rebars were placed in more than 300 pillars in the one of the R&P mines of the Viburnum Trend. Weakly (1982) has documented the method employed, reinforcing pattern, cement grout mixture, convergence instrumentation, and results. In the Old Lead Belt areas, pillars to be reinforced were wrapped with used hoist cable, with a load of 5.5 t (6 st) placed on each wrap (Wycoff 1950), but this reinforcement method is not as fast, economical, or effective as use of fully grouted rebars in the pillars.

Among examples of massive backfill are the Leadwood mines of the Old Lead Belt, where this method was used only about 132 m (425 ft) below surface. However, the back was thin-bedded dolomite, interbedded with shale and glauconite, and badly fractured and leached. The roof bolt was originally developed in these St. Joe mines in the late 1920s as a means of tying the layers together to act as a beam (Weigel 1943; Casteel 1964); the roof bolts were used with channel irons to form a crude truss. Even though the rock in the pillars provided poor support because it contained bands of

high-grade galena, for economic reasons pillar removal and slabbing took place over a period of 25 years. Occasionally local cave-ins would occur after an area had been pillared, but since the cave-ins were beneath uninhabited St. Joe–owned land, they were of no real concern. However, when slabbed pillars between two smaller cave-ins began to fail and a third and fourth cave-in occurred in more critical areas, there was a considerable amount of concern. Initial extraction of some of the area involved multiple-pass mining and room heights were mostly 6.1 to 12.2 m (20 to 40 ft). Final mining of the area had resulted in ore extraction of approximately 95%. To stop caving in the third and fourth areas, in around 1962 more than a million tons of uncemented, cycloned sand tailings were put into the mines, filling the rooms nearly to the back. The backfill was very successful in controlling the converging, failing ground.

The end result of use of these methods is comparable to the overhand-cut-and-fill practice of deliberately mining pillars very small and immediately filling in around them. This method, known as postpillar mining, was used in the Falconbridge nickel mines (Canada) (Cleland and Singh 1973), the Elliot Lake uranium mines (Canada) (Hedley and Grant 1972), and in some mines in San Martin and Niaca (Mexico) and San Vicente (Peru). The end results for the two mining methods, with very small pillars encapsulated in sand tailings, are similar.

VENTILATION

Most of the literature on ventilation design for R&P mining is written for coal mines. However, a few considerations are unique to metal and aggregate R&P mines. R&P metal or aggregate mines differ from R&P coal mines in the following respects:

- Everything is larger. It is not uncommon to have entry drifts of 9 × 9 m (30 × 30 ft) and rooms stoped out to 12 × 15 m (40 × 50 ft). A lot more air or a stream of high-pressure directed air is required to meet the required minimum velocity across the working face.
- Stopings are difficult to build and the total force against them can be enormous. Many R&P mines rely on auxiliary fans to pick up air from the main ventilation drifts and carry enough air through vent tubing to serve the needs of the active face.
- Ventilation doors are similar in design to airplane hangar doors. Again, the total force against these doors, which must be controlled automatically, is enormous.
- Air stratification in large stopes can be a problem.
- Diesel equipment is used extensively, and the exhaust must be diluted to meet particulate standards.
- Ventilation fans can be placed underground, if it is beneficial to do so.

THE EFFECT OF CHANGING MARKET CONDITIONS ON R&P MINE PLANNING

Market conditions are important in planning for R&P mining, even during the stages of feasibility planning. An advantage of R&P mining for metal or any commodity that is gradational in value is that mining methods and approaches are flexible and can be changed quickly in response to changing market conditions—more quickly, in fact, than is possible for other mining systems.

Another advantage of R&P mining is that, if the ore body is continuous, new faces are continuously being opened. A stope only four pillars wide can have as many as 15 faces open simultaneously for drilling and blasting. Imagine how many faces would be exposed to drilling and blasting if a stope were 10 pillars wide. For metal mines, this offers a great deal of flexibility; one can mine the grade of ore that is most desirable at the current market price. For at least short periods of time in each stope unit, it is usually possible to work only the higher-grade or lower-grade faces of a particular mineral, although doing so usually has a drastic effect on the grade within a few days. During initial mining of the high-grade Fletcher mine in southeastern Missouri (United States), after operation for only 3 to 4 years, approximately 50 to 70 faces were open for mining on any given day although only 10 to 12 were actually worked. One can then select the faces to be mined so as to maintain the grade of lead, zinc, or copper ore that can best be handled by the concentrator and still optimize the financial objective of the mine.

Spare equipment can be put into reserve stopes to increase production if the remaining materials flow can handle the added capacity. However, if this is done too often or for too long, mine development must also be accelerated. Old stopes, if maintained, can be reactivated quickly for mining of lower-grade minerals that have become financially worth mining.

Lower-grade ore can be left in the floor or the back of stopes until price rises, at which point the reserves are readily available for quick mining. This technique is often overlooked by those unaccustomed to planning R&P metal mining, where mineral values are gradational. The optimal technique is first to mine the better areas of the mineral reserve and maintain a grade of ore that satisfies the economic objectives at that time. Then when economics change, the lower-grade areas left as remnant ore reserves can be mined.

In spite of these considerations, however, even in R&P mining, drastic changes in the rate of mining (momentum) cannot be assumed to be free. It often takes several months with an increased labor force to regain a production level that seemed easy to maintain before a cutback in mine production. If spare equipment is used to increase production, maintenance will probably convert from a previous preventive-maintenance on-shift schedule to a breakdown overtime schedule, at least until permanent additional equipment can be obtained. Nevertheless, the necessary changes can be made.

As discussed in the section on pillar robbing, another method for achieving economic flexibility with R&P mining is to slab or remove high-grade pillars. Then, even in the later years of the mining operation, some "sweetener" is left to blend with the lower grade. Although not unique to R&P mining, this technique is easier to accomplish in an R&P operation than in other more complex mining systems.

CAPITAL AND OPERATING COSTS FOR HARD-ROCK R&P MINING

Capital and operating costs for hard-rock R&P mining are usually considerably less than for other hard-rock mining systems at the same daily production. However, panel caving is not comparable because R&P mines are not normally built to produce the equivalent lower tonnage per day.

Table 13.1-2 shows estimated preliminary capital costs for R&P mines. The original estimates (Stebbins and Schumacher 2001), based on 2000 data, included cost contingencies of 7.2%

Table 13.1-2 Estimated preliminary capital costs for R&P mines developed from shafts (mid-2009 dollars)

Daily tonnage, t (st)	1,200 (1,323)	8,000 (8,819)	14,000 (15,432)
Total capital cost	$39.8 M	$125.0 M	$152.8 M
Total capital cost/daily tonnage	$33,200	$15,600	$10,900

Source: Adapted from Stebbins and Schumacher 2001.

Table 13.1-3 Estimated direct operating costs for hard-rock R&P mining (2008 dollars)

	Cost, US$	
Activity	**Per metric ton**	**Per short ton**
Drill & blast labor	0.47	0.43
Loading & hauling	0.73	0.67
Maintenance labor, repair, parts, & tools	1.84	1.67
Indirect labor	1.14	1.04
Overtime	0.15	0.14
Other materials & tires	0.64	0.58
Sundry supplies	0.49	0.44
Diesel fuel	1.60	1.45
Drill steel & bits	0.26	0.24
Grease & oil	0.76	0.69
Roof supplies	0.13	0.12
Tire recapping	0.18	0.16
Other outside services	1.10	1.00
Blasting supplies	1.11	1.00
Underground prospecting	0.38	0.35
Fringes on direct labor	0.55	0.50
Total direct operating cost	11.53	10.46

to 7.6%. The contingencies were removed, the percentage of the remaining total was calculated for each element of capital cost, elemental capital costs were escalated using the proper indexes for the time period and totaled, and a 25% contingency was added to the total. These costs include all equipment, preproduction development, mine-surface facilities, engineering and project management, working capital, and cost contingencies.

Table 13.1-3 shows estimated direct operating costs for R&P mines. The estimates are based on 1998 data from six highly productive R&P mines that vary in daily production from about 2,300 to 6,300 t (2,500 to 7,000 st) per day. The estimates were escalated to 2008 using the proper mining-unit inflation index for each cost element, and a 20% contingency was added. It is noteworthy that the six mines have very large rooms, are highly mechanized, and are considerably more productive in tons per worker-shift than is average for the industry (the latter is about 40–50 t [44–55 st] per worker-shift).

CHAPTER 13.2

Room-and-Pillar Mining in Coal

Jerry C. Tien

INTRODUCTION

After the coal seam is reached by means of a slope or shaft, the room-and-pillar (R&P) mining method can be used to extract coal. Room-and-pillar (also called bord-and-pillar) mining is an "unsupported" mining method used to extract mineral deposits that are roughly tabular and generally flat-lying such as coal. Using this system, the coal seam is extracted across a horizontal or nearly horizontal plane while leaving "pillars" of unmined coal to support the overburden and leaving open areas or "rooms" underground.

This method is termed *unsupported* because no artificial pillars are used to support openings. The roof is supported by natural pillars left standing—usually in a systematic pattern—and generous amounts of roof bolting and localized support are also usually used. The key to successful R&P mining is selecting the optimum pillar size, which varies depending on many factors, varying between 40% and 60% of the seam volume and proper pillar layout. With proper planning, this method provides a very effective means for extracting coal.

The productivity of R&P mining operations experienced a distinct step-change in the latter part of the 20th century as a result of increasingly powerful mining equipment, technical progress, and rationalization of efforts, and is now an indispensable method in underground coal mining. Worldwide today, it is estimated that at least 60% of coal mined underground uses the R&P mining method, although the exact amount of coal mined using the R&P mining method is difficult to obtain—the 60% figure is estimated by examining major coal-mining countries. For example, the world's number one coal-producing country, China, has at least 85% of its coal mined using R&P mining; more than 95% of China's coal is mined underground. More than 60% of U.S. coal mined underground comes from the R&P method (including 10% coal from longwall operations). It is estimated that less than half of Australian underground coal is mined using the R&P method. South Africa produced 43% of that country's total coal production using R&P mining in 2008. It is also estimated that at least 60% of India's coal comes from R&P mining.

In the mid-1980s, R&P mining using either drilling and blasting or a continuous miner was the dominant method in underground coal mining, producing about 87% of all the coal mined underground in the United States. Following the growth of longwall methods, this dropped to approximately 60% in 2007 (including the coal from longwall gate road development). Even longwall mining operations require highly efficient R&P units for timely entry development, producing an estimated 20% of total coal production. It probably will be difficult for R&P to compete costwise with longwall operations in all circumstances, but with its modest capital requirement and versatile operation, the R&P method has been able to compete head to head in terms of cost per ton of coal extracted with longwall mining in many cases.

ROOM-AND-PILLAR MINING

Early mines using the R&P method were developed more or less at random, with pillar sizes determined empirically and headings driven in whatever direction was convenient. For example, in Australia in the early days, the rooms were laid out systematically to suit hand shoveling and endless rope haulage. In modern coal mines, however, rooms and pillars are typically laid out orthogonally in a regulated pattern (Figure 13.2-1).

In addition to support, coal pillars are also expected to restrict surface movement, protect critical airways from the effect of high load distribution and abutment stresses, form ventilation partitions for airflow distribution, act as yield (sacrificial) pillars to provide temporary support in high lateral-stress situations, and as shaft pillars to protect air shafts and other critical mine structures. Barrier pillars can be used to form a load-bearing framework to minimize the impact of ground movement from adjacent workings, to isolate major faults and local joints, to protect critical roadways, to separate adjacent mine leases, and most importantly, to provide a barrier to large masses of water-filled old workings.

R&P mining has two basic operations: entry development and coal production. The former is to develop mine entries to access coal seams and construct the necessary support infrastructure to facilitate coal production. Although in inclined coal seams it might be necessary to excavate either above or below strata to access the coal seam, most entries are in the

Jerry C. Tien, Department of Mining and Nuclear Energy, Missouri University of Science & Technology, Rolla, Missouri, USA

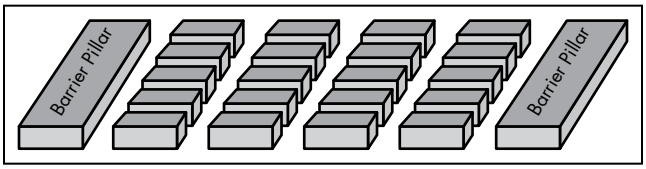

Figure 13.2-1 Room-and-pillar layout with five entries and long barrier pillars

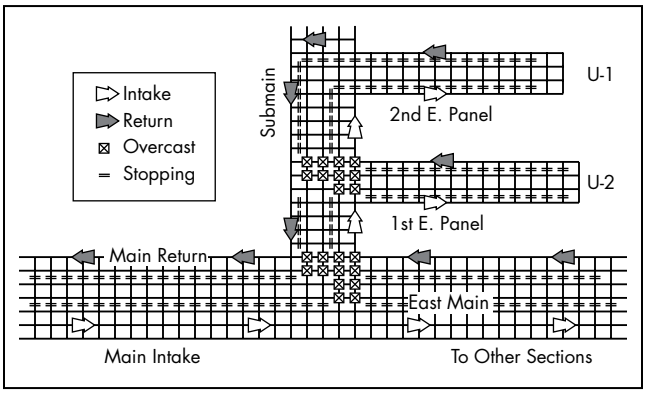

Figure 13.2-2 Mine section with two operating units, seven-entry main, five-entry submains, and four-entry panels

coal seam itself, which also produces coal in the process. Both horizontal and inclined R&P operations require other support operations such as roof bolting, ventilation, face cleaning, and transportation.

The mine layout has to be carefully planned to accommodate all functions for maximum efficiency. Development openings (entries) and production entries (rooms) closely resemble each other—both are driven parallel and in multiples, and connected by crosscuts to form pillars. Driving multiple entries simultaneously is necessary for high production and operational efficiency; it also facilitates ventilation, roof bolting, and coal transportation routes in the face area.

Usually, a hierarchy of entries exists in underground coal mines. Main entries are driven mainly to divide the property into major areas and usually serve the life of the mine for ventilation as well as for worker and coal transport. Submain entries can be regarded as feeders from the mains that subdivide each major area. From the submains, panel entries take off to subdivide a block of coal into panels and rooms for orderly coal extraction. It can be seen in Figure 13.2-2 that the East Main has a 3-2-2 or intake-neutral-return arrangement, and the submain off the East Main has the same arrangement (intake-neutral-return) but in 2-2-1 layout. The number of intake entries exceeds the number of return entries indicating it is a blowing system (with a fan on top of an intake air shaft) where neutral air travels away from working faces.

The number of development entries in any area can vary between three and seven, or as many as eleven in some cases; the exact number is often a balance of the following factors:

- Expected load on the pillar due to its depth or other geotechnical concerns
- Coal production
- The system that supports the expected production (number of pieces of mining equipment that are operating, labor and material transport, ventilation, etc.)

It is critical that a proper balance be achieved between the optimum coal extraction ratio and the size of pillar necessary to support the overburden.

Geotechnical Design for R&P Mining

Because of the complicated and varying nature of rock strata, it is customary to start the basic pillar design by assuming (1) rock strata to be homogeneous, uniform, and horizontally bedded deposits; (2) a uniform pillar layout; and (3) the rock materials are competent. Other factors such as pillar shape (uniformity of distribution and cross section and height–width ratio), true pillar geometry (outside dimensions minus an outer shell of distressed materials that in effect support very little load), and true mechanical behavior of pillar materials also have to be considered.

Bieniawski (1987) suggested the following eight-point general pillar design approach:

1. Data collection to (a) obtain a uniaxial compressive strength of roof rock and coal (σ_c); (b) spacing, condition, and orientation of geological discontinuities; and (c) groundwater condition.
2. Determine roof span and support methods.
3. Estimate pillar strength (σ_p) by considering size effect using

   $$\sigma_p = \sigma_1 [0.64 + 0.36 (w/h)]$$

   where σ_1 is the strength of a cubical specimen of critical size or greater (e.g., about 3.3 ft for coal), w is pillar width, and h is pillar height.
4. To obtain pillar load using

   $$S_p = 1.1H\left(\frac{w + l}{l}\right)^2$$

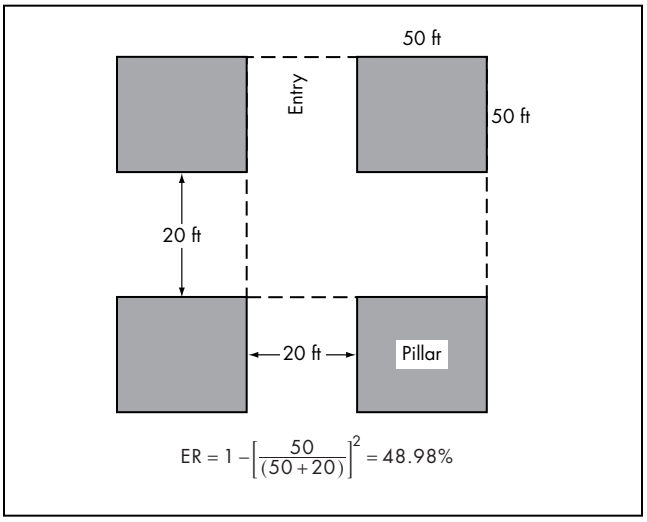
   where S_p is pillar load (psi), H is the depth below surface (ft), w is pillar width (ft), and l is the roof span (ft).
5. Select a proper safety factor, F (ranges between 1.5 and 2), $\sigma_p = FSp$, and solve for pillar width.
6. Determine extraction ratio (ER) using

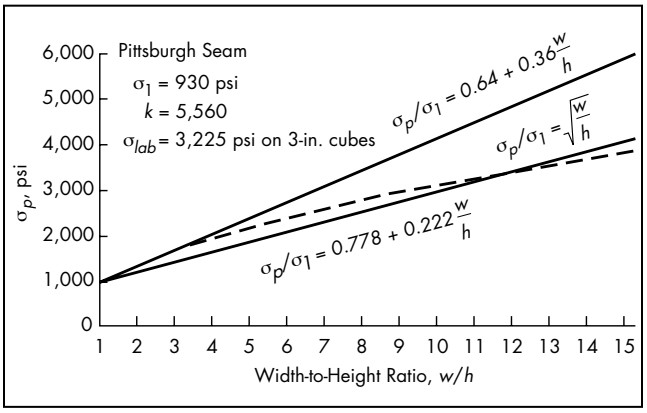
   $$\text{ER} = \frac{(w + l)^2 - w^2}{(w + l)^2} = 1 - \left[\frac{w}{w + l}\right]^2$$

   If the ER is not acceptable and needs to be increased by decreasing the pillar size, select a new width and repeat Steps 3 through 6. Figure 13.2-3 shows that a 50 × 50 ft pillar with 20-ft width will result in nearly 50% ER.

   The optimum ER must be a compromise between the safety of the structure and the cost of mining and conservation of resources. Considering all factors, the extraction ratio for R&P mining ranges from about 50% to 60% for underground coal mining, as shown in Figure 13.2-3.
7. Cross-check results by using the Holland formula ($\sigma_p = \sigma_1[0.778 + 0.222w/h]$) and the Obert–Duvall formula ($\sigma_p = \sigma_1\sqrt{w/h}$). The Holland formula is valid for pillar width-to-height ratio and the recommended safety factor is between 1.8 and 2 (Figure 13.2-4).
8. Exercise engineering judgment by considering a range of mining and geological parameters to assess the various options for mine planning in accordance with the local mining requirements.

For example, a coal mine in the Pittsburgh seam (United States) is currently mining at 500-ft deep with stable pillars and roofs of w = 40 ft, h = 10 ft, l = 18 ft, and k = 5,580 psi





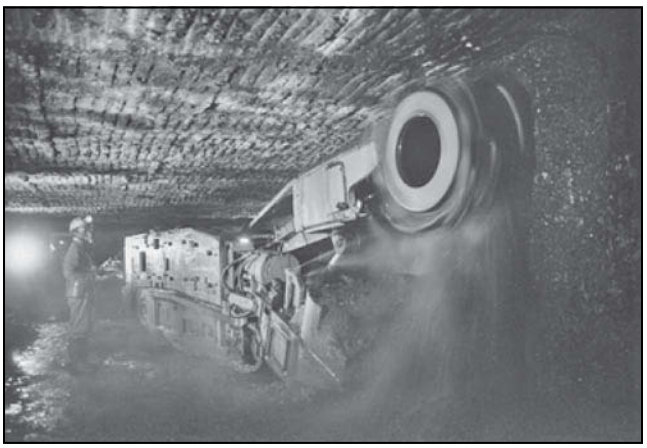


Figure 13.2-3 Extraction ratio calculation for a 50 × 50 ft pillar with a 20-ft-wide entry

Source: Bieniawski 1987.

Figure 13.2-4 Pillar strength in the Pittsburgh seam versus *w/h* ratio as predicted by three formulas

Figure 13.2-5 Continuous miner at work

for the Pittsburgh seam. K is a constant for actual pillar material, defined by $k = \sigma_c\sqrt{D}$, where σ_c is the uniaxial comprehensive strength of rock specimens tested in the laboratory having a diameter or cube size dimension of D (in.). Mining is planned at 1,000 ft. Calculation shows that pillar stress (S_p) = 1,150 psi. For a 1,000-ft depth, using proper pillar strength (σ_p = 1,934 psi), safety factor (F = 1.67), and extraction ratio (0.52), the resulting pillar width will be 65 ft.

After coal is mined, it is hauled away using shuttle or ram cars to a properly located breaker station (usually 200–250 ft away from the working face) where it is crushed and transported to the surface by conveyor.

Practical limitations exist on R&P mining in coal operations. That is, at depths greater than 1,300–1,600 ft, this method may become very difficult or uneconomic to practice, owing to excessive roof pressure and the larger pillar sizes that are required. However, depending on other parameters, there are always exceptions. For example, KGHM is mining copper in Poland by the R&P method below 3,300 ft.

Continuous Mining Method

With a continuous mining method, separate unit operations of drilling, cutting, blasting, and loading are replaced by a single high-performance continuous miner (CM). As the steel drum (cutterhead) spins in a circle, the tungsten carbide steel teeth or cutting bits break the coal from the face. The coal falls onto a steel apron where moving arms load the coal onto a short conveyor on the back of the CM and transport it to a shuttle car waiting at the rear (Figure 13.2-5).

The shuttle car is driven to a feeder breaker three to four breaks (180–280 ft depending on pillar sizes) away and loads the panel conveyor, which carries the coal to the surface. After one working face is completed, the CM then moves to the neighboring face and the process is repeated.

A typical CM measures approximately 33 × 11 × 4.5 ft (length × width × height, respectively). The depth of each cut in a working face has increased today to 30–40 ft ("deep cut") because of more powerful and reliable machines, but this requires multiple passes and resetting of the miner to complete cutting in one face. Efficiency of the miner operator and coordination of other auxiliary functions such as face cleaning, establishing ventilation, and roof bolting are all key factors in determining the face advance rate and productivity. Remote-controlled CMs are now the norm in the industry, and they have significantly enhanced face productivity and safety.

A typical (standard) continuous mining section uses one set of equipment with one crew operating in a panel of three to seven entries. The section is equipped with one CM, two to three shuttle cars or ram cars, one roof bolter, and a section scoop for auxiliary jobs. In addition to a section foreman, a CM section would have nine to ten workers: two CM operators (one operating and one assisting/relieving), two roof bolters, three shuttle car operators, one mechanic, and one general laborer).

In addition to the standard unit, U.S. coal mines have also been using either a double or a super unit arrangement: The former uses two sets of equipment and two or nearly two crews operating side by side in a panel with 8–13 entries; the latter uses two sets of equipment and one crew plus two extra workers operating side by side in a panel with 4–13 entries. Depending on the mine's specific condition, either method has been used successfully in developing long-distance mine mains with multiple entries.

Since the late 1970s, mining machines progressed steadily from 440 V to 950 V with an increase in productivity. By 1990 virtually all CMs were powered by 950 V. The demand for larger, more-powerful mining equipment prompted the need for increased voltage even further for a CM. Since input voltage varies directly with mining rate and motor torque varies with the square of the voltage, higher voltages for a given size cable also lead to a lower power voltage drop. With further improvement in shielding technology, high-voltage miners have become available. For example, Joy Mining Machinery's 14 CM series high-voltage (2,300 V) continuous miner can mine up to 38 t/min, depending on the seam thickness. Special design, use, and maintenance precautions are needed to ensure an equivalent level of safety when high-voltage systems are used in permissible areas. In the United States, mining equipment operating above 1,000 VAC requires a petition for modification including an approval examination by the Mining Safety and Health Administration for each high-voltage CM deployed inby (the distance between where one stands and the face). CMs capable of cutting 19.7 ft of coal seam have also been produced.

Ongoing improvement in CM performance in both productivity and reliability has brought about a dramatic increase in coal production. Under certain conditions, CM units have been able to deliver more than 3,000 t/shift on a regular basis.

Conventional Mining (Drilling and Blasting) Method

Conventional mining is cyclical, employing mobile mechanized mining equipment to carry out production unit operations in five distinct steps:

production cycle = cut + drill + blast + load + haul

A cutting machine cuts a 5–7-in. slot or kerf at about 10 ft in length to improve breaking during blasting. A drill is then used to drill holes into the coal face in a predetermined pattern, which are then loaded with permissible explosives. After the coal is shot and fragmented by a qualified shot firer (following strict safe-blasting procedures), it is scooped up and loaded into a waiting shuttle car that transports the coal to a conveyor-belt loading head (feeder breaker) for transport to the surface. In some smaller mines, the coal is hauled in rubber-tired trailers drawn by battery-powered tractors. After the first working area is completed (depending on specific practice, this could be the first heading on the right in a panel if the mine works from right to left direction), the crew moves to the adjacent workplace and the steps repeat, as shown in Figure 13.2-6. Coal mined at the face is transported using a shuttle car or ram car to the breaker where it is transferred to the conveyor belt.

Several other auxiliary functions must also accompany production functions: face cleaning, roof control, proper face ventilation, cables and equipment advances, and movement of materials and supplies. As a result, multiple entries are necessary such that all functions can be performed at separate faces without delays.

Depending on the face advance rate and traveling distance, as well as the change-out points due to multiple hauling units, the location of the dumping point (breaker) needs to be located in a position that minimizes haulage travel time and congestion.

In the United States, haulage entries where coal is transported are separated from both intake and return airways, thus

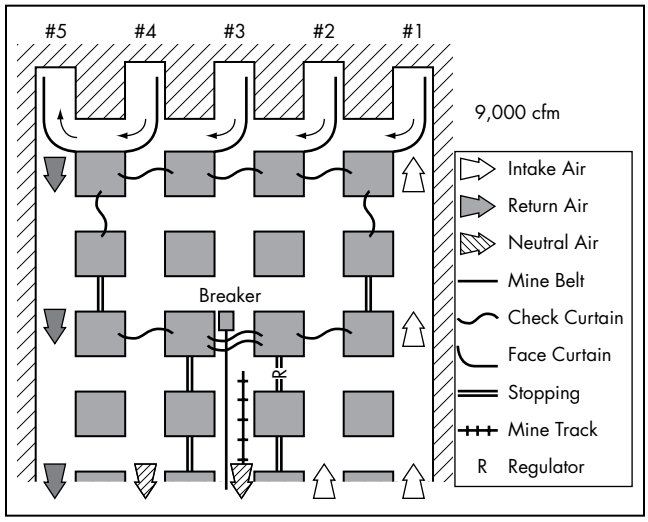

Figure 13.2-6 A five-entry unit with mining progressing from right to left

the introduction of "neutral" entry airways, which should not be used in the face area but be channeled directly into the return airway.

Increased safety concerns, efficiency demand, and the need to operate several pieces of mining equipment simultaneously have caused this conventional mining method to fall out of favor, and it is slowly being replaced by the continuous mining method. In 2008, only 0.6% of all coal mined underground in the United States was mined using this method.

KEY AUXILIARY FUNCTIONS

To provide a highly productive mining environment while maintaining safety, a well-coordinated mining plan that incorporates several key support functions is critical. The top two such functions are effective ground control and proper face ventilation.

Ground Control in Coal Mining

Ground control is concerned with both the short- and long-term stability of mine accesses and entries as well as subsidence control. Although no method of roof control yet devised has proven to be universally acceptable for the wide range of strata conditions, perhaps the most significant development in coal mine ground control during the 20th century was the introduction of roof bolting in the late 1940s and 1950s (Figure 13.2-7). Being able to provide effective and efficient ground control is essential to ensure safety and productivity in underground coal mines.

The theory of the interaction between roof bolts and the rock strata is complex and several models are available: beam theory (roof bolts bind together several weak strata into one stronger "beam"), suspension theory (weak members of the strata are suspended from a strong anchor horizon), and the keying-effect theory (roof bolts act much like the keystone in an arch). All seem to be able to explain at least part of the support phenomenon under certain conditions.

From an engineering standpoint, roof bolts are inherently more effective than the wooden timbers they replaced, they greatly accelerated the transition to trackless, rubber-tired face haulage, and they significantly facilitated coal production in underground coal mining.

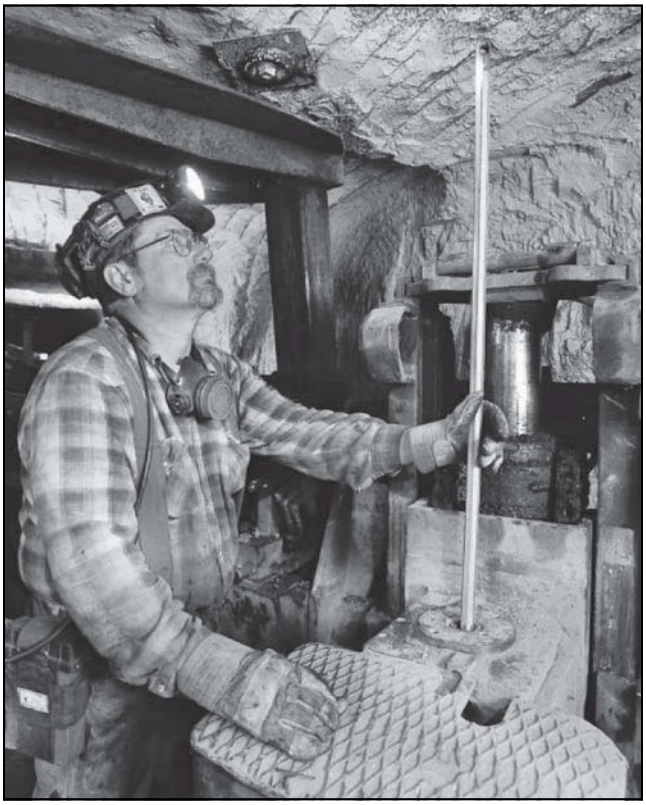

Figure 13.2-7 Roof bolting has become an integral part of the mining cycle

Steel bolts, usually 4–6 ft long and 0.6–1 in. in diameter, are inserted in holes drilled into the roof strata by a roof bolter and are secured as primary roof support by friction or resin. Various types of bolt systems are commercially available (frictional, tensioned, nontensioned, fully-grouted tensioned) and accepted by the United States and world mining industry.

The tensioned bolt system (also referred to as an active system) includes the conventional point-anchored mechanical bolt, a tensioned combination bolt, partially grouted tensioned rebar bolt, mechanically anchored resin-assisted bolt, partially grouted cable bolt, and so on. The nontensioned "passive" bolts include the fully grouted resin bolt and resin-anchored cable bolt. The fully grouted tensioned bolt combines the advantages of both the tensioned and nontensioned bolt. Roof channel, roof mat, roof pan, wire mesh, and shotcrete have also been used in combination with roof bolts for surface restraint. They are used to support small pieces of loose rock or as reinforcement for shotcrete, and the latter to provide support to the rock surface between bolts. Shotcrete provides the added advantages of reducing the rock exposure, thereby minimize weathering effects.

Today, all major mining countries have mandatory safety and ground control standards for underground coal mines. In the United States, specific regulations on roof support standards are set forth in Subpart C, Title 30, Part 75 of the Code of Federal Regulations (CFR 2010). Regulations stipulate that "no person shall work or travel under unsupported roof" underground, and "the roof, face and ribs of areas where persons work or travel shall be supported or otherwise controlled to protect persons from hazards related to falls of the roof, face or ribs and coal or rock bursts; no person shall work or travel under unsupported roof." Additionally, there are detailed regulations dealing with roof bolting, including installations, conventional roof support, pillar recovery, and automated temporary roof-support systems.

Source: Barczak 2005.

Figure 13.2-8 Cribs and steel plates used to reinforce roof support

Additional supporting systems, either temporary or permanent in nature to meet specific geological conditions, are commonly used. Wooden cribs or posts, trusses, cable bolt, steel set, and wire mesh or shotcrete have all been successfully applied in underground coal mines. Wooden cribs (Figure 13.2-8) are prop timbers or ties laid in alternative cross-layers (i.e., log-cabin style) to effectively provide significant reinforcement capacity over a large deflection range. However, crib support systems restrict airflow, generate floor heave, and permit large roof deformations that can lead to failure. In other words, they have to be used carefully.

Roof truss as a means of secondary or supplemental mine roof support has been receiving increasing acceptance in recent years, particularly in bituminous coal mines. In those entries where long life is required or doubtful performance from other forms of support seems likely, trusses in many cases have provided the necessary protection for continuing operations. Steel trusses employ a combination of steel rods anchored into the roof to create zones of compression and provide better support for weak roofs and roofs over wide areas.

The aforementioned roof bolts used to reinforce the roofs of mines, although effective, are relatively expensive and by definition inflexible. Cable bolts use strand cable coupled with properly designed couplings. These are not only more economical, they provide relative flexibility as compared to the steel bar. This support system has been recognized as an effective ground control system in underground coal mines.

Steel sets are also commonly used as long-term support of underground openings such as inclined mine entries, main travelways, belt entries, and so on. The operator generally connects the steel set with tie rods, inserts wood blocks between the arch sets as lagging, and backfills the voids between the

steel set and roof. Under some extreme geological conditions, yieldable arches are used to provide effective ground support in areas of excessive ground movement or faulted or fractured rock. They are designed such that when the ground load exceeds the design load of the arch as installed, yielding takes place in the joints of the arch permitting the load to settle into a natural arch of its own and thus bring all forces into equilibrium. The arch is often stronger after yielding than before due to increased joint overlap.

Ventilation

Proper ventilation is critical in any underground coal operation because of the presence of methane and coal dust as well as diesel particulate matters from diesel-powered equipment. Control of these hazardous pollutants has become increasingly challenging because of increasing mine sizes, coal production, and the use of diesel-powered mining equipment in recent years.

Engineering control techniques commonly used for ventilation purposes range from simple dilution with sufficient air quantity, water sprays and water additives, and local dust collectors to complex drainage systems to remove the gases prior to mining in many gassy mines. Nevertheless, dilution remains the most common method used. In general, the reduction in pollutants is roughly proportional to the increase in airflow; therefore, providing sufficient airflow underground remains the first priority in controlling the underground atmosphere.

However, providing the necessary additional air quantity can be difficult and expensive because, for a given fan pressure (H, in. water), the quantity of air (Q, ft^3/min) delivered is inversely proportional to mine resistance (R):

$$Q = \left(\frac{H}{R}\right)^{1/2}$$

where R is determined from the physical characteristics of mine airways: airway frictional factor, airway perimeter, air-traveling distance, and average airway cross-sectional area shown as

$$R = \frac{KOL}{5.2A^3n^2}$$

where K is airway frictional factor (lb·min^2/ft^4); O is airway perimeter; L is traveling distance, which increases with increasing mine size (ft); A is average cross-sectional area (ft^2), and n is the number of entries.

In general, R&P mining will have low mine resistance because of multiple (parallel) entries. However, this can be both advantageous as well as challenging; the air needs expensive channeling systems (continuous stopping lines and overcasts) to effectively "push" fresh air to the working faces.

In the United States, mines using the R&P method have always been laid out in a structured and hierarchical fashion—intake, return, and neutral (belt and track) airways are always clearly defined and grouped by stopping lines in all mains, submains, and panel layouts, as shown in Figure 13.2-2 (where all three intake, two neutral, and three return airways are separated by stopping lines.) A great number of overcasts (or undercasts) are used to separate the intake, neutral, and return airflows. The number of entries at an intersection will determine the number of overcasts (or undercasts) for effective air distribution. For example, as many as 16 overcasts at one single intersection may be necessary to fully separate a 7 × 5–entries intersection.

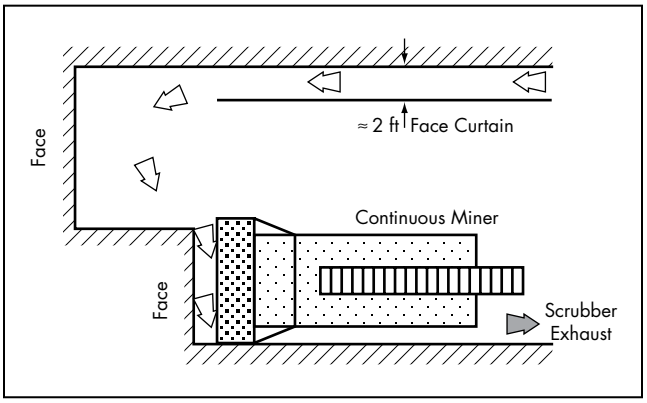

Figure 13.2-9 Scrubber at work

The power (AHP, or air horsepower) required to circulate a certain amount of air quantity (Q) under H (in. water) can be calculated using the following equation:

$$\text{AHP} = \frac{HQ}{6{,}345} = \frac{(RQ^2)Q}{6{,}345} = \frac{RQ^3}{6{,}345}$$

Alternatively, it is proportional to the cube of air quantity delivered. In other words, double the air quantity quadruples the mine pressure, which requires eight times the amount of energy compared to that needed before the change.

In the face area, U.S. federal regulation (CFR 2010) requires that 9,000 cfm of fresh air is to be delivered to the last open crosscut, properly installed face curtain (or brattice) in each individual heading used to push air to the deepest penetration, and check curtains must be designed to isolate the dusty air generated in the feeder breaker area from being blown to the face area, as shown in Figure 13.2-6.

Perhaps the most prolific success story in face ventilation since the 1980s has been the use of a machine-mounted flooded-bed scrubber (Figure 13.2-9). Flooded-bed scrubbers are devices installed on CMs to collect dust-laden air through several inlets near the front of the continuous mining machine. Inside the scrubber, the dust-laden air passes through a knit wire-mesh filter panel and is wetted with water sprays, where the dust particles are captured by the water. This filtered air then enters a demister where water is removed before the treated air is discharged at the back end of the miner.

Today, scrubbers are widely used on CMs in the United States and are highly successful in reducing coal dusts in the face area. Efficiencies for removal of respirable dust typically run from 90% to 95%, provided that screens are washed relatively frequently.

Many factors influence scrubber efficiency: scrubber capacity, face ventilation method (blowing or exhausting curtain or tubing), amount of fresh air reaching the beginning of the face curtain or tubing (a minimum of 3,000 cfm by regulation), ventilation setback distance (distance from the end of the face curtain or tubing to the deepest penetration), and CM location. Water-spray locations will also affect scrubber capture, with studies showing that by placing water sprays outby (away from the face), the scrubber inlets between the spray inlets and the rear end of the machine make these water sprays act as small jet fans. This arrangement will potentially induce additional airflow alongside of the machine and provide best results.

Another way to reduce dust includes displacement, which uses the airflow in a way that confines dust and methane sources and keeps them away from workers by forcing the dust and/or methane downwind of the worker. In addition, modifying the CM cutting cycles by leaving roof coal in place until it can be cut to a free face generates less dust and sometimes provides better extraction control.

OTHER ESSENTIAL AUXILIARY SERVICES

Other auxiliary operations are essential to the performance of an operating unit: coal haulage, power supplies, pumping, materials and supplies, stopping lines, and overcast construction.

A CM is not truly continuous but often only operates for less than half of the time, with the other half either employed for tramming (from location to location) or waiting for haulage vehicles to unload coal. Different methods have been used to minimize this nonproductive time in order to realize CMs' true production potential in the face area. The proper number of haulage vehicles for the face and an optimum distance between the face and the feeder breaker are the most commonly used measures to minimize a CM's waiting time. Face haulage uses either an electric-powered vehicle with an umbilical cable, rubber-tired shuttle cars, or battery-powered ram cars. Today it is common to use three haulage vehicles with well-planned travel routes to maximize efficiency, a compromise between optimum coal haulage and minimum congestion.

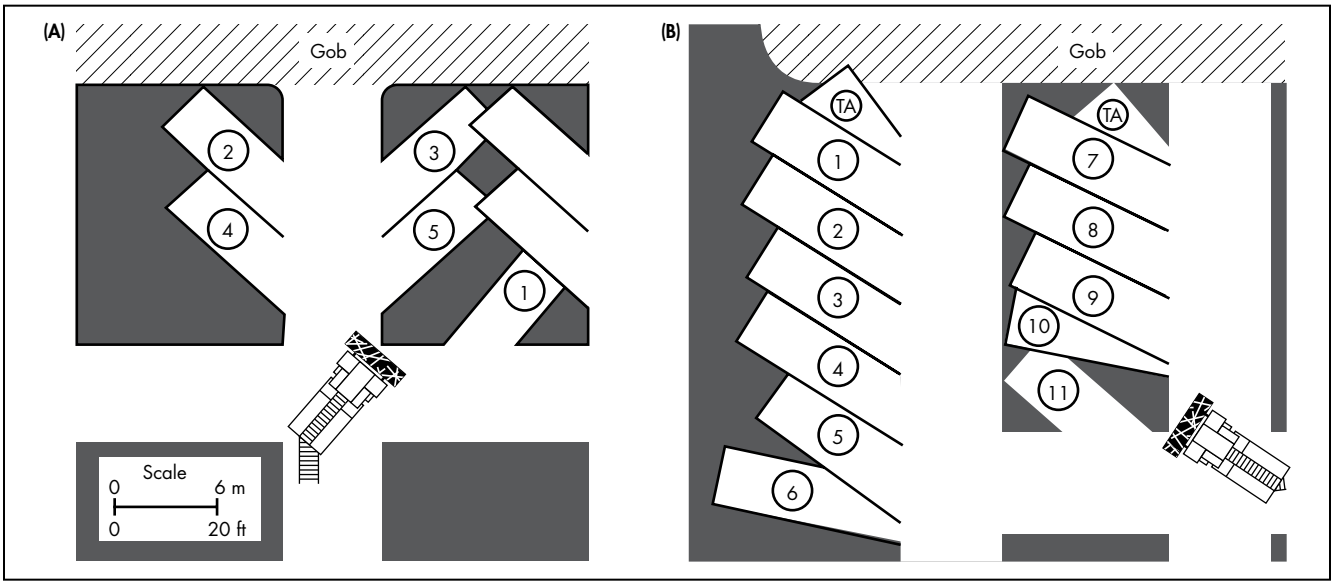
Flexible conveyor trains (FCTs) have also been used in some mines to minimize the CM's waiting time. They are electric-powered, self-propelled conveyor systems that provide continuous haulage of material from a CM to the main mine belt. The FCT uses a rubber belt similar to a standard fixed conveyor. The FCT's conveyor belt operates independently from the track chain propulsion system, allowing the FCT to move and convey material simultaneously. Available in lengths of up to 570 ft, the FCT is able to negotiate multiple 90° turns in an underground mine infrastructure, thereby greatly facilitating face haulage.

In addition to face haulage, proper planning is also critical to ensure an efficient haulage system to transport coal from the face area to the panel belt and ultimately to the surface through panel and main conveyor belts.

To prevent explosions from settled coal dust on the floor, rib and roof areas of mine entries are covered with pulverized limestone (inert) dust or rock dust. Studies show that during an explosion the rock dust disperses, mixes with the coal dust, and prevents flame propagation by acting as a thermal or heat sink (i.e., the rock dust reduces the flame temperature to the point where combustion of the coal particles can no longer occur). Under U.S. federal law (CFR 2010), all underground areas of a coal mine, except those areas in which the dust is too wet or too high in incombustible content to propagate an explosion, must be properly rock-dusted to within 40 ft of all working faces. Rock dusting is usually carried on a third or idle shift to not interfere with routine production.

In coal, methane drainage is still an art, but some of the drilling technology (e.g., directional drilling from both surface and underground) borrowed from the petroleum industry has been practiced at some gassy mines since the mid-1990s and has obtained quite satisfactory results; its performance is still continually being assessed.

PILLAR EXTRACTION



Only after careful review of pillar performance to date and pillar-extraction plans, and upon approval from regulatory agencies can coal pillars can be systematically removed after primary mining to maximize coal production. Some of the commonly used extraction methods are the "Christmas tree" or "split-and-fender" extraction methods. The former is favored because it does not require place changes and bolting. A third system is the "pocket-and-wing" method, which can fully extract large pillars. The general procedure is to extract one row of pillars at a time, leaving the mined-out portion, or gob, free to subside. Whereas extraction of all the coal in a pillar is a desirable objective, partial pillar-extraction schemes are more common. These are usually accomplished by CMs (or hydraulic mining with augers) driving into pillars according to predetermined extraction plans (Figure 13.2-10).

Pillar-extraction plans must be properly designed according to site-specific geotechnical and operational parameters (equipment and timber availability and cost, pillar dimensions, major geological features/structures, roof competency, seam thickness, extraction span or cavability, gob edge, and depth of cover) to ensure pillar stability during extraction. Case histories attributed to roof falls have found that both weak rock and competent immediate roof strata cause pillar failures. Hazards associated with pillar extraction also tend to intensify with depth; failures include both squeeze (nonviolent gradual pillar failures) and bumps, both of which are generally more severe at depth. Design of pillar-extraction schemes requires geotechnical input from specialists.

SYSTEM RATIONALIZATION AND OPTIMIZATION

Traditionally, coal productivity has always been measured by tons per workshift or similar measures based on total tonnage. Other factors such as size distribution, dust generation, and waste management also need to be considered at the planning stage to meet specific contractual demands and processing capacities at the surface preparation plant.

In the face area, CM cutting, loading and tramming capabilities, miner coal haulage, face layout, and so on must all be carefully planned and matched in order to achieve optimal overall efficiency. Materials handing still represents a significant component of the operational cost. A study on coal mining production costs in the United States (Chugh et al. 2002) shows that, of the total production cost, labor (with benefits) constitutes 47%, mining-related costs (supplies, maintenance, power, and other direct costs) uses another 29.5%, with the remaining designated to depreciation, taxes, and other expenses. Of this total production cost, half goes to face production, outby construction uses another 25%, coal processing and waste management uses 15%, and the remaining 10% is allocated to transportation. The same study indicates that face haulage is still the major bottleneck to productivity despite the use of more powerful high-voltage CMs. The study compares a Joy 14CM15 miner (995 V) with a high-voltage 14CM27 miner (2,300 V) in the Illinois coalfields. Results show that the high-voltage miner outperforms its counterpart in cutting and loading rate (by 29.89%), tons per car (by 8.64%), and tramming rate (7.84%), but they perform equally in tons per shift. (True productivity gains of the high-voltage miner were not fully realized because of the batch haulage system delays.) In most countries, the major impediment to productivity is still the time required to install roof supports.

SUMMARY

With its low capital investment and great flexibility, R&P mining continues to be an indispensible method in underground coal mining. In some cases it is the only method to access remnant parcels of coal that would otherwise be abandoned using longwall mining. It is also essential in gate road development in longwall mining, and under special circumstances, with proper planning, it may (in cost terms) even compete with longwall mining.

Although the basic methods of operation in R&P mining remain similar, there are a variety of systems with minor variations from location to location depending on local specifics. It is all a matter of system optimization—what would be an optimal number of entries or haulage method in one location may not be so in a different location depending on advance rates, ground control concerns, and dust and methane emissions that dictate ventilation practices. The optimum plan for a site is a trade-off of such factors. For example, the more entries, the higher the coal production, although at the expense of advance rate. On the other hand, fewer entries will cause congestion but will provide faster advances. Modern high-speed computers and simulation packages are ideal for modeling these scenarios for optimum performances.

A CM must be matched with a compatible haulage system in order to realize its full potential. Options could be a high-voltage miner matched with a continuous haulage system, a batch haulage system, or a surge car. Another benefit is that the high-voltage miner generates 43% less dust; using surfactants reduces that by an additional 6%.

Underground coal mining has always been a cost-competitive industry and will continue to be so in the foreseeable future. Results from continuing efforts to reduce production costs and/or increase productivity to stay competitive have been quite impressive. According to the U.S. Energy Information Administration (2010), in the period from 1949 to 1999 the underground coal productivity per worker-hour rose from 0.68 t/h (short tons per hour) to 3.99 t/h, a 587% increase, and to 4.04 t/h in 2004, a 594% increase from 1949 and a historical high. This rate decreased to 3.17 t/h in 2008.

The continuing improvement in equipment technology, system monitoring, automation, and system optimization in R&P mining make this method more productive and indispensible in underground coal mining.

CHAPTER 13.3

Shrinkage Stoping

Jack Haptonstall

INTRODUCTION

Shrinkage stoping is a vertical overhand stoping method in which most of the broken ore remains in the stope to provide a working floor for the miners. The broken ore also provides wall support until a stope is completed and ready for drawdown of the remaining ore.

In general, the method is used in steeply dipping (>50° dip) narrow ore bodies with regular boundaries. Ore and waste (both the hanging wall and the footwall) should be strong, and the ore should not be affected by storage in the stope. The method is labor intensive and cannot readily be mechanized. It is usually applied to ore bodies on narrow veins or to ore bodies for which other methods cannot be used or might be impractical or uneconomical. The method can be easily applied to ore zones as narrow as 1 m (3.1 ft), but it can also be successfully used for extraction of much wider stopes. The method is most efficient when drilling of the ceiling or back is done with uppers instead of horizontally.

Shrinkage stopes are mined upward in horizontal or inclined slices. Usually about 35% of the ore derived from the stope cuts (the swell) can be drawn off (shrunk) as mining progresses. As a consequence, no revenues can be obtained from the ore remaining in a stope until it is finally extracted and processed for its mineral values.

Logically, ore broken in a shrinkage stope should be free flowing, and broken ore should not pack or re-cement itself together. Neither the ore nor the adjacent country rock should contain undue amounts of clay or other sticky material that would cause the broken ore to hang together in the stope and make it difficult or impossible to draw. The ore should not readily oxidize, which may cause the broken ore pile to re-cement itself and consequently "hang up." Also, oxidation of the ore minerals may have an adverse effect on recoveries of values in subsequent beneficiation of the ore. To avoid mining excess amounts of waste as dilution from the stope back, ore developed for shrinkage stoping should be fairly continuous along the strike of the vein or ore body. In many cases, however, it may be possible to mine around waste areas and leave them in place as random pillars.

In designing for shrinkage stoping, consideration must also be given to the plunge or rake of the ore body, especially where an entire ore body or ore shoot may be mined as a single stope rather than as preestablished stope panels with defined vertical endlines. A stope with a shallow plunge or rake (<50°) may be difficult to mine by shrinkage methods because the ore moves away too quickly from the predeveloped extraction system, occasioning the need for additional development of the system. Further development, especially raising, is also often required when the ore abruptly extends beyond stope endlines.

Following is a summary of the parameters for the application of shrinkage stoping to a particular ore body (Boshkov and Wright 1973; Lucas and Haycocks 1973; Morrison and Russell 1973; Lyman 1982):

- **Ore characteristics:** The ore should be strong and nonoxidizing, should not pack or stick together, and should not spontaneously combust.
- **Host rock characteristics:** The host rock should be characterized by moderately strong walls that are free of clay or geologic structures such as faults, joints, and so on.
- **Deposit shape:** The deposit can be almost any shape, but it should have uniform, definitive boundaries.
- **Deposit dip:** The dip should be greater than the angle of repose (>39°) and preferably steeper than 50°.
- **Deposit size:** Width of the ore deposit should be narrow to moderate; the deposit can be of any length and height.
- **Ore grade:** Average ore grade should be moderate to high.
- **Production rates:** Production rates should usually be small to moderate.

Vertical longitudinal sections of typical shrinkage stopes are shown in Figures 13.3-1 through 13.3-3.

DEVELOPMENT AND PREPARATION

Areas selected for shrinkage stoping are generally developed by drifting in the vein or ore body on two levels that are spaced vertically at predetermined intervals that customarily

Jack Haptonstall, Mining Consultant, Pincock Allen & Holt, Lakewood, Colorado, USA

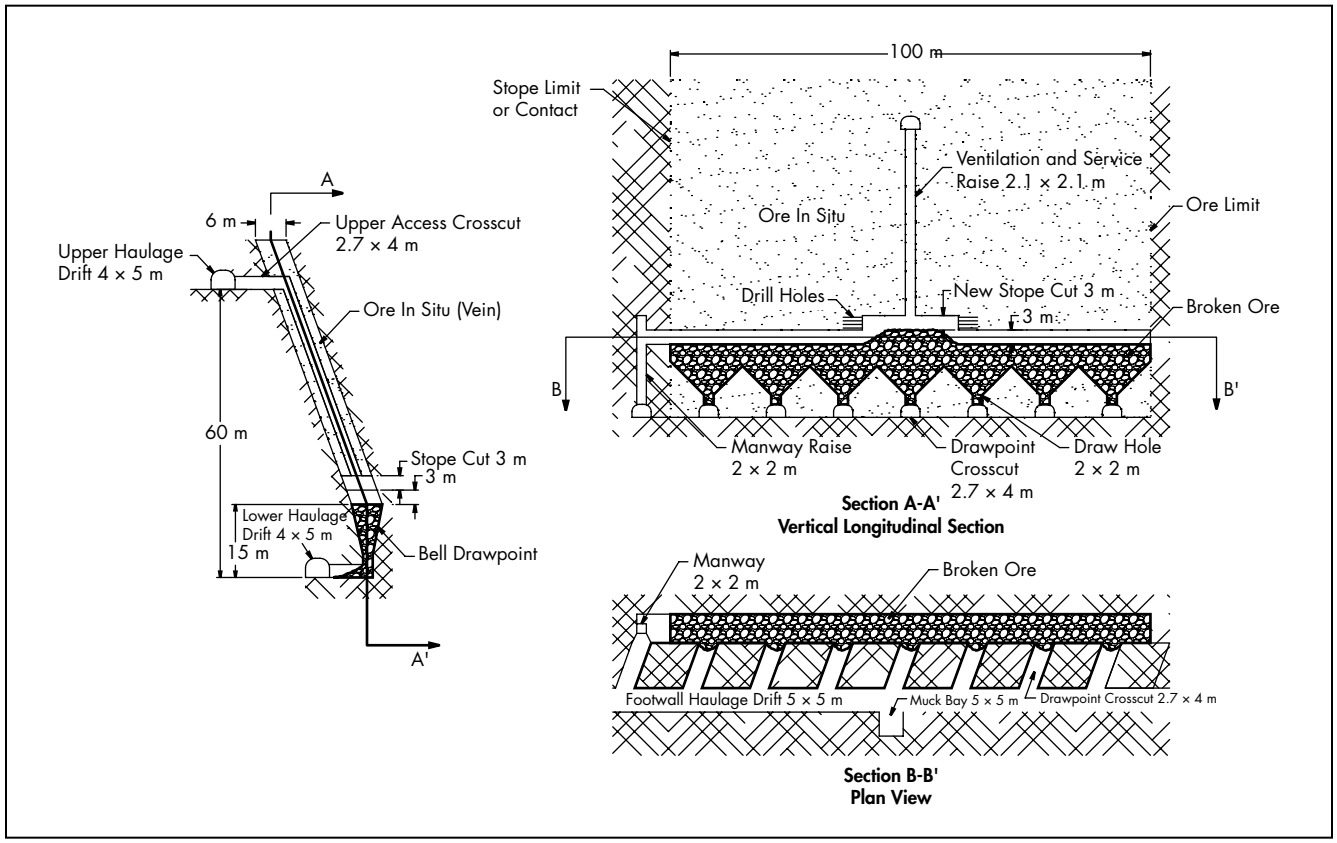

Figure 13.3-1 Idealized shrinkage stope with drawpoint extraction

vary between 30 and 180 m (100 and 600 ft). After a viable ore body has been established, the next phase is to develop one or more raises to establish vertical ore continuity and provide a ventilation opening and access to the stope. In some cases the raises are not developed, and access is only from the sill level below the stope.

Raising may be done conventionally with platform-type raise climbers or mechanically with raise-boring equipment. Drifting is normally done using conventional drill-and-blast track or trackless methods.

Stopes may be prepared with extraction raises on 7.6- to 9-m (25- to 30-ft) centers the full length of the stope block. Each raise is fitted with a chute (except for manways and/or service ways) that is normally of timber construction. Extraction raises are belled out and hogged over (mined over or excavated) to form the undercut for the start of the first stope cut (see Figure 13.3-2).

Another method used for preparing a stope is to blast down at least two cuts from the ore zone, clean up the broken ore, and install stull timbers or timber sets in the sill drift below the stope. Timber chutes or chinaman chutes are installed at approximately 7.6- to 9-m (25- to 30-ft) intervals as part of the timbering. A chinaman chute is a timber platform constructed below the caps of the timber sets; ore is shoveled from the platform into cars spotted below it.

Both of the foregoing types of stope preparation are still used, but on a very limited basis. A more common method for preparing shrinkage stopes in modern operations is to drive a sill drift along the vein or ore body as well as an extraction drift in the footwall of the ore zone and parallel to it. The footwall drift is normally situated about 7.6 to 15 m (25 to 50 ft) from the ore body. Subsequently, draw-hole extraction crosscuts are driven from the footwall drift into the sill drift on 7.6- to 15-m (25- to 50-ft) centers. The back of the ore body sill drift is then drilled and blasted down, and the swell is extracted via the draw holes, either with rail-mounted mucking machines or with load-haul-dump (LHD) units. See Figures 13.3-1 and 13.3-4).

Obviously, other variations for the preparation of shrinkage stopes have been used successfully. These may include preparation with short crosscuts into the waste footwall from the ore sill drift, driving finger raises back up to the ore and preparing the first stope cut from the finger raises. Another variation might be the elimination of the construction of chutes or drawpoint crosscuts and drawpoints, electing instead to extract ore from the ore sill drift with remotely controlled LHD units.

STOPING OPERATIONS

When an ore block has been developed for shrinkage stoping, a manway is usually constructed in the raise to the next level. One or more manways and service ways are usually constructed with timber on one or both ends of the stope. Often a timber slide is installed in one of the manways for hoisting and lowering supplies and equipment into and out of the stope; hoisting and lowering are often done with an air or electric single-drum (tugger) hoist, which is installed in the level below the manway. After the manways, ventilation raise(s), and service ways have been established for a stope, mining can commence.

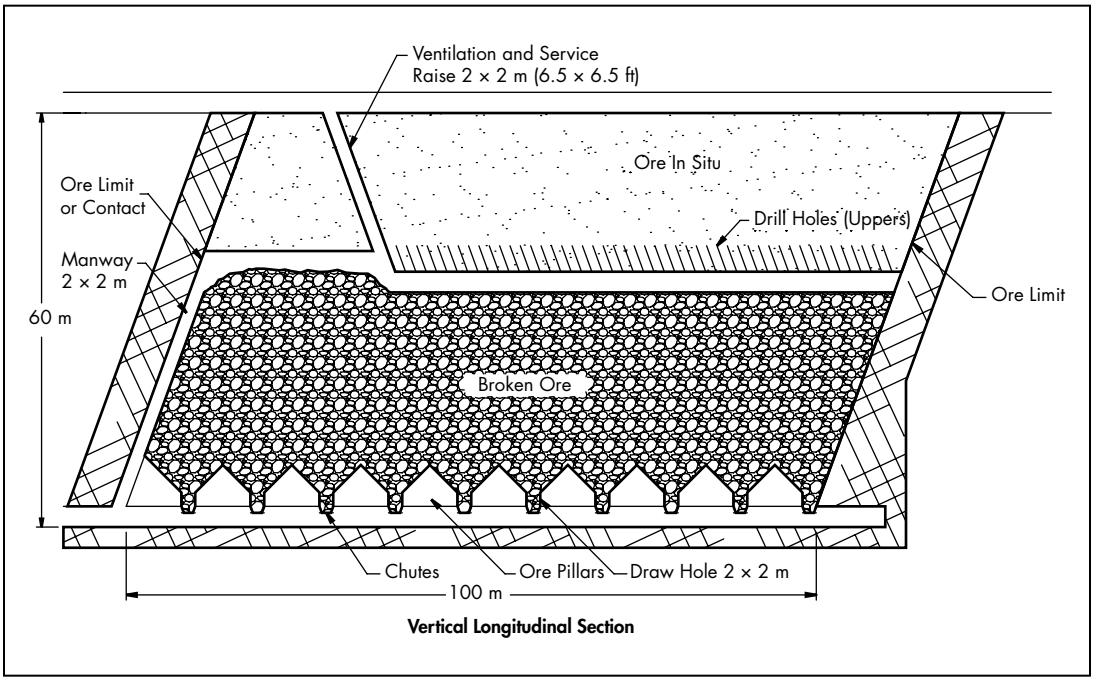

Figure 13.3-2 Idealized shrinkage stope with chutes

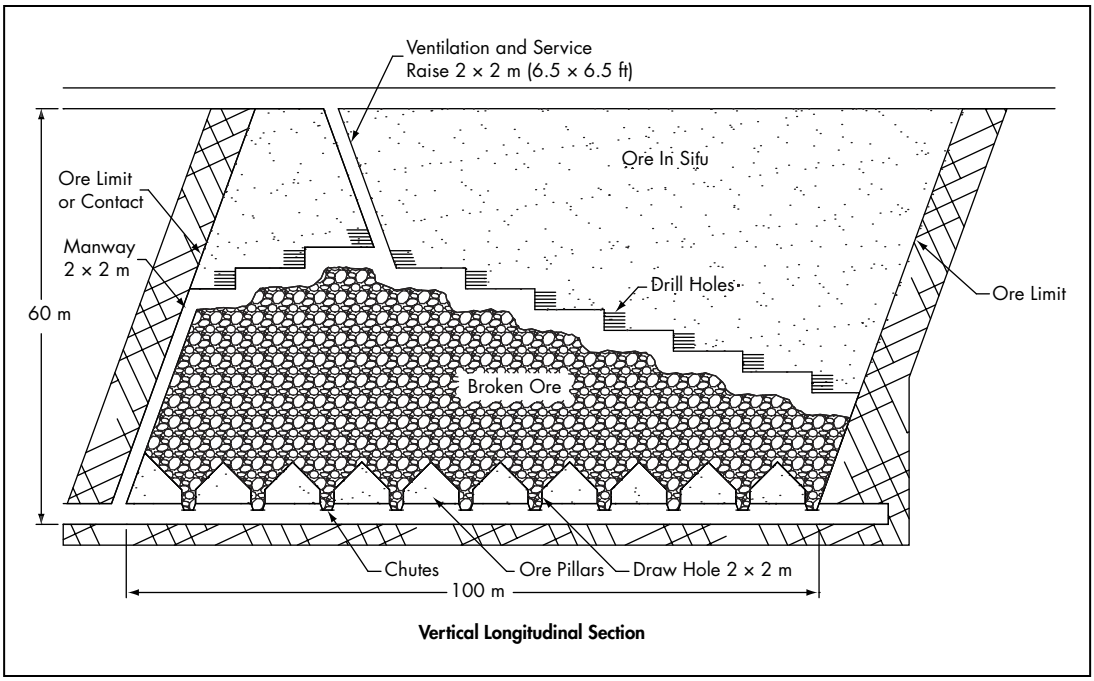

Figure 13.3-3 Idealized rill shrinkage stope with chutes

Drilling of a shrinkage stope back is usually done with handheld stoper or jackleg drills, although mechanized drill wagons or jumbos have been used in wide (>5.0 m [>16.4 ft]) stopes. Back stoping (vertical or near-vertical drilling) is the preferred mode of operation, but breasting down (horizontal drilling) is also common. Upholes are generally 1.5 to 2.4 m (5 to 8 ft) in length, and usually all drill holes are loaded and a complete cut is blasted simultaneously. Breasts are drilled with 1.8- to 3.0-m (6- to 10-ft) holes or normally are blasted once per shift. Drill holes are loaded with ANFO (ammonium nitrate and fuel oil) products, water gels, and slurry blasting agents. Primers are usually water gel sticks or dynamite, and holes are initiated using nonelectric, electric, or fuse-blasting systems.

After a cut or round has been blasted in a stope, drawdown (emptying out) of the 35% swell is necessary. Leveling of the muck pile is required as a next step to provide a work platform and facilitate drilling the next vertical or horizontal cut. Leveling of the ore in the stope can be done with hand

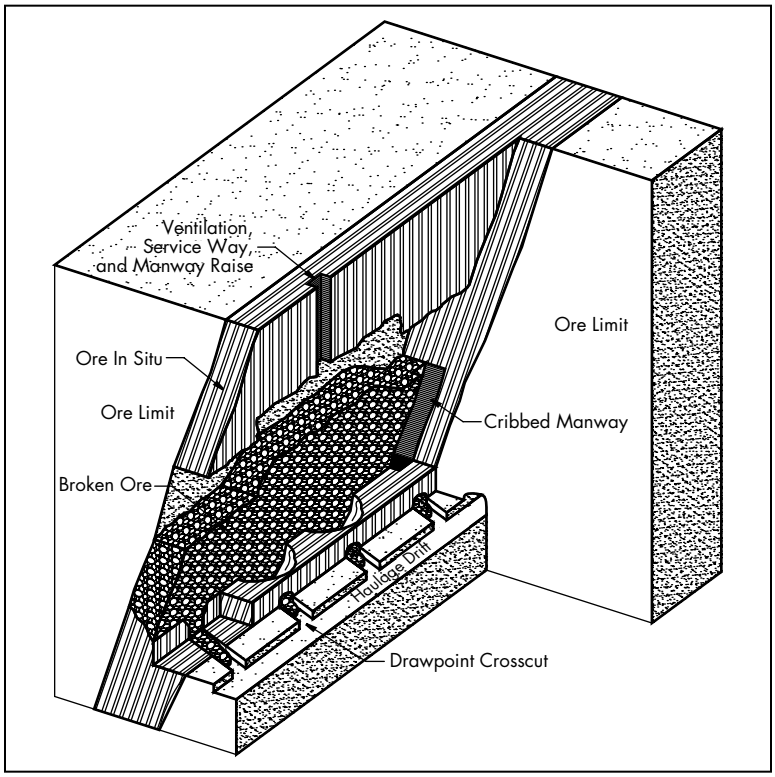

Figure 13.3-4 Isometric view of shrinkage stope with LHD drawpoints

shovels for small stopes, with two- or three-drum air or electric slushers for stopes that are longer and/or wider, and with LHD units for large stopes. After leveling, construction of manways and service ways and drilling of the next stope cut are done to continue the mining cycle.

Variations for establishing openings for manways, ventilation raises, or service ways may include strategically cribbed timber raises, steel culverts or rings, or even timber sets within the confines of the stope. These installations may be desirable during the mining phase but may create safety problems or nuisances during ore drawdown due to the collapse of the structures for these facilities. Pinning, stulling, or wedging these installations to the stope walls may prevent their destruction during drawdown. However, if the construction materials are dragged down with the broken ore, they can cause hang-ups in the extraction drawpoints or chutes.

A stope should have strong self-supporting walls to permit the application of shrinkage stoping. Excessive dilution through scaling of walls can preclude use of the method. Good mining practice and government regulations dictate a minimum ground support program for stope extraction. Shrinkage stoping has inherent dangers, merely because workers must be in the excavated area to drill, load rounds, and install ground support and stope services—all while standing on a broken ore pile. Many serious accidents have occurred when voids in the broken ore pile suddenly collapsed, dragging miners and equipment down into the void. In other cases, a chute or draw hole over which miners were working had mistakenly been pulled, with the same result. The requirement that miners use safety belts in a stope may reduce the danger, but it also reduces the workers' flexibility.

Ground support is usually minimal in shrinkage stopes, especially when the method is applied in areas of a vein or ore body that are steeply dipping, have strong ore and wall rocks, and have few structural features (e.g., faults, fractures, or joints) in the walls or within the vein or ore body. However, modern mining practice is to err on the side of safety, and so in most cases ground control is a primary function. Rock bolting of stope backs and ribs with mechanical or grouted rock bolts is the preferred method of ground support in shrinkage stopes. However, in very narrow stopes (e.g., <2.0 m [<6.6 ft] wide), correct installation of bolts in the walls is quite difficult because the bolts must be placed perpendicular to the planes of the hanging wall and footwall. More often than not, bolts in narrow stopes are installed at acute angles to the walls, which diminishes the effectiveness of the installations. Stulling of the ribs and back is still practiced; recent South African innovations in stull installation have made it a much more attractive option.

Stulling is simply the installation of timber props from wall to wall or floor to back. Typically, a board headpiece is inserted between the head end of the stull and the rock hanging wall, and the stull is secured by pounding wedges between the rock footwall and the butt end of the stull. In the past, the butt ends of stulls were almost always installed in a hitch cut from the rock with a hammer and chisel. The invention of the Jackpot headpiece has resulted in efficiency improvements in the installation of stulls. The Jackpot is a hollow steel can that fits over the butt-end of a timber stull and is pumped up hydraulically to pressurize the stull against the ribs or back of the stope. The unit eliminates the need to cut a hitch in rock to accommodate the stull, cut the stull to a precise length, and then try to tighten the installation with wooden headboards

and wedges. Leaving pillars in areas of low-grade ore or waste within the stope boundaries is a very acceptable approach to supplementary wall support. The pillar should be shaped in such a way that ore does not remain on top of it on drawdown of the stope.

Sampling of narrow shrinkage stopes is usually done by taking either channel or chip samples at systematic intervals (e.g., 1.5 m [5 ft]) from the stope back, ribs, or face. Samples are usually taken by hand; sometimes mechanical means can be applied in the process. When high sulfides are present, X-ray analyzers can be used for sampling. In wider stopes, drill sampling of the back and ribs can be done. The drill sample holes may crisscross the stope back according to a predetermined pattern and may also be drilled into the stope walls. Drill cutting samples are collected in a canvas sample bag or other container through a hose and funnel or other device.

STOPE DRAWDOWN

Shrinkage stope drawdown usually results in a consistent and steady supply of ore to the process plant and/or mine stockpiles. If a mine has several shrinkage stopes in various phases of the mining cycle, there is no reason the ore flow to the plant or stockpiles should ever diminish after completion of the initial stopes in the mine plan. Maintaining a steady ore flow from shrinkage stoping is largely dependent on engineering the optimum production rate for a given operation.

Completed stopes can be drawn down from strategically placed chutes and from drawpoint crosscuts, or they can be remotely mucked with LHD units. In some mines, slusher trenches developed below the stopes have been used effectively to remove broken ore from shrinkage stopes. Haulage from the stope extraction points can be done using trackbound or trackless equipment. Chutes should be robustly designed and well constructed to ensure that they will not be destroyed during the extraction phase.

Shrinkage stopes usually should be drawn down evenly so that if the stope walls do peel or slough, the waste material remains atop the pile and does not add dilution to the broken ore. After a stope drawdown has started, ground control of the walls, pillar recovery, ore hang-ups, and so on, is minimal. Reentry of miners into a stope during the drawdown phase is not recommended.

One of the most dangerous jobs in a mine is the drawdown of shrinkage stopes, especially where the ore contains blocky or sticky material that may cause the broken ore to hang up in the stope. Stope hang-ups are often removed by washing them down with water, by destroying them with explosives, or by blowing them down using high-pressure air (blowpipes). In the past, miners entered completed stopes to pick them down by hand, but as has been stated previously, this is unsafe and not recommended.

A summary of the advantages and disadvantages of the shrinkage stoping method is shown in Table 13.3-1.

VARIATIONS AND APPLICATIONS

Variations of shrinkage stoping include inclined or rill shrinkage and long-hole shrinkage. Large pillars or small isolated ore blocks may sometimes be recovered using shrinkage methods. Certain underground openings, such as short shafts, may also be excavated using shrinkage methods.

A mine that employed shrinkage stoping as a primary mining method was the now closed Homestake gold mine in Lead, South Dakota (United States). The Homestake ore bodies were mainly fracture fillings situated in the limbs of folds. “Bullpen” stopes (i.e., fixed-minimum-width shrinkage stopes laid out in a transverse direction to the long axis of a large ore body) 15 m (50 ft) wide were developed across the great Main Ledge ore body. Stopes were mined over timbered sills, where strategically located chinaman chutes were constructed for ore extraction. Stopes were mined overhand for about 21.5 m (70 ft) to within 9.1 m (30 ft) of the next level. Ore pillars 7.6 m (25 ft) thick were left between the primary stopes, and these, along with the crown pillars left over in the primary stopes, were subsequently extracted with square-set stopes. Homestake abandoned this type of shrinkage stoping just before World War II.

A second example of large-scale shrinkage stoping is the shut-down Idarado mine located between Ouray and Telluride in Colorado (United States). The Idarado ore bodies were mainly steeply dipping veins with excellent ore continuity. Shrinkage stopes were mined along the veins’ full width, spans that varied between 1.5 and 7.6 m (5 and 25 ft). The consistent ore continuity permitted the mine planners to divide the veins into stope panels generally 122 m (400 ft) long and about 61 m (200 ft) high. Panels were prepared over a slusher trench situated about 6.1 m (20 ft) above the primary on-vein drift. Raises on 7.6-m (25-ft) centers, developed from the slusher trench, were belled out and interconnected above the slusher trench to form the opening for the first stope cut. Ore extracted from the stope was slushed from the extraction raises to a chute in the exact center of the stope. The Idarado operations were closed in 1979.

Variations on the Idarado system were practiced at the Morococha and Casapalca mines of the Cerro de Pasco Corporation in the Andes Mountains of central Peru in South America and at the Tayoltita mine in the state of Durango, Mexico. Stopes in these mines were prepared conventionally over the main on-vein development level by driving 7.6-m- (25-ft-) long raises on 7.6-m (25-ft) centers. The raises were belled out to form the opening for the first stope cut about 5 m (16 ft) above the main level. On completion of this step, each raise was fitted with a timber chute for ore extraction. (See Figures 13.3-1, 13.3-2, and 13.3-4.)

In all of these examples, a raise was first developed through each ore block or stope panel for ventilation, manway, and service way. Manways from the sill level were carried as timber-cribbed raises within the stope, as stulled and lagged raises on the ends of a stope, or—as in the case of the Idarado mine—as boreholes located 3 m (10 ft) inside the footwall of the stope. In the vein mines, drilling was done with pneumatic handheld stopers or jackleg drills, whereas in the Homestake mine, drilling was done with bar-and-column Leyner-type drills.

The terms *inclined shrinkage* and *rill shrinkage* refer to an application in which multiple faces or benches for drilling are carried along the back of the stope as it is mined upward (Figure 13.3-3). This system was common practice at the Pachuca mine in the state of Hidalgo, Mexico. Stopes were developed conventionally over pillars as described previously, and chutes on 7.6-m (25-ft) centers were installed on the extraction raises. Pachuca miners preferred to use jackleg drills rather than stopers, and with the rill system multiple faces were available for breast stoping in a given shift (see Figure 13.3-3).

Table 13.3-1 Advantages and disadvantages of shrinkage stoping

Advantages	Disadvantages
Shrinkage method is easily adapted to narrow veins.	Method requires steep dip (>60°).
Stopes do not require backfill.	Method requires strong ore and walls.
Stope extraction system is usually simple.	Stoping is labor intensive and efficiencies are low at about 3 to 9 t (3.3 to 9.9 st) per worker-shift.
Stope drawdown provides a steady, consistent supply of ore.	Only 35% to 40% of ore is available for extraction during mining cycle.
Application of method requires a minimum investment in equipment and machinery.	Very little mechanization of stoping is possible.
Stope development is uncomplicated and minimal.	Excessive clay or oxidation of ore may result in stope hang-ups or problems in ore dressing.
Reasonable selectivity is possible.	Ground control is sometimes difficult to install.
Ground support of ore and walls is minimal.	Risk exists of losing stope if drawdown is not properly controlled.
Gravity aids drawdown of stopes.	Mining costs are usually moderately high to very high.
Mining recovery is good (75% to 100%).	
Dilution is low (0% to 20%).	

Source: Morrison and Russell 1973; Lucas and Haycocks 1973; Hamrin 1982; Lyman 1982.

Long-hole shrinkage (Figure 13.3-5) is developed in the manner previously described. The method was applied with limited success at the Stillwater mine near Nye, Montana (United States). In this method, drilling of the stope block is done from vertical raises driven through the ore block or panel on 15- to 30-m (50- to 100-ft) centers. Raises in this application are preferably developed with raise climbers or with cage raising techniques. The raise climber platform or the cage serves both as the entry/exit vehicle for the raise and the platform from which to drill and blast the stope block. Long holes are drilled from the raise, parallel with the strike of the ore zone, and these are also loaded and primed from the climber or cage platforms. Initiation of the stope blast is done from a safe area on the service level below the stope.

Shafts, winzes, or other large underground openings may be developed through shrinkage methods. Often these excavations are done as described previously for the long-hole shrinkage application. In certain situations, conventional shrinkage of a shaft, winze, or other excavation may be necessary.

SAFETY, EFFICIENCIES, AND COSTS

Shrinkage stoping has largely been discontinued in most countries because it has numerous safety hazards, is very labor intensive and largely inefficient, and is generally expensive. Coupled with these reasons is that more than 60% of the mined ore remains in the stope until stoping is completed, which may take many months and sometimes even years. During this period, amortization of the investment required to develop and mine an ore block by shrinkage stoping may outweigh any advantage in applying the method to a particular operation (see Figure 13.3-5).

Typically, the efficiencies in a modern shrinkage stoping operation are in the range of about 0.3 to 1.2 t (0.3 to 1.3 st) per worker-hour. In western operations, very few miners have experience in the development and operation of shrinkage stopes, but the method is still widely practiced in Latin America and in developing countries elsewhere in the world.

Costs in a typical North American shrinkage operation are currently on the order of US$25 to US$50/t (US$55/st), with more than 50% of the costs assigned to labor. Operations in Latin America or Asia may enjoy lower costs because labor is less expensive, but efficiencies are generally not equal to those of North American operations.

CASE STUDY: EAGLE RIVER MINE

The Eagle River gold mine is owned and operated by Wesdome Gold Mines of Toronto, Ontario, Canada. The mine is located near the northeast corner of Lake Superior, 50 km (31 mi) west of the town of Wawa, Ontario. It is accessible by gravel roads connecting Trans-Canada Highway 17 near Wawa to the site.

The Eagle River mine has been in production for about 12 years. Historic production from the mine is about 22,900 kg (711,000 oz) of gold from mining and processing about 2.4 Mt (2.64 million st) of ore. The mine is currently being operated at a production rate of 100,000 t (110,000 st) per year.

Geology

The Eagle River ore deposit occurs in the Mishibishu greenstone belt, which is a broad arcuate belt about 60 km (37.2 mi) long and 18 km (11.1 mi) wide. The area in which the Eagle River deposit occurs contains magnesium-rich tholeite, calc-alkaline andesite, dacite, and minor rhyolite. The ore occurs within shear-hosted near-vertical quartz veins that have mineable widths of 1.5 to 7.5 m (4.9 to 24.6 ft). The ore zones of the Eagle River mine are of a series of quartz lenses that to date have been traced over a strike length of 2.5 km (1.5 mi) and a depth of 650 m (2,132.5 ft). At least four distinct ore zones or shoots have been developed, and these vary in length from 50 to 250 m (164 to 820 ft).

Ore Reserves and Mining Method

Proven and probable ore reserves at the end of 2007 were 253,000 t (278,300 st) at an average grade of 12.9 g gold/t (0.37 oz/ton). The mining method, formerly all shrinkage stoping, was changed to long-hole stoping in 2000.

Details regarding shrinkage stoping are as follows:

- Stope heights are 100 m (328 ft) with drawpoint scoop-tram/truck mucking and hauling.
- Two raises with doghole accesses are driven on the boundaries of ore blocks, which can be up to 100 m (328 ft) long.
- Two people work a stope, breasting toward the middle. Breasts are 2.5 m (8.2 ft) high and 3 m (9.8 ft) long and fill a void measuring 3.5 m (11.4 ft).
- Uppers at one end of a stope provide the start for the next lift.

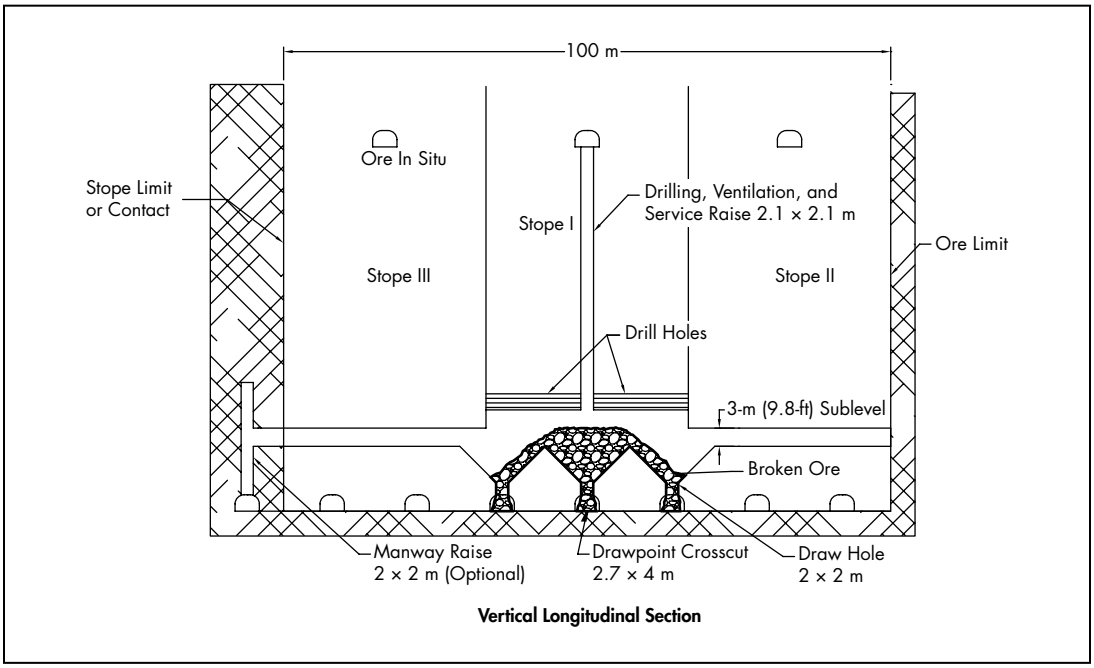

Figure 13.3-5 Idealized long-hole shrinkage stope

- Dogholes are staggered at 10-m (32.8-ft) intervals in both access raises. No stull timbering is required. Ladders provide access from dogholes, at least one of which is always available because of stagger.
- Productivity is 15 t (16.5 st) per worker-shift.

Details regarding long-hole stoping are as follows:

- Sublevels are spaced at 15 m (49.2 ft); jackleg and slusher subdrifts are driven from a central mill hole.
- Slot raises are developed as drop raises.
- Drill holes are 50-mm- (2-in.-) diameter downholes on a 3×3 m (9.8×9.8 ft) pattern.
- Productivity is 40 t (44 st) per worker-shift.
- Retreat mining is practiced with haulage and drawpoints on main levels spaced at 60-m (196.8-ft) intervals.

Equipment, Productivity, and Costs

Equipment includes 3.8-m^3 (5-yd^3) diesel LHD units, 25-t (27.5-ton) trucks, two-boom drift jumbos, scissors lifts, raise climbers, jacklegs, and stoper drills.

Productivity is about 15 t (16.5 st) per worker-shift in stopes. The shrinkage mining cost is unavailable. The long-hole mining cost is about US$40/t (US$44/ton).

SUMMARY

The labor intensity of shrinkage stoping as well as the limited mechanization possible for the method precludes its wide-scale application in most modern mining operations. However, in some applications, the method may be appropriate—for example, in a mine in which the ore occurs in very narrow veins and cannot be economically extracted using other methods.

CHAPTER 13.4

Sublevel Stoping

Rimas T. Pakalnis and Paul B. Hughes

INTRODUCTION

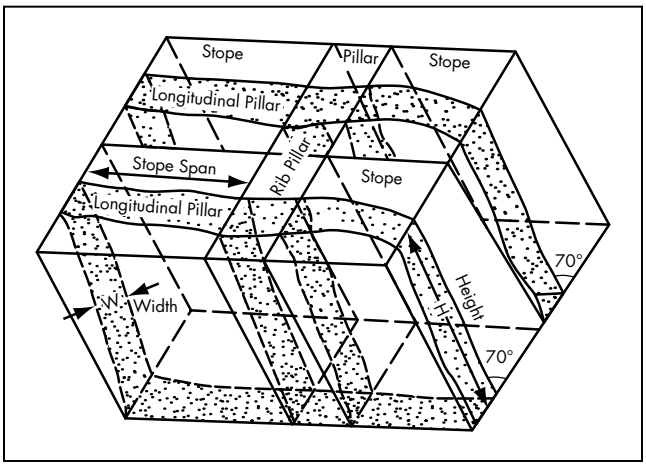
This chapter refers to the generic mining method of sublevel stoping. The most commonly used sublevel stoping mining methods are sublevel open stoping, long-hole open stoping or blasthole stoping, and vertical crater retreat (VCR). Variations of this method include vein mining, transverse stoping, Avoca, longitudinal, and other less-used methods such as slusher mining of uppers. The shrinkage stoping method is also a variation of sublevel stoping and is discussed in Chapter 13.3.

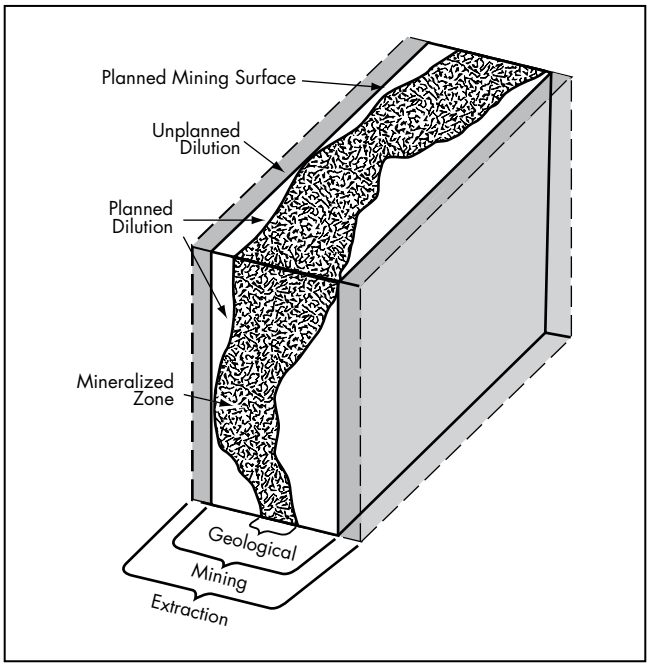
Definitions

Following are definitions of general terms for this mining method, also shown schematically in Figure 13.4-1.

- **Span:** The length of the stope along the strike.
- **Width:** The perpendicular distance between the footwall and the hanging wall.
- **Height:** The distance along the exposed hanging wall and not the vertical height between levels.
- **Longitudinal pillar:** A pillar aligned along the strike of the stope.
- **Rib pillar:** A pillar aligned transverse of the stope, perpendicular to the strike.
- **Sill pillar:** Horizontal pillars that separate levels or stopes.
- **Dilution:** The reduction of ore grade due to mixing of ore with barren rock.
- **Internal dilution:** Rock that must be mined because of the geometry of the ore body and the requirement to mine rectangular areas. The term is synonymous with *planned dilution.*
- **External dilution:** Dilution caused by sloughing or failure of stope walls and back and is outside the blasted stope boundary. External dilution is defined as the external waste tonnage divided by the ore tonnage. The term is synonymous with *unplanned dilution*.

Sublevel stoping, in the absence of consolidated fill, employs pillars to separate the individual stopes to reduce the potential for wall slough. Sublevel stoping requires a straight/linear layout of stope and ore boundaries. Inside of the stope, everything is ore with no chance of recovering small mineralization in the wall rock. This method requires knowledge of the ore boundaries as shown in Figure 13.4-2.





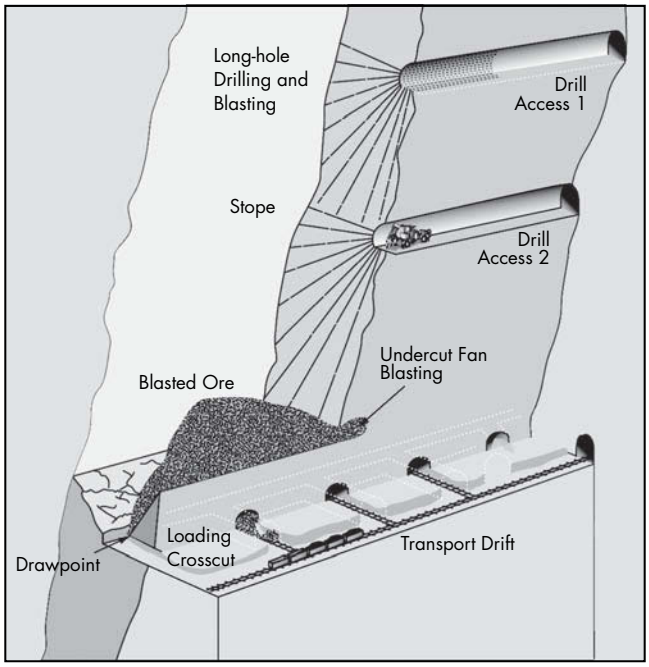


Figure 13.4-1 Terms used in sublevel stoping

Sublevel stoping with no fill is a mining method in which ore is mined and the stope is left empty. The result is a large void that requires individual pillars be placed to separate the stopes. Sublevel stoping is largely restricted to steeply dipping ore bodies (50°–90°) with a competent hanging wall (HW) and footwall (FW). Figure 13.4-3 shows the general approach to sublevel stoping whereby ring drilling is used from levels generally spaced ~20 m apart in a vertical dimension. Level spacing is largely limited by the length of the production holes, which range in diameter from 50–75 mm and maximum lengths of 25 m. This can be modified if in-the-hole (ITH) drills or top hammer tube drills are used. Characteristic with the sublevel stoping method are the intermediate levels, which largely differ from long-hole (blasthole) stoping as depicted in Figure 13.4-4 where the intermediate level has been removed. In sublevel stoping the mining is accomplished from individual levels at predetermined vertical intervals. These intervals are largely governed by

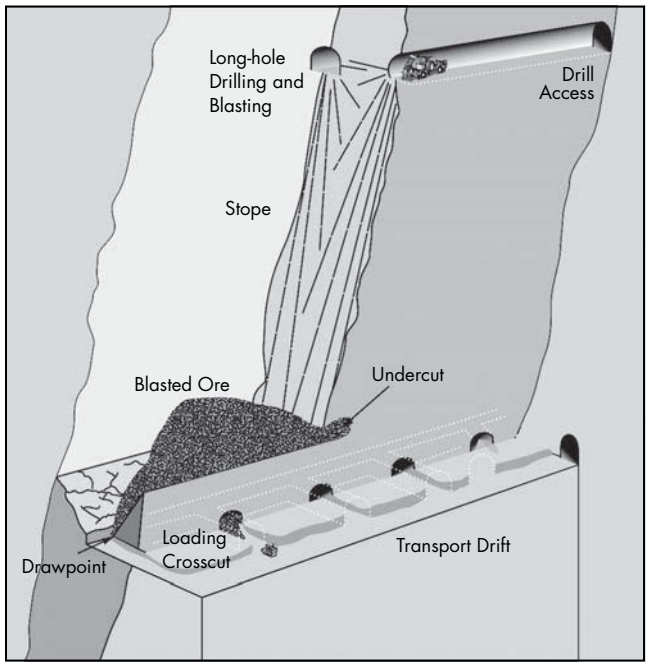
Figure 13.4-2 Defining dilution

Source: Hamrin 2001.
Figure 13.4-3 Sublevel open stoping

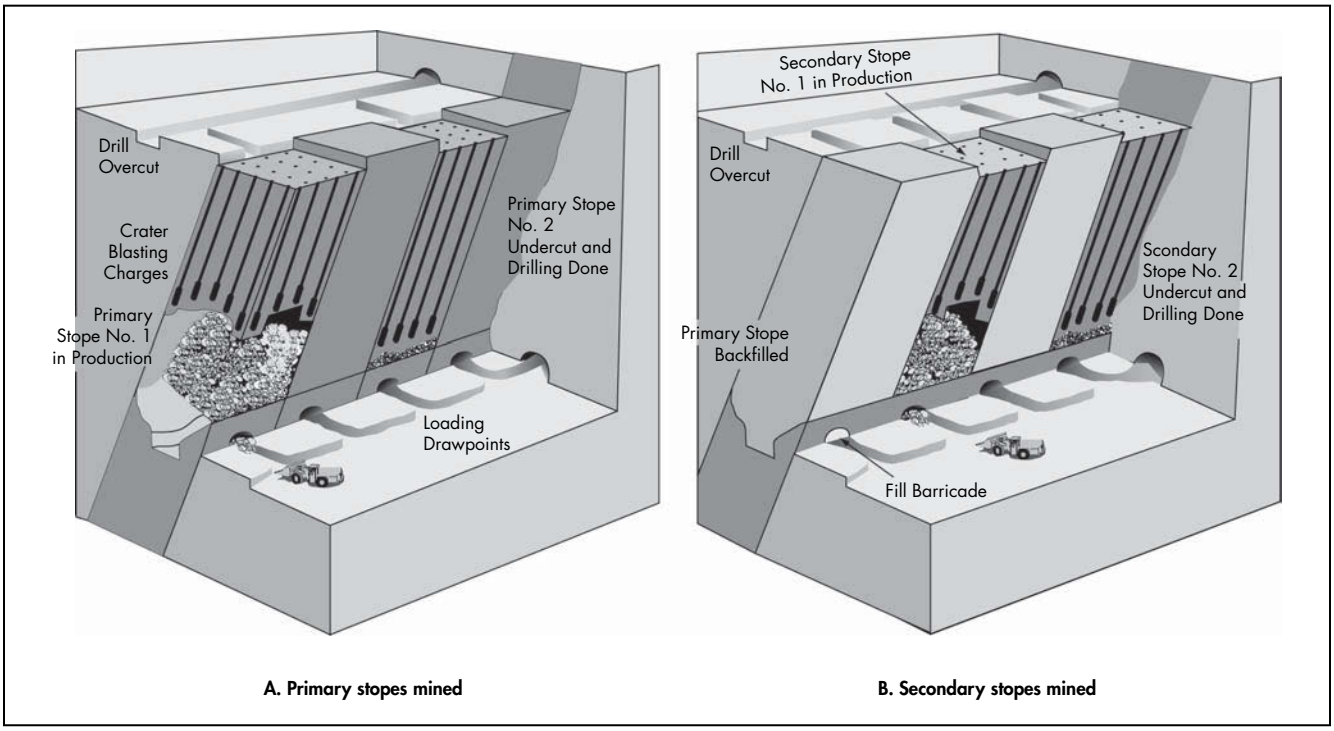
- Ore geometry, in order to minimize internal dilution by enabling the extraction of irregular ore bodies,
- Rock mechanics constraints in terms of minimizing the external dilution through wall slough, and/or
- Operational restrictions such as drilling equipment constraints.



Sublevel and long-hole methods require blasting into a "vertical slot/free face," whereas a VCR, shown in Figure 13.4-5, differs in terms of blasting to a horizontal free face, which is largely confined due to the muck remaining within the stope as only the swell is drawn.

Variations of the sublevel method include narrow vein mining/Alimak, Avoca, longitudinal, sublevel retreat, and transverse stoping, as well as historical methods such as slusher and track mining (Haycocks and Aelick 1998).

SUBLEVEL STOPING REQUIREMENTS AND CONSTRAINTS



The following variables must be addressed in sublevel stope designs:

- **Size:** The minimum width generally ranges from 3 m to 6 m; however, in isolated cases it reaches 1.5 m (Clark and Pakalnis 1997) and lower (0.8 m). The width is governed by the production blast pattern, which, with the use of 50-mm blastholes, is typically 1.2 × 1.2 m, and the stope layout is based on this spacing (Figure 13.4-6).
- **Shape:** The shape is preferably tabular and regular in shape from level to level.
- **Dip:** The dip is preferably greater than the angle of draw, which typically is in excess of 50° in practice. The concern also is that a shallow hanging wall dip will result in a less-stable HW configuration because of gravity influences and increased wall exposures between vertical stope horizons, all resulting in increased potential for external dilution.

Source: Hamrin 2001.
Figure 13.4-4 Long-hole or blasthole stoping

- **Geotechnical:** This requires a moderate to strong ore strength and generally a competent HW-FW as these will be exposed and affect the level of external dilution. The ore will determine the potential pillar sizes, hole squeeze, and block size that affect production stope productivity (Pakalnis 2002).
- **Stope spans:** Since this is a nonentry method, stope spans can be larger. The span should be designed to control

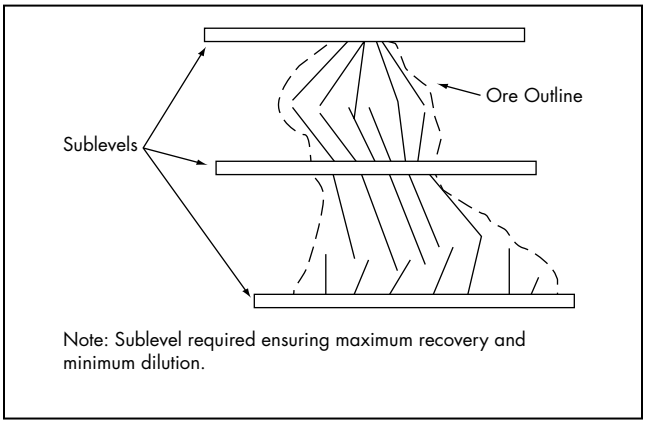

Figure 13.4-7 Geometric constraints

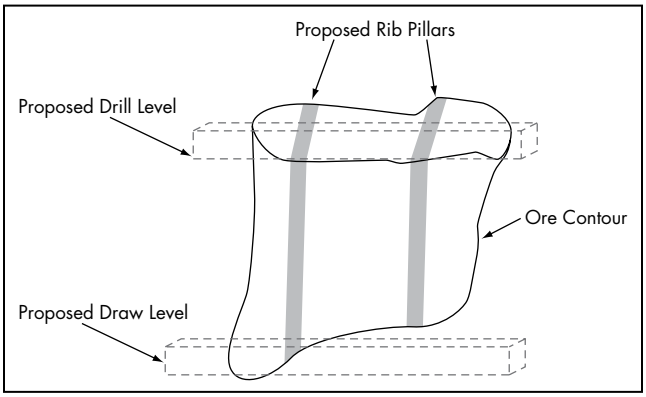

Figure 13.4-8 Initial stope planning

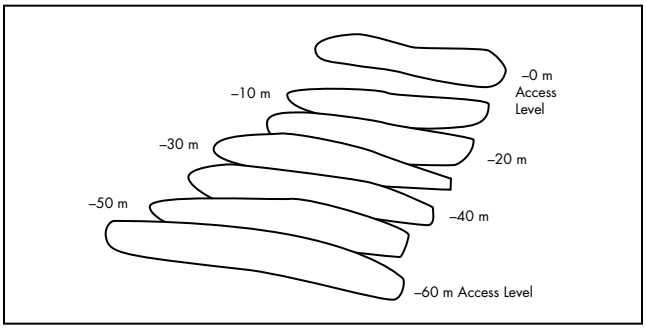

Figure 13.4-9 Composite plan section of ore body used to design blast layout

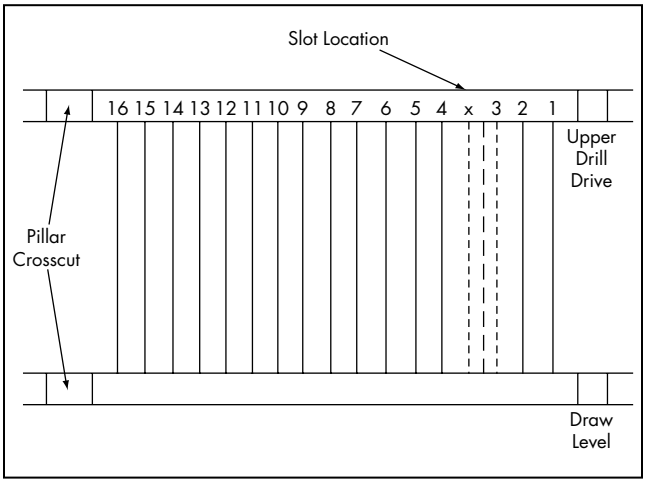

Figure 13.4-10 Longitudinal section of blasthole layout

external dilution and avoid stope collapse and air blast. Span length is governed by HW rock mass quality and generally is in the range of 30+ m with the stope height (inclined) in excess of 30 to 60+ m.

- **Pillar size:** The purpose of the pillars is to support the crosscuts and divide up the stopes. The size of the pillars is dependent on induced stresses, structure, rock mass, and operational constraints.
- **Selectivity:** Selectivity is limited because waste zones can be incorporated as pillars. Changes in ore-body geometry outlines are difficult to address unless the ore body narrows to the next pillar or sublevel where the drill pattern can be modified (Figure 13.4-7).

DESIGN CONSIDERATIONS FOR SUBLEVEL STOPING

General Design Guidelines

The design of a sublevel stope starts with an engineered layout that incorporates the geometry of the stope, stope span, stope height, pillar dimensions, drill levels, and draw levels (Figure 13.4-8). This layout is then superimposed upon the ore contours (plan) as defined from the upper drill drive to the lower draw level horizon. The example shown in Figure 13.4-9 is a schematic of a 60-m long-hole stope (151-mm blastholes) with geologic contour intervals shown every 10 m in the plan.

The resultant longitudinal composite is shown in Figure 13.4-10 employing a ring burden (distance between drill rings) of 3 m from pillar/stope boundary to pillar/stope boundary.

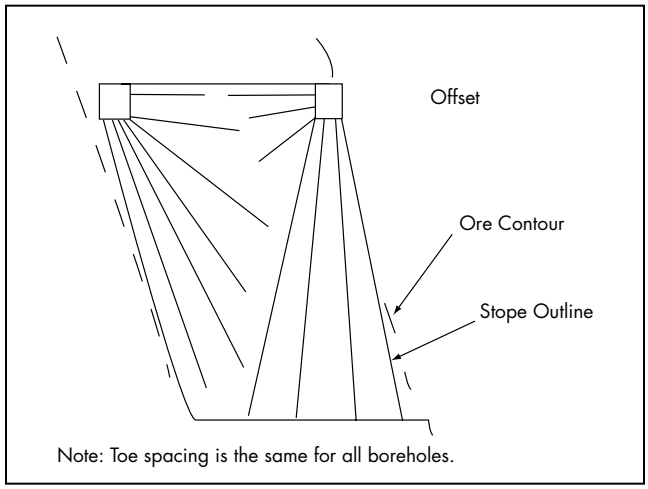

Figure 13.4-11 Ring section

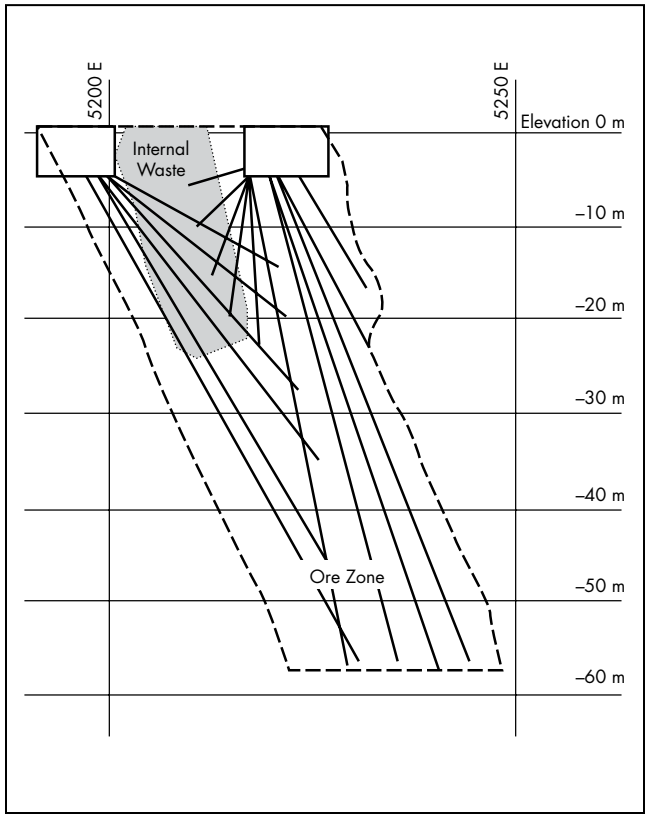

Figure 13.4-12 Engineered ring section, looking north (example)

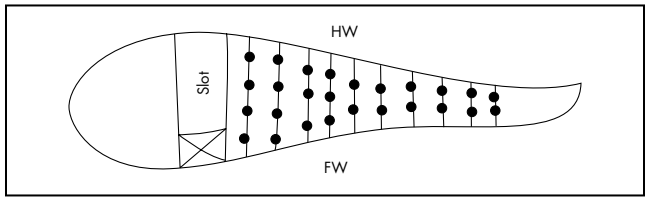

Figure 13.4-13 Location of slot raise (plan view)

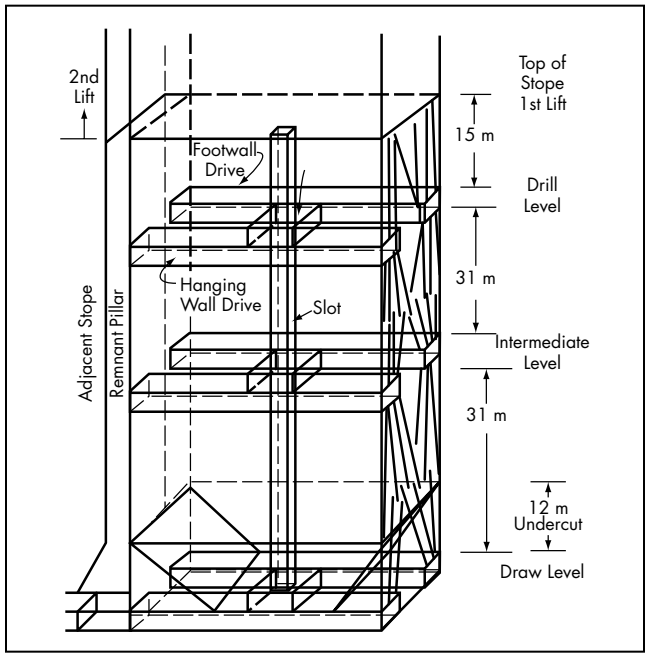

Figure 13.4-14 Sublevel open stope

The ring section is shown in Figures 13.4-11 and 13.4-12 with toe spacing (distance between toes of blastholes) of 4.2 m. The ring section incorporates the geological ore outline as defined by the geologic level contours with the stope outline coinciding with the drilled-and-blasted layout.

Development Considerations

Sublevel stoping uses long-hole drilling employing extension drill steels to achieve the appropriate blasthole depth. When ring drilling is used, the entire cross section of the stope is drilled with holes that radiate from the drill drive. The drilling pattern is matched to the shape of the ore body and location of the drill drift. Parallel holes are drilled when the drill drive can be silled out from the HW-FW, but this largely is constrained by the stability of the exposed working back. Two principal drill systems exist: top hammer and in-the-hole hammer. Both require long-hole rock drills equipped with extension steel in 1.2–1.8-m-long sections. Top hammer drills are more suited for narrower ore bodies (sublevel stoping), while ITH hammers are more suited for wider ore bodies (long-hole stoping). These will be discussed in a later section.

The blast layout for the individual rings will incorporate the ring number, hole number on that particular ring, the amount of explosive required (kilograms), delay interval, angle of hole to be drilled, length of hole to be drilled, and the depth of collar (stemming) to be used.

A slot raise must be developed in order to accommodate the swell of the blasted muck. It generally is developed at the extremity of the stope as shown in Figure 13.4-13, and subsequently the slot raise is enlarged FW to HW to open up the area for blasting. Generally, one cannot blast rings into a narrower void, so the slot should be located in the largest area of the stope.

Ore Handling Considerations

Ore handling in sublevel stoping involves removal of the ore at the bottom of the stope, and historically it involved track and/or slushers to remove the muck. This process is now conducted largely by trackless mining equipment such as scoop trams used for drawpoint loading into mine trucks and/or orepasses as shown in Figures 13.4-3 and 13.4-4.

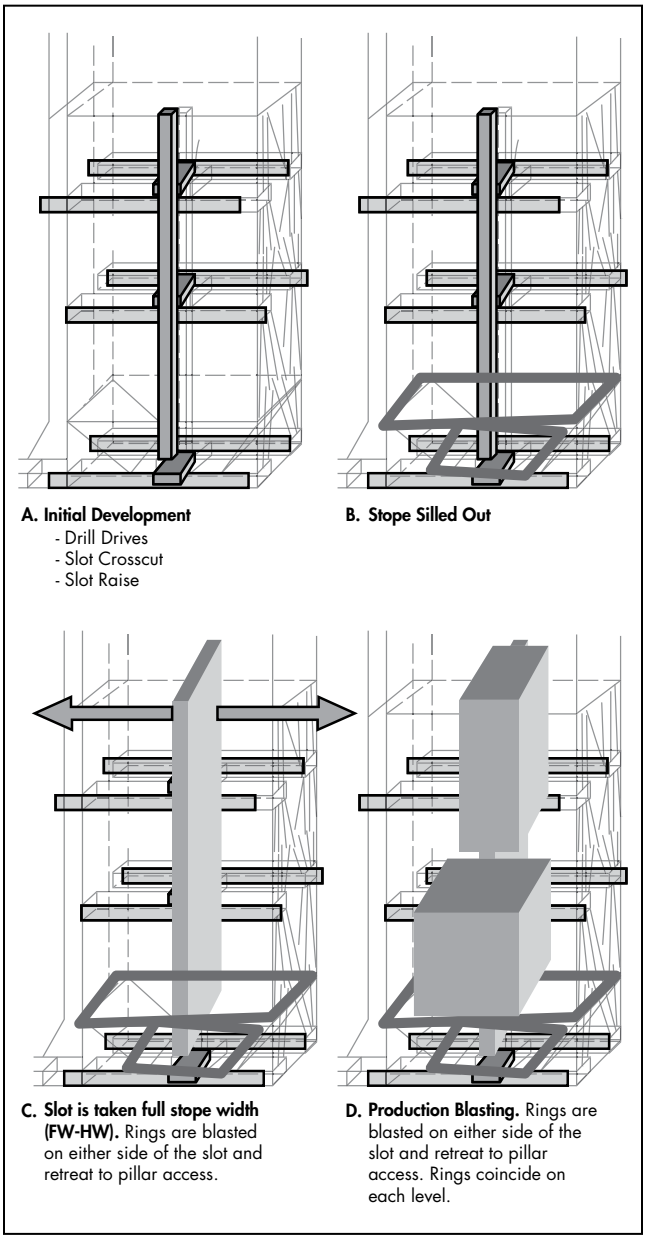

Figure 13.4-15 Sublevel open stope development

Sublevel Stoping

Sublevel stoping design is schematically shown in Figure 13.4-14, and the sequence of development and extraction sequencing is shown in Figure 13.4-15. The dimensions noted in the figures are typical of sublevel stoping dimensions and are employed solely to assist in the description of the method and not intended for design, as the dimensions of a stope are based on the geometry of the ore body and operational constraints.

This mining method employs sublevels located approximately 20–30 m apart. The distance between sublevels is largely governed by the length of hole that can be drilled with

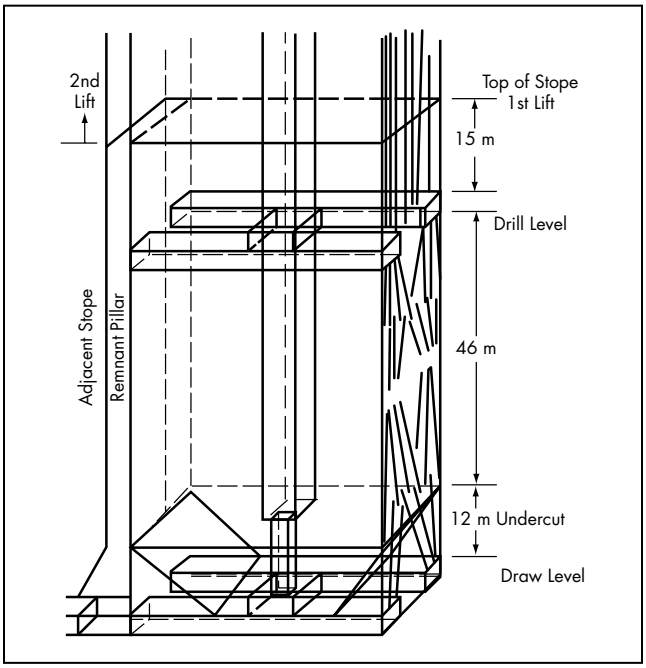

Figure 13.4-16 Long-hole open stoping

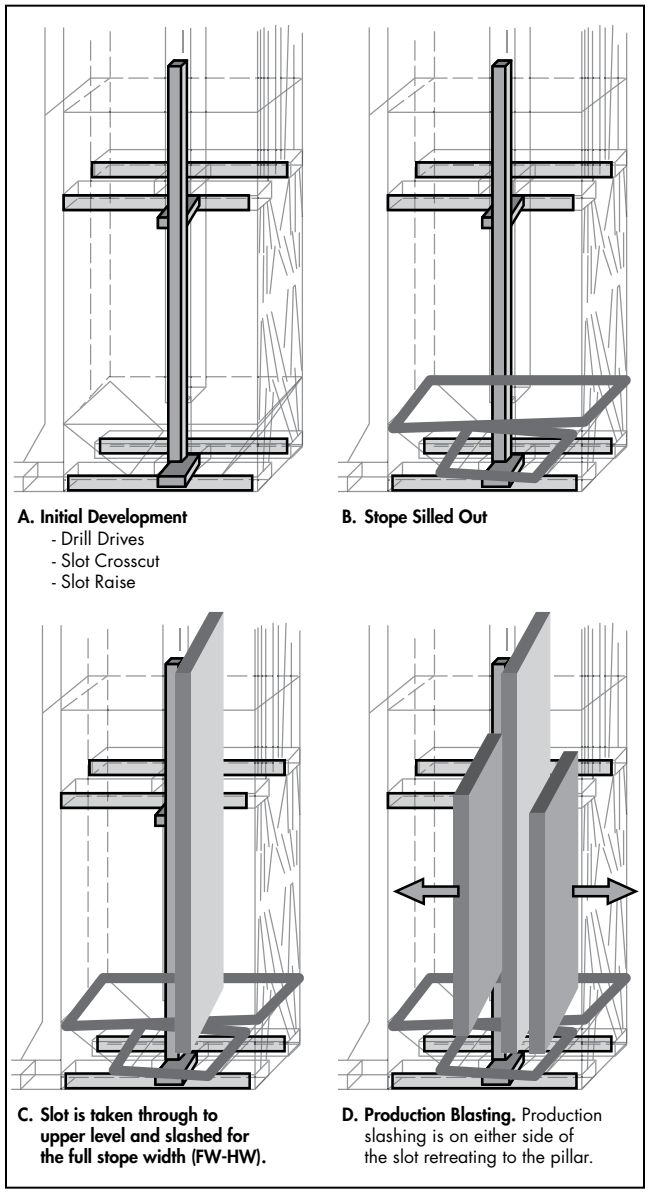

Figure 13.4-17 Long-hole open stoping development/mine sequence

minimal drill-hole deviation (under 2%). The drill-hole diameter ranges from 50–75 mm using top hammer drills, which restricts the length of the hole to generally under 30 m with blasthole burden and toe spacing between approximately 1 × 1 m and 2 × 2 m (typically 1.2 × 1.2 m). Modern tube drills (top hammer) at 100 mm in diameter are able to drill 35–40-m-long holes.

Generally, if the stope width (HW-FW) is greater than 15 m, an FW and HW development drive as shown in Figure 13.4-14 is used; otherwise, only a center drive in the middle of the stope is developed.

The initial development is shown in Figure 13.4-15A, whereby the drill drives, slot x-cut, and raises are driven. The drill drives are comprised of the draw level, intermediate level, and the upper drill level. The undercut (Figure 13.4-15B) is silled out for a vertical height of approximately 12 m above the draw level. The height of undercut or void can be minimized through the use of programmable detonators, ensuring that sufficient void is created for the subsequent blast. The undercut serves the purpose as well to ensure breakthrough of the holes from the upper drill drive. A 2 × 2-m slot is bored/blasted to the full length of the level above the upper drill level (Figure 13.4-15B), which is subsequently slashed to 3.7 × 3.7 m for the full stope height and width from FW to HW (Figure 13.4-15C) to provide sufficient void space for the subsequent rings to be mined. Production blasting (Figure 13.4-15C) is comprised of individual rings blasting into the void for the full stope width on either side of the slot. This assumes pillar access exists on either side of the slot. Normally the production rings blasted from the intermediary level correspond to a similar set of rings on the upper drill level (Figure 13.4-15D) to ensure that a void from draw level to upper drill level exists. The geometry shown in Figure 13.4-14 employs a ring burden of 1.5 m and toe spacing of 2.1 m. The stope is normally drilled off prior to commencement of blasting, and only the holes that are scheduled for the blast are loaded. The upholes from the intervening levels must ensure interleaf coverage of approximately 1 to 2 m. The example shown in Figure 13.4-15 uses 15-m-long drill holes with uppers and downholes, and 1–2-m interleaf coverage.

Long-Hole Stoping

Long-hole (blasthole) stoping development is shown in Figure 13.4-16 with the sequence of development and extraction shown in Figure 13.4-17. The subsequent examples given are typical of long-hole stoping dimensions and are employed solely to assist in the description of the method and not intended for design, as these dimensions change based on the geometry of the ore body and operational constraints.

Long-hole stoping largely eliminates the intermediary level with the draw and drill horizon interval governed by the length of hole that can be drilled with minimal drill-hole

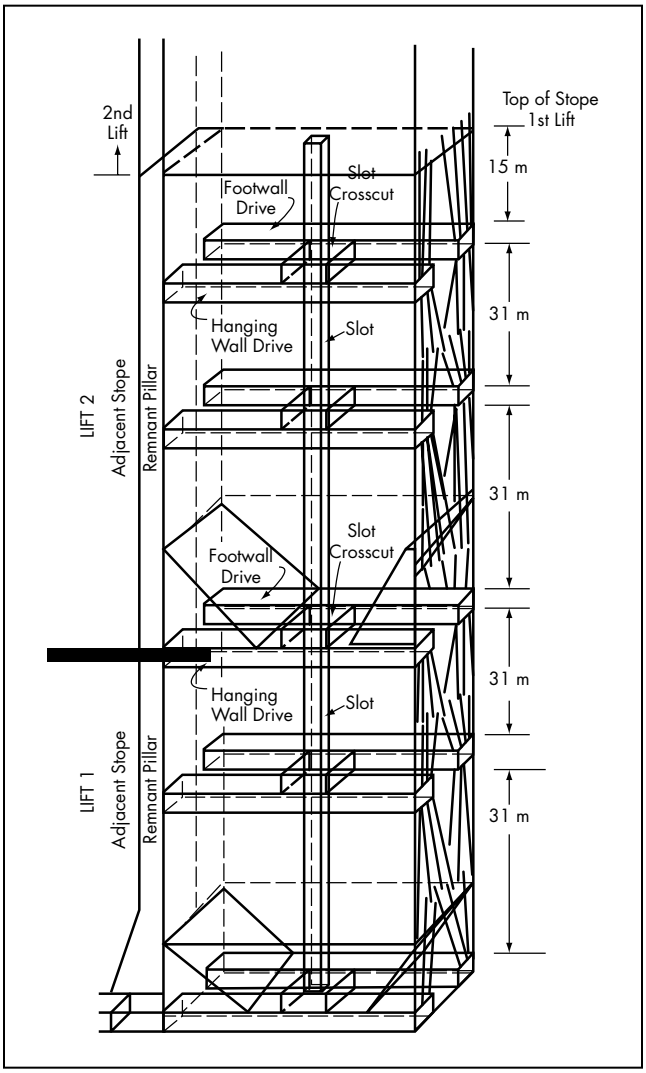

Figure 13.4-18 Piggyback stope

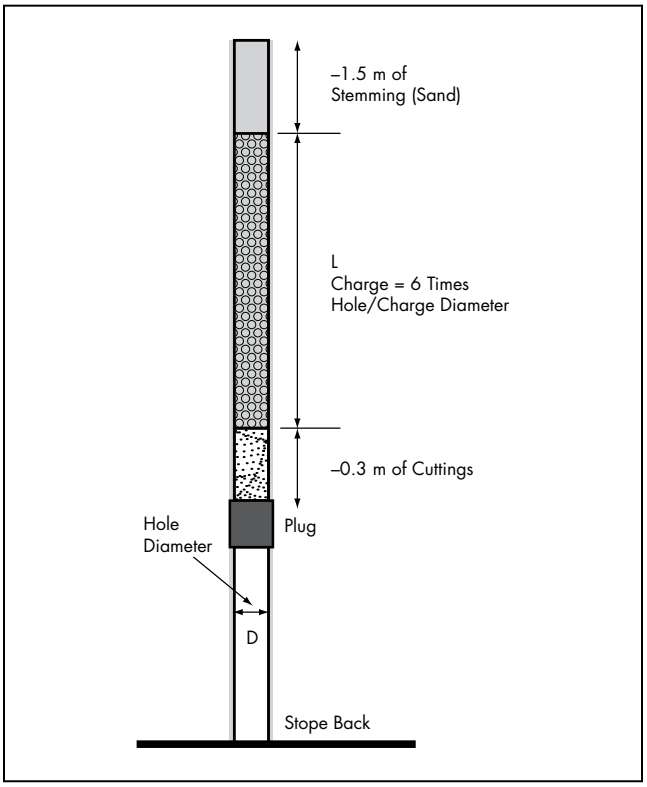

Figure 13.4-19 Typical cross section of a VCR-charged hole

deviation (under 2%). The drill-hole diameter ranges from 75 to 150 mm using ITH hammer bits, thereby enabling the lengths to approach 30–60 m in length with blasthole burden and toe spacing approximately 3–4 m^2 (3 × 3 m). The development is as shown in Figure 13.4-17. Generally, if the stope width (HW-FW) is greater than 15 m, an FW and HW development drive is used as shown in Figure 13.4-16; otherwise, a center drive is driven in the middle of the stope.

The initial development is shown in Figure 13.4-17A, whereby the drill drives, slot crosscut, and raises are driven. The drill drives are comprised of the draw level and the upper drill level as the intermediary level has been removed. The undercut (Figure 13.4-17B) is silled out for a vertical height of ~12 m above the draw level. A 3.7 × 3.7-m slot is bored/blasted to ~12 m above the upper drill level (Figure 13.4-17B), which is subsequently slashed to 6.1 × 6.1 m for the full stope height and width from FW to HW (Figure 13.4-17C). Production blasting (Figure 13.4-17D) is comprised of individual rings blasting into the void for the full stope width on either side of the slot. This assumes pillar access exists on either side of the slot. The geometry shown in Figure 13.4-16 employs a ring burden of 3 m and toe spacing of 4.2 m with 150-mm-diameter blastholes. The stope is normally drilled off prior to commencement of blasting. The example shown in Figure 13.4-17 uses 46-m-long downholes and 15-m upholes.

A variation in the above sublevel and long-hole mining methods is to use nonconsolidated backfill above the upper drill drive of Lift 1 and subsequently drawing out from the level that serves as the draw horizon for the level above (Lift 2) as shown in Figure 13.4-18. This negates the need for cones in ore and consequently maximizes ore recovery as shown in Figures 13.4-15 and 13.4-17. The cones can be eliminated with the use of remote mucking equipment; however, the equipment will be traversing under potentially extended, unsupported spans (see Figure 13.4-5).

Vertical Crater Retreat

As shown in Figure 13.4-18, a VCR is a variation of long-hole open stoping where the "free face" is not a vertical slot but a "flat back" at the base of the block to be mined. Spherical charges are used to break the ore into slabs as shown in Figure 13.4-5 and have a length/diameter (L/D) ratio of 6:1. Field testing has shown that a ratio of explosive column length (L) to hole diameter (D) of 6 or less will behave similarly to a spherical charge. Blasting is carried out in horizontal slabs with only the swell being mucked at the drawpoint. This is a form of shrinkage stoping where the broken stope muck provides passive support to the stope walls. The ore is recovered at the base of the stope through drawpoints. Similar requirements and constraints to that of sublevel stoping exist except for the need for a competent HW-FW due to the option of maintaining the stope full of muck.

Development is similar to that of long-hole stoping, requiring an upper drill horizon and draw level, and it is

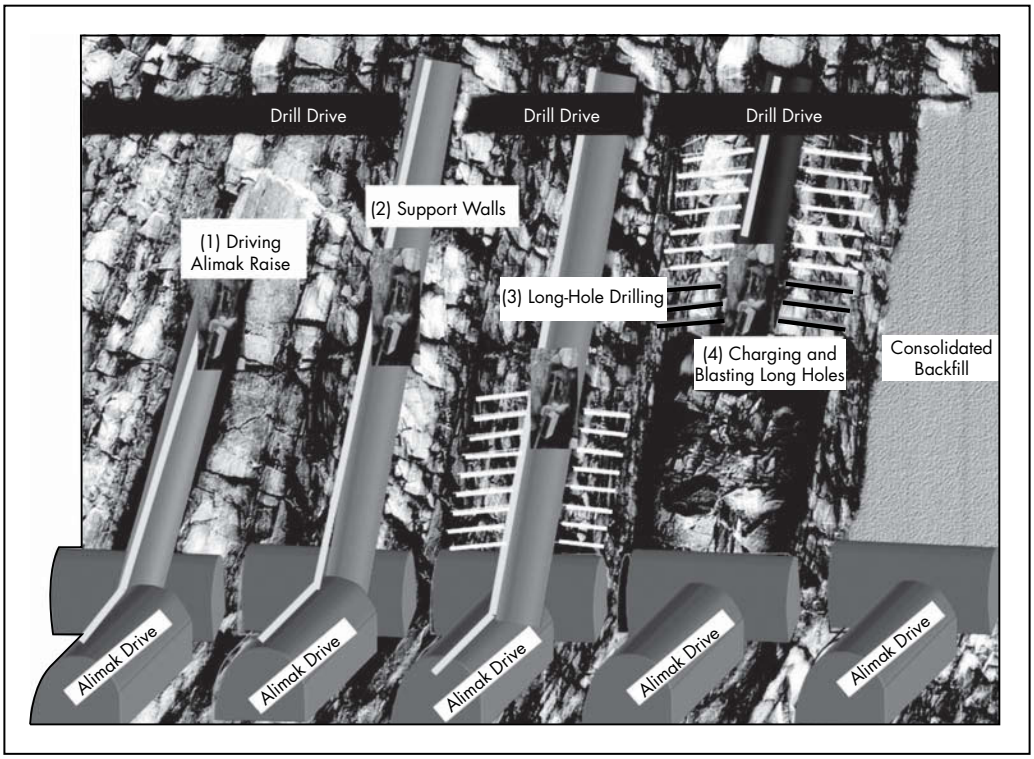

Figure 13.4-20 Alimak raise mining

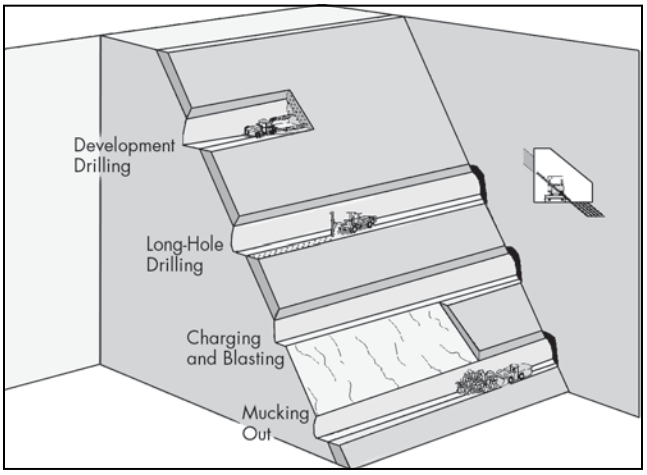
generally recommended to sill out at the drill horizon to provide drill coverage for the entire block.

The vertical separation between drill and draw level is largely a function of the ore regularity and drill accuracy as detailed in general for the long-hole mining method. The dimensions are similar to that of long-hole mining where ITH drills are employed with heights ranging from 30–60 m and 75–150-mm drill diameters are used. A typical loaded blasthole for VCR is shown in Figure 13.4-19 employing a single deck charge.

Advantages of the VCR are the high productivity associated with this bulk mining method and the ability to mechanize. The ability to only muck the swell enables support to the stope walls. An advantage of this method over shrinkage is the nonentry and high mechanization associated with VCR.

Disadvantages of this method are the extensive pre-stope planning and development that is required prior to commencement of production mining, as the stope must be largely drilled off prior to bench blasting. Similar disadvantages to that of shrinkage mining exist in having the broken ore within the stope until the end of mining of the block.

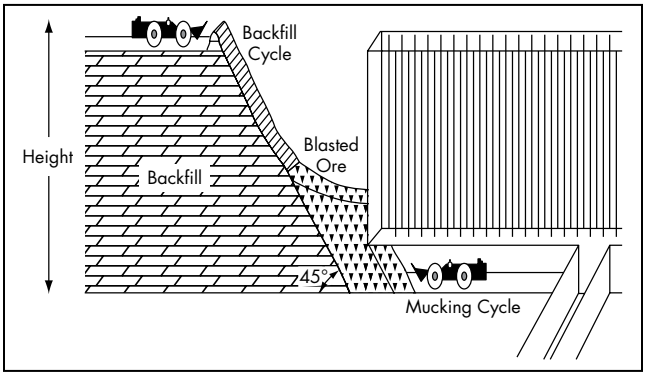
VARIATIONS ON SUBLEVEL STOPING



The sublevel mining method has variations that have been implemented and will be discussed in the context of its similarity with sublevel stoping.

Vein Mining

Vein mining—also termed *Alimak mining*—has been employed within narrow vein ore bodies as detailed in the Namew Lake mine (Canada) case study (Madsen et al. 1991). Access to the ore is gained by a bored raise/Alimak such as that shown in Figure 13.4-20. The diameter of the raise is approximately 2–3 m and extends from draw level (Alimak drive) to upper drill drive as shown in Figure 13.4-20 (item 1 in the figure) and spans the length of the ultimate stope span with similar constraints as those detailed for sublevel stoping. Support may be in the form of cable bolts (item 2) in the HW providing the final wall support on stope extraction. The ore is drilled laterally by conventional drills, long-hole jumbos, or other methods and ranges from 5 m to 15 m in length to the adjacent stope (item 3) with blasting from the draw level vertically to the upper drill level (item 4). An intervening pillar may be left between stopes or the stope mined from one Alimak raise to the next depending on the geotechnical constraints. The major advantage is the ability to mine narrow ore bodies with minimal horizontal development. The vertical height of the Alimak is largely limited by operational and geotechnical constraints and reaches heights of 30 to 100 m. Blasthole sizes are generally 50–75 mm with burdens and spacing similar to that of sublevel stoping (1–2 m^2).



Transverse Open Stoping

Variations of sublevel stoping with delayed fill are shown in Figure 13.4-5. This mining method is largely used for stope widths in excess of 20 to 30 m or as dictated by geotechnical stable back spans; otherwise, conventional longitudinal or strike mining is used. Figure 13.4-5 shows the objective is to recover the secondary pillars between the primary stoping blocks, which can be excavated by sublevel stoping (general) and subsequently filled with consolidated fill that can be comprised of hydraulic fill, paste, or cemented rock fill. Mining of the secondaries occurs after curing of the primaries to a strength that is able to withstand minimal dilution. Generally, the binder content ratio is 30:1 to 20:1 (fill to cement by volume). Alternatively, a permanent pillar is left behind to confine

Source: Hamrin 2001.

Figure 13.4-21 Longitudinal mining without fill

Source: Caceres 2005.

Figure 13.4-22 Longitudinal mining with fill (Avoca)

the unconsolidated fill with only primaries excavated along the strike. With this variation the secondaries are narrow pillars left behind (approximately 3–5 m). A disadvantage of this method is its inability to follow the variations of an irregular hanging wall dip.

Longitudinal Mining

Figure 13.4-21 shows sublevel extraction employing mucking along the strike (retreat). This is a variation of conventional FW drawpoints as shown in Figure 13.4-21. The stopes with no fill are as shown in Figure 13.4-21 and with delayed fill are as shown in Figure 13.4-22. The delayed fill method of longitudinal mining is also referred to as Avoca mining. Having longitudinal mucking access requires that remote load-haul-dump (LHD) equipment be used. This method is also referred to as sublevel benching.

CONCLUSION

Sublevel stoping accounts for more than 60% of all underground production in North America. This is largely due to the developments of extension steels, hollow tube and special long-hole rock drills, and ITH drilling techniques requiring less development and greater production capacities. Several variations exist; however, characteristic to this method is the development from a top drill drive and removal of muck from a draw level below for a steeply dipping stope. The variations of the method are selected to suit the ground conditions and operational requirements of the mine.

An essential part of sublevel stoping is the stope extraction sequence. The extraction sequence is governed by the development, rock mechanics, tonnage requirements, and, if applicable, fill cycle.

Sublevel stoping is a safer mining method because the operator is never within the stope under the unsupported back. Further, the mining method works on a retreat pattern where the equipment and operator work under a supported back. This mining method is suitable to modern hauling equipment including the use of remote LHD units where the operator is removed from any potential hazard associated with the stope.

An important safety consideration with open stoping is to ensure that drawpoints remain full above the brow of the stope. Adhering to this safety standard largely eliminates the risk of potential air blast due to hanging wall collapse.

The main advantage of sublevel stoping is the efficiency associated with drilling, blasting, and loading operations as they can be performed independently from each other. A high potential exists for mechanization with moderate to high productivities of more than 25 t per worker-shift.

The main disadvantage is the complicated and comprehensive development that is needed and the requirement for regular tabular ore geometries.

CHAPTER 13.5

Cut-and-Fill Mining

George Stephan

DEFINING CHARACTERISTICS

Cut-and-fill is the broad descriptive term applied to mining methods requiring that excavated voids be filled with barren material to facilitate the continuation of ore production. This fill is required to provide support for subsequent openings or to provide a working platform for further mining. Cut-and-fill methods may be applied in conjunction with other conventional methods, such as blasthole stoping, or they may be methods that stand alone, such as drift-and-fill.

Classic cut-and-fill mining involves the successive mining of horizontal or inclined slices upward through a relatively narrow and subvertical tabular ore body. This is followed by the placement of uncemented waste rock or hydraulically placed sand fill to create a new, higher working level to gain access to ore above and to support the ground below. Raises maintained up through the fill (and occasionally down from upper levels) provide for access, ventilation, ore removal, and the drainage of water from the fill material.

Modern variants may use paste fill and typically use ramp access to allow the use of mechanized mining equipment. These techniques preclude the need for raises.

None of the cut-and-fill methods described herein can match the productivity or the low mining cost of mass mining methods. Cut-and-fill methods are chosen because they are more economically attractive than other extraction methods available for the same situation.

FAVORABLE CONDITIONS

Cut-and-fill methods are applicable to a wide variety of situations, including the following:

- Ore zones are irregular in shape and orientation.
- Ore grade is high and dilution control is critical.
- The precise contacts between ore and waste are structurally critical but not readily visible.
- The waste rock is weak.
- Ore zones are large, but their rock quality is weak.
- Localized underground stability is required.
- Surface disturbance must be minimized.
- The value of the ore makes recovery of support pillars economically viable.
- The reduction of surface waste storage is important.
- The need exists to advance a working platform for the upward mining of the ore body.

Cut-and-fill methods are favored when the ore value is relatively high and ore recovery rate with minimal dilution cannot be satisfactorily accomplished by open stope mining or caving methods. If the openings are small enough and the ground conditions are competent, irregular ore boundaries can be mined with open stope methods without backfill. However, when the openings are larger and the ground conditions are less favorable, backfilling becomes necessary for safe economic production.

Fill methods are useful when regional stability is needed. This is the case where large empty stopes could adversely affect the stability of permanent mine access drifts, shafts, and raises. These stresses could also affect new mine production stopes and surface infrastructure.

There is also the advantage that fill can provide a relatively inexpensive and convenient way to advance a working platform to maintain access to the ore for drilling, blasting, and mucking. Another advantage is that ventilation air can be managed more efficiently because vacant and unused mine openings are closed by backfill.

LIMITATIONS

These factors limit the applicability of cut-and-fill:

- The availability of a sufficient quantity of a suitable fill material type
- The cost of binding agents (if required)
- Production, preparation, transportation, and placement cost of the fill material
- Storage and reclamation facilities to match the mining cycle demand
- Congestion and interruption of production mining activities

George Stephan, Senior Consulting Engineer, Stantec Mining, Tempe, Arizona, USA

The principal drawback for the cut-and-fill methods is the additional cost of producing, preparation, transporting, and placing the backfill.

Not all readily available fill materials are appropriate; the backfill material must match its intended use. The material that is most readily available and least expensive may not have characteristics that would allow its use as fill material. The material most readily available also may not be usable in the stope designs dictated by the size and shape of the ore body. Further, the least expensive delivery system may not be practical.

Assumptions about fill availability should be verified early in mine planning. Suitable aggregate for cemented rock fill may not be available near the mine site. Both sand fill and paste fill generally make use of tailings from an on-site mill. For sand fill, however, sufficient coarse fraction may not be available within the tailings, either because of the fineness of the grind or because of the need to supply coarse fraction for tailings dam construction. Conversely, the grind may be too coarse to provide sufficient fines for paste fill.

In addition to the added cost, backfilling operations can result in congestion, maintenance, and cleanup problems underground. Cut-and-fill imposes limitations on the sequence and timing of production that, if not carefully controlled, may take precedence over the maximization of production grade. Usually, conventional ground support in the form of rock bolts, wire mesh, and shotcrete still will be required to temporarily support the stope openings during production mining.

The cost of producing and placing fill requires consideration of the mining method trade-offs. Unless the deposit simply cannot be mined by any nonfill method, the additional cost and the advantages of using fill must result in additional ore production (increased recovery), reduced dilution, and/or cash cost reductions sufficient to justify the additional cost of the fill and its preparation and placement.

TYPES OF CUT-AND-FILL METHODS

There are numerous cut-and-fill methods and many hybrid combinations. The following is a basic set of descriptors:

- Vertical progression of the mining
  - Underhand (mining beneath the backfill)
  - Overhand (mining on top of the backfill)
- Mining method
  - Drift-and-fill
  - Postpillar
  - Bench-and-fill
  - Blasthole stoping
  - Uphole, flat-back slicing, or back stoping
- Type of fill
  - Cemented rock fill
  - Uncemented rock fill
  - Sand fill (hydraulic)
  - Paste fill
- Timing
  - Concurrent (placed during the cycle of stope advance)
  - Delayed (placed after the excavation of the stope is complete)

Cut-and-fill mining is extremely flexible, and various combinations of mining methods and fill materials can be used to cope with specific mining situations. However, some combinations are not feasible, such as underhand drift-and-fill with uncemented rock fill. Further discussion regarding possible combinations can be found in the "Cemented Fill Stopes" and "Uncemented Fill Stopes" sections.

METHOD SELECTION CRITERIA

Ore-Body Morphology

The size, shape, orientation, and degree of boundary uniformity of the ore body are the first considerations in selecting a cut-and-fill method. The use of fill for support and for provision of the necessary platform to access the ore provides the operator with great flexibility for adjusting the excavation to irregularities along the boundaries of the ore body. Alternative methods (that do not use fill) may result in unsafe working conditions, excessive dilution, or insufficient recovery. Cut-and-fill methods can be adapted to flat, vertical, undulating, or even en echelon zones and to situations in which the ore-body shape and attitude change quickly along the strike or dip.

Access, Infrastructure, and Development Cost

Typically, overall project cost for access and infrastructure to support cut-and-fill mining is less than the cost for bulk mining methods like block caving. Overall project cost is greater, however, than the cost for room-and-pillar or open stoping.

The use of fill for support, rather than leaving unmined pillars of ore, results in greater recovery of ore because fewer unrecoverable ore pillars are left behind at the conclusion of mine operations. In methods such as shrinkage stoping, much of the broken ore is left (albeit temporarily) in the stope to provide wall-rock support and a working platform from which to mine the whole block of ore. Although the shrinkage ore is withdrawn at the completion of the stope, the use of fill as a working platform and wall-rock support results in a faster return on the cost of mining.

Amenability to Mechanization

The mechanization of cut-and-fill mining has two phases: mechanization of the ore extraction (i.e., the cut) and mechanization of the fill process. The mechanization potential for ore extraction with cut-and-fill methods varies widely. The ground conditions that dictate the use of cut-and-fill mining may also limit drift dimensions or, alternatively, may require flexibility to adapt to varying stope conditions. This reduces the size of trucks and loaders that can be used. Options associated with production and delivery of fill are covered in Chapter 13.6. By itself, the use of fill seldom enables an increase in the level of mechanization.

Dilution

Cut-and-fill methods increase the extractable yield of ore bodies and reduce dilution from boundary overbreak. However, the effect of dilution from fill must be considered in any economic analysis. Fill dilution generally carries no recoverable value, whereas overbreak into country rock may carry at least some value because of its proximity to the ore. Dilution from fill can come from stope ribs where the adjacent stopes have been previously backfilled. If the stope in production is above a previously filled stope, the mucking operations will typically remove a layer of fill material from the floor to clean up as much ore as possible. Less fill will be taken if the floor surface is cemented fill. Conversely, ore can be lost in the floor of a stope if ore is used to build a roadway on top of the fill. Fine

ore, which usually contains a significant portion of value, can be lost into the fill from the cut below if the fill is not well consolidated at its placement.

The dilution potential of various fill materials can differ significantly. Uncemented rock and sand fill typically dilute at the highest rates. Dilution is usually less with cemented rock, sand, and paste fills. However, dilution from cementing agents may have an adverse effect in the metallurgical plant. This difference in behavior must be included when evaluating the relative costs of using these fill materials in the mining operation.

Geotechnical Constraints

The in-situ geotechnical environment—including the rock quality of the ore and country rock, geologic structures, ore-body depth, water, and regional stresses—determines the size and shape of the stopes that can be excavated before placing fill. The ground support required to provide a safe working environment is also dictated by the geotechnical situation. Cut-and-fill methods frequently rely on the initial mining of stopes in virgin ore zones. These stopes are called *primary stopes*. They are subsequently backfilled to provide support for the mining of adjacent stopes, which are called *secondary stopes*. The size, shape, and mining sequence of the primary and secondary stopes are dictated by the geotechnical conditions of the ore and country rock and the mechanical properties of the planned fill material. Sometimes it is advantageous to place higher-strength, higher-cost fill in a primary stope and lower-strength, lower-cost fill in a secondary stope. The flexibility to control and differentiate fill quality and properties according to the application is crucial to mine operation, safety, and cost control.

Sill pillars and crown pillars are used to separate stoping zones vertically. The dimensions of these pillars are determined by the geotechnical environment and the stresses induced by mining. If these pillars contain valuable ore, it may be desirable to place highly engineered fill to facilitate the safe recovery of this ore. The objectives are to use cut-and-fill mine planning to maximize the extraction of the ore body and to avoid sterilizing any portion such that it cannot be safely recovered.

Availability of Fill Material

The availability of fill material (rock, sand, or paste) affects the selection of cut-and-fill methods. The quantity, engineering properties, and cost must be matched to the planned use. For example, if the on-site mill tailings are unsuitable, a nearby source of alternative material must be found. Similarly, if the price for cement is unreasonably high, the cost and availability of the various fill alternatives must be weighed against the engineering requirements of the selected cut-and-fill method. The safest and least expensive combination of fill material and cut-and-fill method must be found and continually reviewed.

The use of tailings for fill is often dependent on mill throughput. An unfortunate side effect of using mill tails, particularly in mines with numerous smaller stopes, is that when stopes stop producing to allow for fill placement, they must rely on continued production from other stopes to provide fill material. The design of the mine must include satisfactory storage capacity for fill because it is usually accumulated at a slow, relatively steady rate—typically as a by-product of the milling operation. When fill is required for placement, it must be delivered at a much greater rate, stope by stope. Careful planning is therefore critical to ensure that a balanced mining/filling cycle is maintained throughout the operation. Failure to maintain a balanced cycle can result in fill shortfalls, leading eventually to loss of production until a proper cycle can be reestablished.

CEMENTED FILL STOPES

The inclusion of a binding agent such as cement in the fill is required when the fill must have sufficient strength to provide support for the excavation of stopes located above, below, or adjacent to the stope being mined. The term *delayed* is used to indicate that extraction of all ore in the stope has been completed before the stope is backfilled.

Occasionally, when the value of the ore in the pillars of a conventional room-and-pillar mine is considered high enough, cemented fill is placed around the pillars to permit recovery of the ore. Placement of cemented fill is also sometimes used to facilitate the later extraction of ore from sill pillars where the fill material is normally uncemented.

The use of hydraulic and cemented fill can cause significant problems with level cleanup, sumps, settlers, and pumps. This is usually worse with cut-and-fill stoping than with sublevel open stoping because there are many more points of drainage to manage.

Blasthole Stoping with Delayed Backfill

Blasthole stoping with delayed backfill is a method that can be applied to ore bodies that are generally tabular and vertical or near vertical. The rock quality of both the ore and the waste needs to be fair to good. Cemented fill for the primary stopes is required when a primary/secondary plan is pursued. Cemented fill allows secondary stopes to be mined subsequently. The secondary stopes may be backfilled partially or completely with uncemented fill.

Longitudinal Blasthole Stoping with Delayed Backfill

Where the ore zone is narrow and the long axes of the stopes are parallel to the strike, the stope orientation is called *longitudinal*. Occasionally the ore is contained in en echelon lenses: narrow parallel zones of ore separated by narrow parallel zones of waste. These conditions require sequences of longitudinal stopes followed by backfilling to prevent stability problems and dilution from the collapse of the waste material between ore lenses (see Figure 13.5-1). The width of the stopes is generally the distance between hanging wall and footwall. The maximum length is generally limited by geotechnical considerations. To minimize dilution from overbreak or slough when the hanging wall is weak, the installation of mechanical support (bolts, wire, shotcrete, or cable bolts) may be required.

Transverse Blasthole Stoping with Delayed Backfill

Where the ore zone has sufficient width, the long-axis orientation of the stopes may be perpendicular to the strike. These are *transverse stopes*. Geotechnical considerations dictate the transverse orientation as well as the stope dimensions. The sequence of lateral and vertical, primary and secondary stope mining, backfilling, and curing requires careful planning (see Figure 13.5-2). After mining begins, the plan seldom permits significant changes; it becomes difficult to adjust the production rate and grade.

Drift-and-Fill

Drift-and-fill is the term applied to projects in which the ore is extracted by excavating parallel drifts through the ore zone and backfilling them before mining the adjacent drift. The drifts are

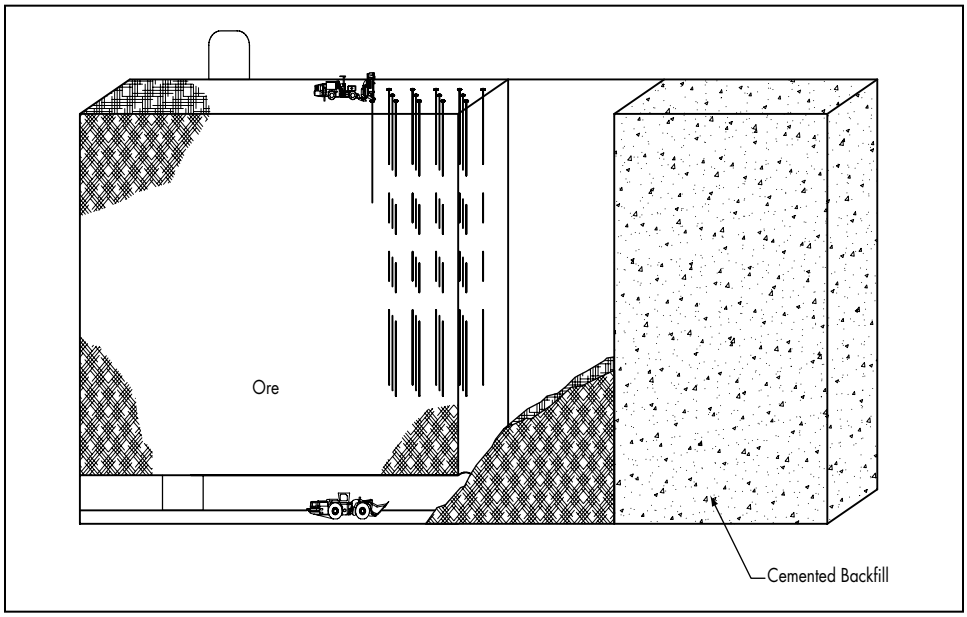

Figure 13.5-1 Typical longitudinal blasthole stoping with delayed backfill

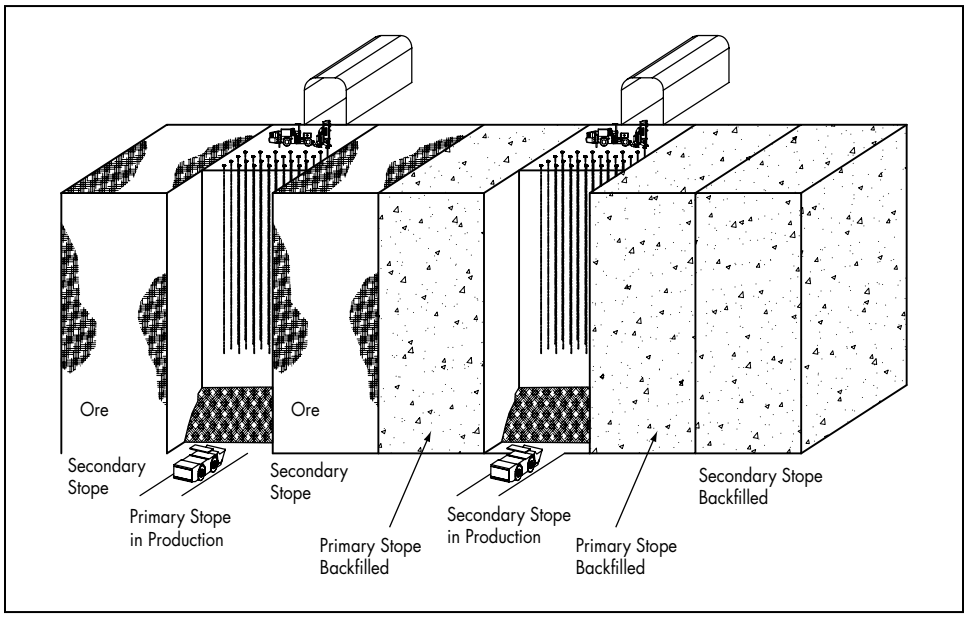

Figure 13.5-2 Typical transverse blasthole stoping with delayed backfill

usually alternately filled with cemented and uncemented rock fill. The orientation of the drifts mined on a level can be longitudinal, transverse, or diagonal to the strike of the ore body. For additional strength, the orientation is sometimes alternated between levels. Excavation of the ore by drifting is less productive and more costly than excavation by blasthole stoping. Therefore, drift-and-fill is usually employed where ground conditions are too weak and the ore boundaries are too irregular for blasthole stoping. Because of its higher associated operating costs, drift-and-fill is best used where the ore grade is high.

Overhand Drift-and-Fill

Overhand drift-and-fill is a bottom-up mining sequence (see Figure 13.5-3). This method is useful where the ore occurs in relatively thin, shallow dipping lenses with weak back or wall rock. The bottom-up sequence may also be desirable because of production grade considerations. Ideally, this method would be used where the rock quality of the ore in the back is not sufficiently high to permit postpillar stoping. This method permits backfilling of secondary stope drifts with uncemented fill, thus reducing costs. The first or lowest cut requires cemented fill in both primary and secondary drifts if mining blocks from below are scheduled to mine up to a previously mined block.

Underhand Drift-and-Fill

Underhand drift-and-fill is a top-down sequence (see Figure 13.5-4). The use of underhand drift-and-fill stoping

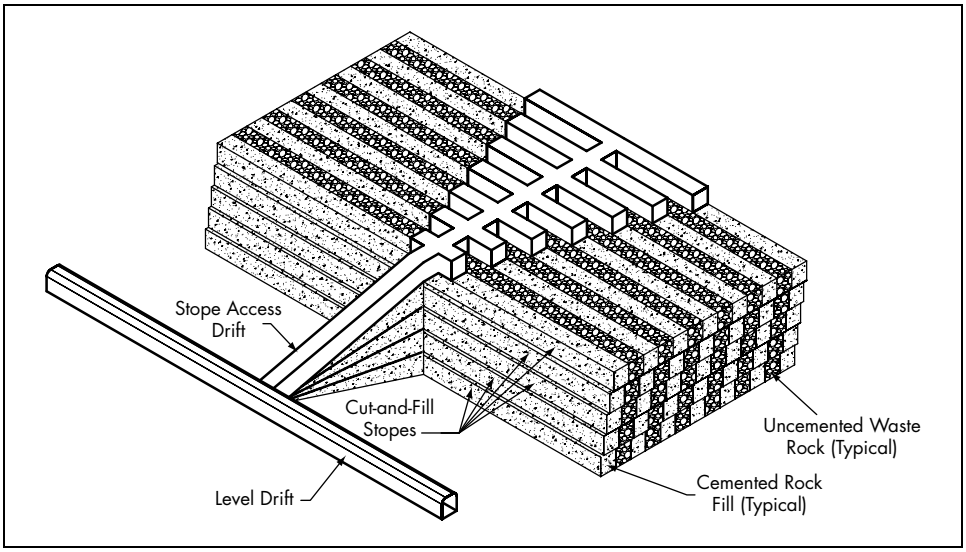

Figure 13.5-3 Typical overhand drift-and-fill

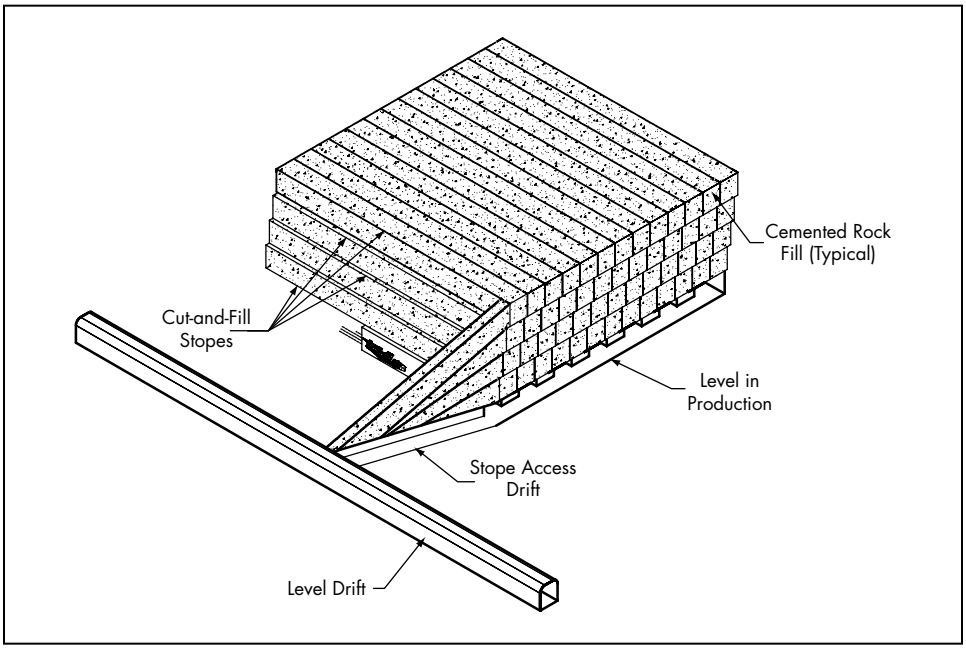

Figure 13.5-4 Typical underhand drift-and-fill

fills the critical need for a method that facilitates the mining of high-grade deposits with weak ore and weak country rock. This method results in the creation of a strong crown pillar of cemented fill beneath which subsequent mining can safely proceed. The initial level may be opened using small drifts that are easily supported. After the upper level is completed and backfilled, succeeding levels below can be opened to more efficient mining widths. Orienting the drifts on each level such that they are not parallel to the overhead drifts reduces the risk of ground falls. The fill material must be carefully engineered and the samples tested regularly. The method may involve the use of mats or tension cables to support and distribute the load above each open drift. The ore zone should be vertical or near vertical to maximize the benefit of employing this method.

UNCEMENTED FILL STOPES

The use of uncemented fill has the advantage of eliminating the cost for cement. Uncemented fill has limitations when used as the primary backfilling material because it lacks the strength of cemented fill. Therefore, it is seldom used where the mining of adjacent stopes or stopes below is planned. The use of uncemented fill dictates a bottom-up mining sequence or the use of substantial sill pillars between levels.

Usually, stope mining with uncemented rock fill has the advantage of being able to use any sort of readily available and inexpensive fill material. Frequently, waste muck from development mining can be used. This relieves the expense of transporting thve waste to the surface for disposal. Alternatively, the rock can be quarried on the surface and delivered to the

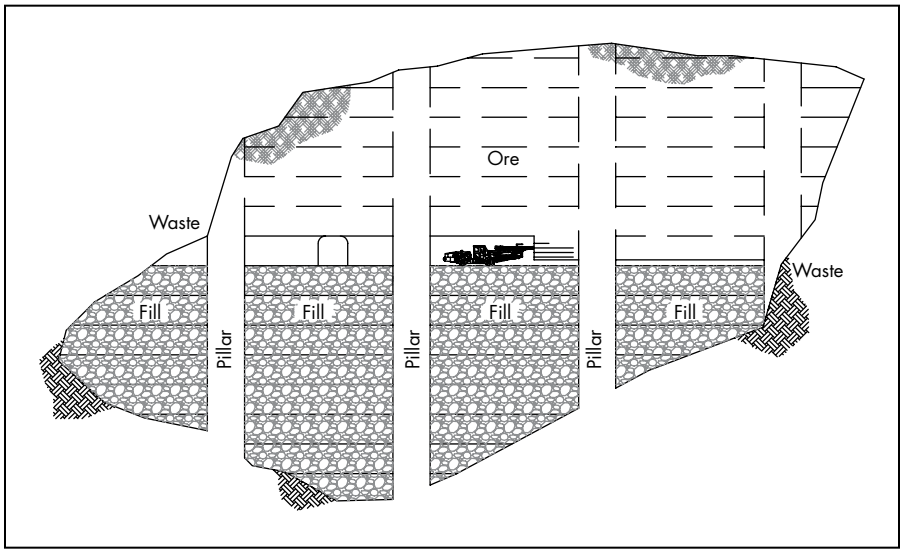

Figure 13.5-5 Postpillar mining

underground stopes via borehole or waste pass. Because of its coarse texture, rock fill is often capped with sand fill or cemented sand fill to provide a mucking surface that is less susceptible to ore loss and dilution.

Postpillar Mining

In horizontal or near-horizontal ore bodies of substantial thickness and width, the placement of uncemented fill serves the primary purpose of providing access to excavate successive slices of ore in a bottom-up sequence. The postpillar method can be described as a room-and-pillar excavation where backfill (usually uncemented rock fill) is placed on the floor so that successive layers can be mined upward through the ore zone (see Figure 13.5-5). The pillars, or at least the upper portions of the pillars, can be preserved and extended upward to continue supporting the back. The pillars can be much taller and more slender when they are surrounded by fill, and so recovery is higher than for nonfill room-and-pillar methods.

Vertical or Near-Vertical Cut-and-Fill Stoping (Conventional or Mechanized)

The use of uncemented fill in narrow-vein stopes that are inclined or vertical provides both stability and a working platform for the upward advance of the excavation of the ore. Hydraulic (sand) fill or rock fill with sand is superior to rock fill alone for this application because greater density is achieved. Frequently, a top layer of cemented fill is used to provide a stronger surface for machine operation and to minimize ore loss and dilution.

Using sand (usually coarse tailings) to backfill stopes was one of the earliest fill applications in mining. It was often used in conjunction with timber support, but the use of timber is now largely supplanted by bolts and shotcrete. The transport, distribution, and placement of fill are as hydraulic slurry via a pipe system. Less frequently, compressed air is used for the transport and pneumatic stowing of the fill. The pipe system prevents congestion of the haulageways and eliminates the need for trucks and loaders. With hydraulic fill, drainage of the excess water must be accommodated with designed filters, drainage raises, sumps, and pumping systems. These features impose substantial operational costs and scheduling limitations. Pneumatic fill systems have increased ventilation requirements and pipe wear as well as the physical limits associated with distribution and the potential health risks of increased airborne dust.

In conventional cut-and-fill stopes, access to the level of the stope cut was gained by timbered or steel-tubbed raises that were maintained and extended up through the backfill from the haulage level (see Figure 13.5-6). In the stope, drilling was accomplished with hand-operated stoper drills for vertical holes or jacklegs for horizontal holes where the cut would be taken by breasting down. Slushers were the principal means for mucking the blasted ore across the stope to the muck raise. From the bottom of the muck raise, chutes were used to transfer ore to muck cars for transport to the shaft by rail. In addition to ore transport, the raises provided manway access, hoisting of supplies, pipe and power reticulation, and drainage of the backfill water.

In the conventional system, it was difficult to bring equipment into or out of the stope; after a piece of equipment had been installed in a stope it remained isolated there, rising with the level of the cut. Low unit cost, light weight, simplicity, and durability were important equipment characteristics; slushers fit this description well. However, they were not as productive for mucking as low-profile LHDs (load-haul-dump units) with buckets.

Overshot muckers powered by compressed air were used at some mines to replace slushers. Overshot muckers are relatively simple to maintain, and ventilation requirements are no greater than those required for slushers.

Eventually, diesel-powered LHDs were placed into service (Figure 13.5-7). With their introduction, ventilation requirements increased and maintenance requirements demanded better access than raises could provide. The cost of LHDs forced the need to achieve higher utilization rates, which in turn made it necessary to allow stope-to-stope movement of LHDs. This change led to the shift from access by raises to access by ramp systems.

Resuing

Resuing is the term applied to the mining method whereby high-grade ore from very narrow veins is extracted selectively before stopes are widened in waste rock to obtain the additional

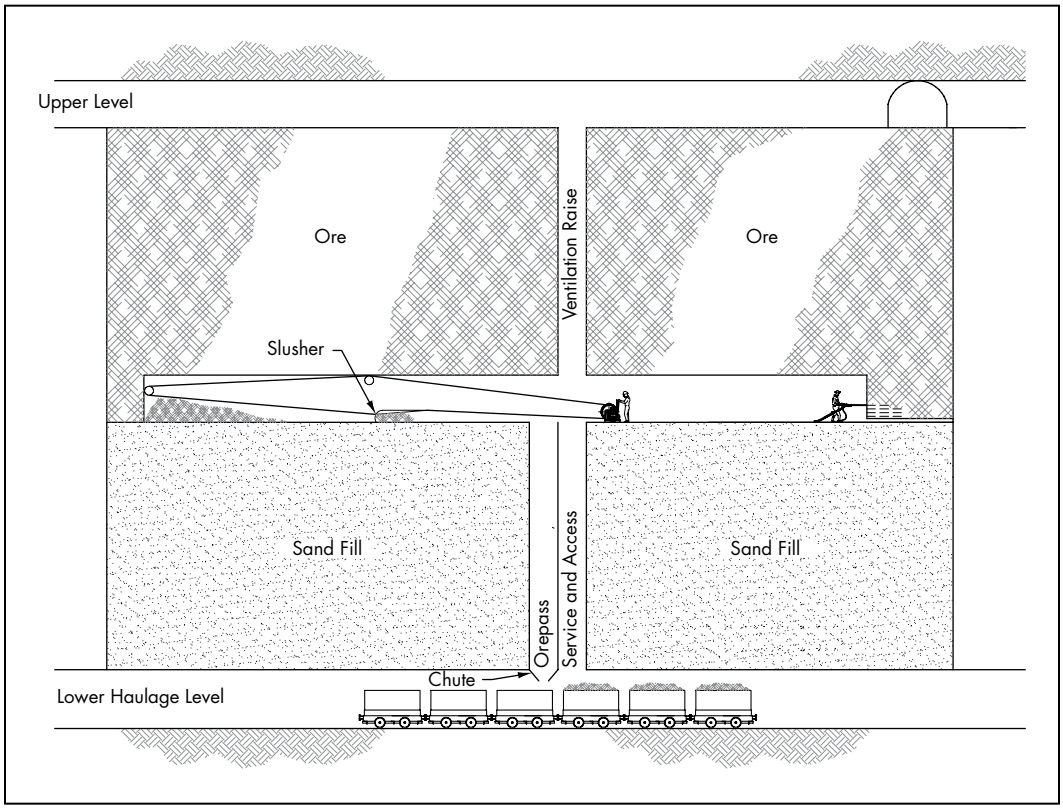

Figure 13.5-6 Conventional cut-and-fill stoping with hydraulic (sand) fill

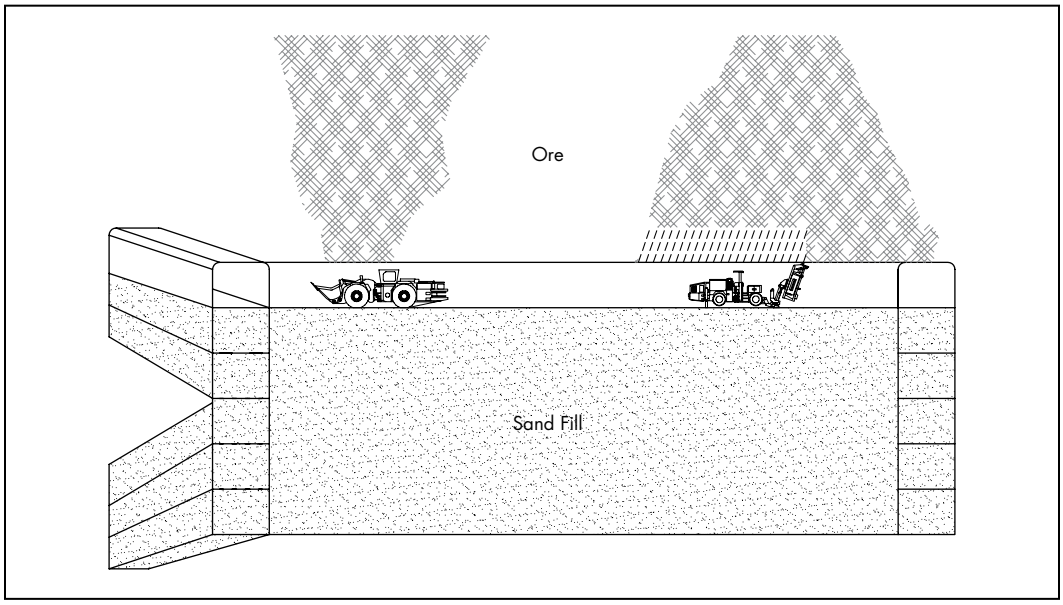

Figure 13.5-7 Mechanized cut-and-fill stoping with uncemented hydraulic (sand) fill

width required for equipment to operate (see Figure 13.5-8). Resuing requires a working platform of fill.

Bench-and-Fill

Bench-and-fill stoping is applied to vertical and near-vertical stopes that have sufficient width, length, and competency of wall rock to permit a system of laterally retreating blastholes followed by advancing waste rock fill (see Figure 13.5-9). This method allows variations in placement of the fill. The amount of waste rock exposed between the blasting and mucking of ore, and the advancing face of waste fill, can be adjusted to suit local conditions. In some cases, the waste fill is advanced such that all open space is completely eliminated. This lack of open space enhances support for weak hanging-wall and

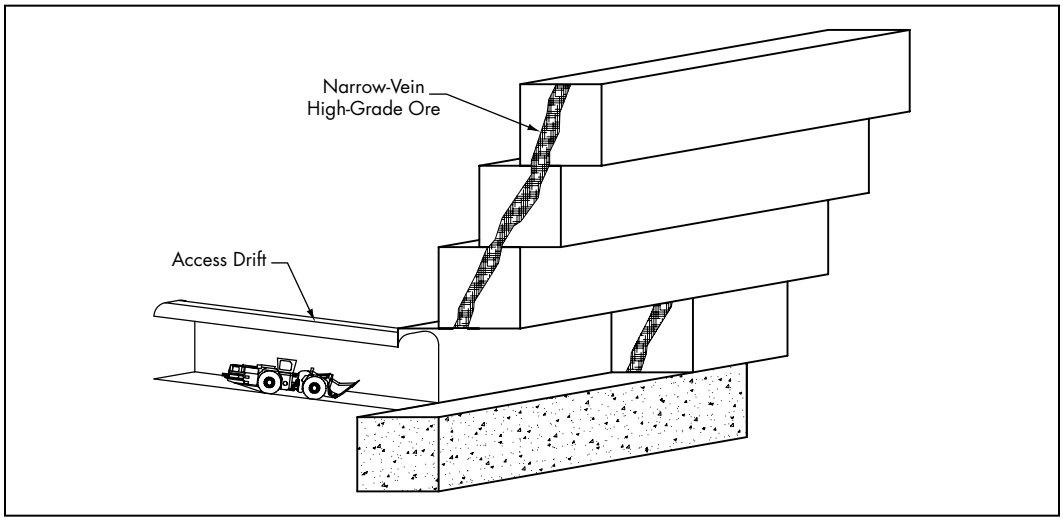

Figure 13.5-8 Resuing

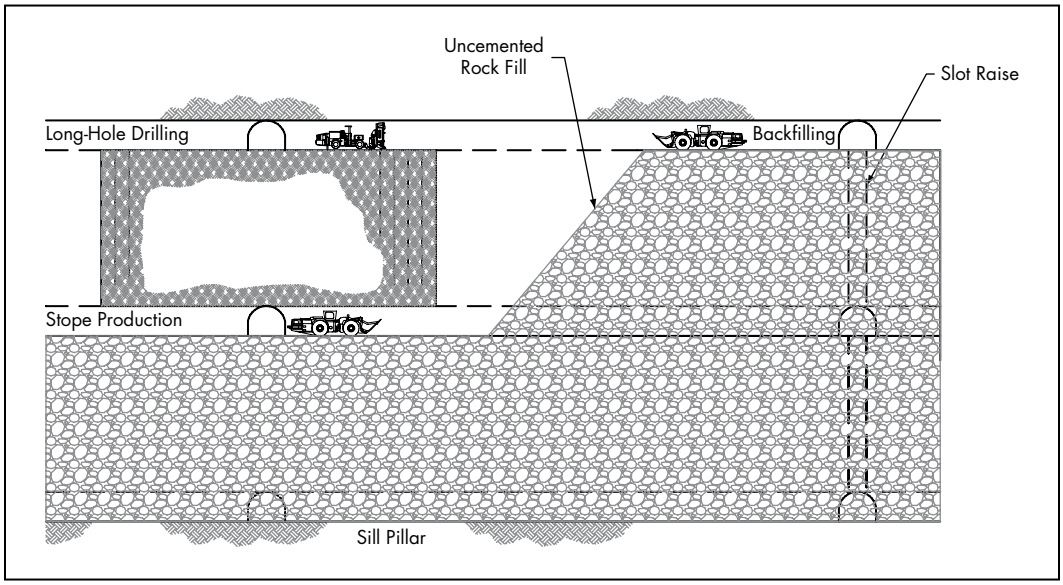

Figure 13.5-9 Bench-and-fill

footwall conditions, thus reducing dilution and ore loss. The use of some cemented fill to augment the uncemented fill can also increase recovery.

EXAMPLE MINES

The mines referenced in this section are using, plan to use, or have used the cut-and-fill methods described herein. Many of these operations use more than one method, and in many cases their specific working methods have evolved over time. For reference and research purposes, the lists include both currently operating and nonoperating mines.

Mines Using Cemented Fill

This group includes mines using longitudinal blasthole stoping with delayed cemented fill, overhand drift-and-fill with delayed cemented fill, overhand drift-and-fill with cemented fill, and underhand drift-and-fill with cemented fill:

- Longitudinal blasthole stoping with delayed cemented fill
  - Garpenberg—Bergslagen, Sweden
  - Zinkgruvan—Bergslagen, Sweden
  - Julietta—Far East Russia
  - K2—Republic, Washington, United States (closed)
  - Kensington—Juneau, Alaska, United States (planned)
- Transverse blasthole stoping with delayed cemented fill
  - Big Gossan—Papua, Indonesia (planned)
  - Cannon—Wenatchee, Washington, United States (closed)
  - Diavik—Northwest Territories, Canada (planned)
  - Greens Creek—Admiralty Island, Alaska, United States

  - Kidd Creek—Timmins, Ontario, Canada
  - Meikle—Carlin, Nevada, United States
  - Mt. Isa—Queensland, Australia
- Overhand drift-and-fill with cemented fill
  - American Girl—Yuma, Arizona, United States (closed)
  - Golden Promise—Republic, Washington, United States (closed)
  - Rosebud—Lovelock, Nevada, United States (closed)
  - Strathcona deep copper mine—Levack, Sudbury, Ontario, Canada (closed)
- Underhand drift-and-fill with cemented fill
  - Apex—St. George, Utah, United States (closed)
  - Bullfrog—Beatty, Nevada, United States (closed)
  - Carlin East—Carlin, Nevada, United States
  - Deep Post—Carlin, Nevada, United States
  - Getchell/Turquoise Ridge—Golconda, Nevada, United States
  - Jerritt Canyon—Mountain City, Nevada, United States
  - Lucky Friday—Mullan, Idaho, United States
  - Rain—Carlin, Nevada, United States
  - Stratoni—Stratoni, Greece
  - Val Chisone—Italy

Mines Using Uncemented Fill

This group includes mines using vertical or near-vertical stoping with uncemented sand fill (hydraulic fill), resuing, postpillar mining with uncemented fill, and bench-and-fill stoping with uncemented fill:

- Vertical or near-vertical stoping with uncemented sand fill (hydraulic fill)
  - Bunker Hill—Kellogg, Idaho, United States (closed)
  - Galena—Wallace, Idaho, United States
  - Groundhog—Vanadium, New Mexico, United States
  - Homestake—Lead, South Dakota, United States (closed)
  - Star—Burke, Idaho, United States (closed)
  - Stillwater—Nye and Big Timber, Montana, United States
  - Sunshine—Kellogg, Idaho, United States (closed)
- Resuing
  - Golden Patricia—Kenora District, Ontario, Canada (closed)
  - Julietta—Far East Russia
- Postpillar mining with uncemented fill
  - Black Cloud—Leadville, Colorado, United States (closed)
  - Christmas mine—Winkelman, Arizona, United States (closed)
  - El Mochito—Las Vegas, Honduras
  - Mantos Blancos—Antofagasta, Chile
  - Milpillas—Sonora, Mexico
  - Rey de Plata—Guerrero, Mexico (closed)
  - Tizapa—Guerrero, Mexico
  - Madero—Zacatecas, Mexico
  - King Island Scheelite—Tasmania, Australia (closed)
- Bench-and-fill stoping with uncemented fill
  - El Peñón—Antofagasta, Chile
  - Ken Snyder—Midas, Nevada, United States (modified)
  - Mt. Isa lead mine—Queensland, Australia
  - Stillwater—Nye and Big Timber, Montana, United States

CURRENT TRENDS

Stope Mechanization

The widespread introduction of mobile equipment (diesel-powered loaders, trucks, drills, and service vehicles) since the 1960s and 1970s has largely replaced the use of jacklegs, stopers, and slushers, the primary underground mining machinery of the prior era. The maintenance and maximum usage of this mobile equipment precludes allowing it to become captive in a single stope. Therefore, access to stope levels is now almost exclusively by ramps rather than by raises.

The demand for ventilation has also been increased because of the increased usage of diesel equipment.

In recent years, production with remote controlled loader operation has been replacing the more costly development of gathering bells and chutes that have been commonly used in blasthole stope mines.

Paste Fill

Mining fill systems based on the use of paste for backfill are supplanting other fill systems for bulk backfill applications. The opportunity to transport and place the material by pipe reticulation substantially decreases congestion in drifts and ramps. The placement rate of paste fill is much faster than placement using trucks carrying fill from a surface or underground batch plant and then having to rely on LHDs and jammers to place the fill into the stope.

The resulting benefits (lower operating costs, lower ventilation demands, and a faster turnaround time for the filled stope) are similar to those achieved by hydraulic systems, but without the water drainage issues. However, paste plants are costly to construct and must be completed during preproduction development.

Cemented Rock Fill

The use of cemented rock fill continues to be a common choice where bulk material handling is not advantageous and where flexibility is important to maintaining operations.

CHAPTER 13.6

Backfill Mining

Douglas F. Hambley

INTRODUCTION

This chapter discusses the design of systems for backfilling underground mines, opening with a short history of backfilling followed by a listing of the types of backfilling systems to be covered in the chapter, and closing with a discussion of sources of further information. Stoping methods that use backfill are discussed in other chapters, especially Chapter 13.5.

Backfilling of mined openings may be performed for a number of reasons. The first is to provide support for walls of an opening in relatively weak rock so that ore immediately above, below, or adjacent to the opening can be mined. Another possible reason for backfilling is to contribute to the support of the roof and walls of a wide opening. In this case, the backfill will not prevent failure in the roof, but it will minimize the displacement of the broken rock and thereby minimize the potential for progressive upward failure, possibly reaching to the surface. This leads to another reason for backfilling, namely minimization of surface subsidence. A final important reason for backfilling is isolation and disposal of mining/milling wastes considered to be unattractive or an environmental hazard on the surface.

Unless otherwise noted, equations in this chapter are given in consistent units. The reader is expected to include units when performing calculations and provide any necessary conversion factors.

BRIEF HISTORY OF BACKFILLING PRACTICES

The backfilling of mined openings has a long history. It is only since about the 1980s that archeologists have recognized that backfilled bell pits in chalk in Europe that date from 2700 BC were actually mines for flint. The workings extended outward from the base of a shaft in all directions without support until it became unsafe, at which time the workings and shaft were backfilled to surface and another pit begun alongside. This method of mining apparently remained in use in near-surface ironstone and coal mines in the United Kingdom until the early 19th century (Shepherd 1980).

Stowing of wastes in workings to allow the mining of adjacent areas was a common practice in the metal mines in Cornwall (United Kingdom) and the coal mines in Belgium in the mid-19th century. Wastes generally consisted of barren or low-grade rock mined as part of the stoping process or in other areas of the mine away from the ore body or seam. However, if wastes obtained in this manner were insufficient, other materials such as sand or smelter slag could be brought into the mine to act as backfill (Callon 1876).

In the Kolar Gold Fields in India, quarried granite blocks were used as backfill/ground support in overhand stopes until the 1940s. The granite blocks were hand fitted to completely span the width of the stope. The advantage of this was that because the deformation modulus is similar to that of the wall rock, significant amounts of stress could be transferred to the blocks from the wall rock, thereby reducing the potential for rock bursts, which were a severe problem in those deep mines. The disadvantage of this method is that it is only feasible where labor is extremely cheap.

Hydraulic backfilling (fill placed hydraulically) has been used in the coal mines in Pennsylvania (United States) since 1884 (Peele 1941). With regard to metal mines, hydraulic placement of sand-sized tailings appears to have been first practiced in the gold mines on the Witwatersrand in South Africa in 1910, its initial adoption in North America occurring in Butte, Montana (United States) in 1917. As in Pennsylvania, the initial use at Butte was to seal off a mine fire in an area of broken ground where other sealing methods were impractical (Rahilly 1923). General rules were developed early from experience concerning the pipe velocities necessary to convey tailings hydraulically without having the pipes "sand out" (fill up from particle sedimentation due to insufficient flow velocity); however, criteria for flow and identification of the different flow regimes that operate with slurries have only been developed since the early 1950s beginning with Durand and his co-workers at SOGREAH (SOciete GRenobloise d'Etudes et d'Application Hydrauliques) in France and others working independently in the United Kingdom (Abulnaga 2002).

In the late 1950s, the International Nickel Company (INCO) of Canada (now Vale Inco) and Falconbridge Nickel Mines Ltd. (now Xstrata) began experimenting with the addition of portland cement to hydraulic backfill. The purpose was to produce a stronger fill that could be used for support in

Douglas F. Hambley, Associate, Agapito Associates, Inc., Golden, Colorado, USA

pillar recovery operations and could provide competent mucking floors, thereby eliminating the need for timber floors. In 1961, with financial support from the two aforementioned mining companies, Canada Cement Lafarge Ltd. began a comprehensive study to develop cemented fill technology that was completed in 1970 with the publication of their findings (Weaver and Luka 1970).

Pneumatic stowing was introduced in Polish coal mines in the 1920s and soon afterward adopted in other coal mining areas of Europe. In North America, the use of pneumatic stowing was promoted by the U.S. Bureau of Mines in the 1960s and 1970s but has not generally been adopted. The method was tested at the Sullivan mine in British Columbia (Canada) in the late-1960s and later used in uranium mines in Grants, New Mexico (United States), and in gold mines in South Africa.

The concept of thickened tailings, developed by Professor Robinsky of the University of Toronto and first applied at the Kidd Creek mine in Timmins, Ontario (Canada), in the mid-1970s, was extended by the late Dave Landriault and others at INCO Metals in the 1980s and later at Golder Paste Technology Ltd. to become paste fill when used for backfill underground. In 1975, pump-pack was developed by the British using broken coal and bentonite, which was a thixotropic material and pumped like a toothpaste but set like a low-strength concrete (Schmidt et al. 1976). Paste fill was developed independently in Germany at the Bad Grund mine in the early 1980s (Jewell 2006).

"Flowable fill" has been used in recent years by, among others, the Office of Surface Mining Reclamation and Enforcement (OSMRE) of the U.S. Department of the Interior to remotely backfill near-surface abandoned mines—especially coal mines—that represent a subsidence hazard. Flowable fill refers to a cementitious slurry consisting of a mixture of fine aggregate or filler, water, and cementitious material(s) that is used primarily as a backfill in lieu of compacted earth. This mixture is capable of filling all voids in irregular excavations and hard-to-reach places (such as under and around pipes), is self-leveling, and hardens in a matter of a few hours without the need for compaction in layers.

TYPES OF BACKFILL

As indicated in the history section, the different materials that have been used to backfill mine openings include the following:

- Dry sand and rock fill
- Uncemented hydraulic backfill
- Cemented hydraulic backfill
- Cemented rock fill
- Paste fill
- Pneumatic fill
- Flowable fill

In subsequent sections of this chapter, each of these alternatives will be discussed. For each, the method of placement, drainage requirements, if any, equipment requirements, pipe wear, and other relevant design and operating topics are considered.

Dry Sand and Rock Fill

Dry placement of stope fill materials is often the simplest method of fill placement and has a long history. In metal mines in North America and Australia that used cut-and-fill or square-set stoping, this method dominated until the 1950s and was still taught as a preferred method of backfilling in some mining schools until the late 1960s.

Advantages and Disadvantages

Although it has generally been superseded by other methods, there are still situations where dry placement of fill has advantages over other systems. For example, if a mine does not have a processing plant on site to provide mill tailings, other fill options must be considered. Such fills could include (1) natural surface sands (glacial till in North America, natural dune sands in Australia); (2) open-cut overburden, specifically quarried surface rock, or even rock generated in local civil works; and (3) underground development waste. Dry fill is also the preferred option in evaporite and gypsum mines where the ore or host rock is readily dissolved in water, or in mines in arid locations where water is scarce.

Dry placement of fill has two main disadvantages. First, it has a relatively low density as placed, which means it can undergo significant compression before it reaches its optimum density to provide stope wall support to prevent spalling of stope walls and minimize stope wall convergence. Second, depending on stope configuration, it may be difficult to place dry fill close to the roof of the opening across the full span of the stope roof.

Transport and Placement of Dry Fill

The first consideration, as with all types of backfill, is the means of transport of the dry fill underground. The most efficient means for transport of sand- or gravel-sized particles is a borehole from the surface. Selection of the size of the borehole depends on two considerations: the required throughput in metric tons per hour, and the size distribution of the particles. For coarse material such as gravel, the particle size will govern, because the diameter of the borehole should, as a general but not necessarily universally applicable rule, be a minimum of three to six times the maximum particle size of the gravel in order to avoid hang-ups. For finer material, the governing concern is the required throughput. In general, boreholes with diameters of 150 mm or 200 mm (6 or 8 in.) will be sufficient for most purposes. However, using this size of pipe, one must never let the pipe fill and possibly bridge, as it may plug.

The most common method of transporting dry fill to the workings is by haulage vehicles. In conventional, older mines, this usually meant railcars, which would dump the fill into a fill raise. More recently, haulage trucks have been used and belt conveyors are also being used for sand, gravel, or rock. All of these placement methods require good access to the workings that need to be filled.

Another important consideration with dry placement of granular fill is the method used to place and compact the fill within the stope. Historically, placement was done by hand, which is slow and costly. If the area to be filled is accessible to mobile equipment, spreading and compaction could be accomplished by means of a hydraulic ram and blade mounted on a haulage truck or load-haul-dump (LHD) vehicle. (The blade is pushed laterally against the fill pile by the hydraulic ram to compact it.) Another placement and compaction method that has been tried is a high-speed throwing belt, the main disadvantage of which is the limited distance that the fill travels beyond the discharge point.

In the case of rock fill, placement is not generally a problem if dumping is from the top of the working. Because of

the mass of the rock pieces, gravity flow is usually satisfactory. However, large blocks contain a significant proportion of voids, and such fill may need considerable consolidation before it can provide significant stope wall restraint. This disadvantage is often resolved by filling the voids with cemented hydraulic fill, as discussed later in this chapter.

Uncemented Hydraulic Backfill System Design

Hydraulic transport and placement of backfill is the method most commonly used in metal mines but less commonly in coal mines. Deslimed and partially dewatered mill tailings are the materials most commonly transported underground hydraulically, but surface sand (e.g., glacial till in North America, natural dune sands in Australia) is also transported in this manner. The fine (slimes) portion of tailings is undesirable because of its slow drainage, but also because of the potentially disastrous consequences of liquefaction resulting from vibrations from, for example, production blasts.

Transport of Slurry Solids Content

Mill tailings generally consist of a heterogeneous slurry with approximately 30%–40% solids by mass and the rest water. The solids and the water represent two separate phases that will readily separate if the flow velocity is insufficient. When a heterogeneous slurry is discharged from a horizontal pipe, the solids will settle out with the coarsest particles settling first. As the solids are discharged, they will gradually form a cone around the end of the pipe, with the finer materials toward the toe of the slope. The slope of the cone varies with the solids content of the slurry; with very dilute slurries, the slope may not exceed 2°–3° and the sediments will be loosely packed, but at solids contents of 60%–70% by mass or more, the slope will approach the angle of repose of the particles and the solids will consolidate readily as they drain.

Hydraulic backfill systems typically operate at solids contents of 65%–70% solids by mass or more. Because, as stated previously, the tailings in the mill typically have a solids content of around 30% by mass, it is generally necessary to partially dewater the tailings prior to transport underground. Dewatering is usually accomplished using hydrocyclones or occasionally thickeners or rake classifiers. Hydrocyclones are vastly preferable because they most effectively deslime as well as dewater. One word of caution: The cut point commonly used by geotechnical engineers for drainage computations is the D_{10} size, whereas the D_{20} or D_{50} size is used by designers of hydrocyclones. Failure to appreciate this distinction could result in having a larger fines content than anticipated in the backfill. It is critical to maintain the design flow rate in a hydrocyclone if the cut point is to be achieved in practice.

Drainage requirements. After hydraulic backfill has been placed in a mined opening, it is necessary to drain away the water for a number of reasons. First, water-bearing sand/slime-sized material, especially if it contains excessive slimes and/or excessive water, can liquefy if subject to vibration caused by a seismic disturbance such as an earthquake, by a rock burst, or by production blasting. Second, drainage of the water is essential to consolidation of the fill. Because the fill is used as the working floor for the next lift in overhand cut-and-fill stoping, it is generally desirable to have it available for production traffic within 24 hours.

Prevention of the phenomenon of liquefaction requires essential consideration in the preparation and placement of hydraulic fill—particularly uncemented hydraulic fill—underground.

A general, but not absolute, rule is that the gravitational percolation rate of water through the fill should exceed 10 cm/h (4 in./h). Because drainage of water from the fill is by gravity with a hydraulic gradient of unity, this percolation rate corresponds to a hydraulic conductivity of approximately 3×10^{-3} cm/s (5.9×10^{-3} fpm), which is a typical value for a well-graded, fine-grained sand. To ensure this drainage rate is achieved, it is customary to remove the fines so that no more than 10% of the solids are finer than 74 μm (200 mesh). However, satisfactory backfilling has been achieved with as much as 10% of the solids finer than 43 μm (325 mesh). Also, hydraulic conductivity is temperature dependent, so as mine water temperature increases, fines content can increase and drainage rates remain satisfactory. Importantly, the converse applies. A comprehensive discussion of hydraulic fill drainage mechanisms is given by Thomas et al. (1979).

To facilitate fill drainage, it is customary to erect fences within the stopes being filled to contain the fill and to drain the water through ladderways or drain towers constructed up through the fill. To allow the fill water to drain without loss of fill fines it is customary to place filter fabrics on the inside of fill fences and outside drainage ladderways and towers inside the site to be filled. Historically, burlap (in North America) or hessian (in Australia) was used as the filter fabric. More recently, these materials have been largely replaced by monofilament geotextiles, though the traditional materials, where available, are still acceptable. To select the correct geotextile, the following filter selection criteria developed by the U.S. Army Corps of Engineers may be used:

- The ratio of the D_{85} (85% finer) size of the backfill to the opening size of the geotextile should exceed 1.0.
- The open area of the geotextile should be less than 40% of its total area.

For most tailings, the D_{85} size will range from 149 to 297 μm (0.0069 to 0.012 in.). Selection of the geotextile should also consider the required water flow rate per unit area of geotextile, which depends on the dimensions of the fill fences and drainage towers.

Backfill transport pipe size requirements. With two-phase (solids/fluid) heterogeneous slurries, the transport velocity in a pipeline must be high enough to prevent deposition of coarse particles. On the other hand, an excessive transport velocity in the pipe will result in excessive friction losses and pipe wear. A flow velocity of 1.5 m/s (5 fps) is often but not always considered the minimum necessary to provide satisfactory results. Conversely, a flow velocity of greater than 2.4 m/s (8 fps) may result in excess friction losses and pipe wear. Table 13.6-1 presents hourly placement tonnages that can be achieved at a pipe velocity of approximately 1.8 m/s (6 fps) and 65%–70% solids density by mass for a material with a specific gravity of 2.65.

Pipe friction losses and pump requirements. In mines accessed by a shaft, transport of backfill underground will be by means of either a pipe in the shaft or a borehole near the shaft (preferable to a pipe in the shaft, depending on shaft function) that connects the backfill plant to the workings. In such cases, the elevation difference is usually but not always sufficient to transport the fill to the working place without pumping. However, where access to the mine is by means of a horizontal adit, gravity flow will, with the occasional

Table 13.6-1 Hydraulic fill placement rate versus pipe diameter

Nominal pipe diameter, mm	50	80	100	150	200
Nominal pipe diameter, in.	2	3	4	6	8
Fill placement rate, t solids/h	15–20	35–40	65–75	145–165	255–290

Table 13.6-2 Fill tonnages handled before replacement by various types of pipe and fittings

Type	Standard (Schedule 40)	Heavy-Duty (Schedule 80)	Rubber-Lined
Pipe, t	250,000	800,000	>800,000
Bends and elbows, t	—	>250,000	>1,300,000
Tees, t	150,000	600,000	>600,000

Source: Adapted from Waterfield 1973.

exception, not be sufficient to transport the backfill slurry and pumping will be necessary. Where mine access is by decline, pumping may or may not be necessary, depending on the general mine layout. In all cases it is prudent to calculate the friction losses in the system. Friction losses are greater than those for water alone, but can be estimated from the conventional Darcy–Weisbach equation using the following adjusted friction factor (Abulnaga 2002):

$$f_m = f_L\{1 + 81C_v[gD_i(\rho_s - \rho_L)/(V^2\rho_L\sqrt{C_d})]^{1.5}\} \quad (13.6\text{-}1)$$

where

f_m = friction factor for the slurry mixture
f_L = friction factor for clear water under the same temperature and pressure conditions
C_v = solids concentration by volume
D_i = inside diameter of the pipe
ρ_s = solids density
ρ_L = water density
V = slurry velocity in the pipe
C_d = drag coefficient, which can be taken as 0.43 in most situations

If a pump is found to be necessary, a centrifugal slurry pump is the most likely selection, pump specification being based on head and flow rate requirements. These are relatively low-head pumps, and it may be necessary to install pumps in series to ensure that varying head requirements are met. However, material will flow through the pump impellers even if the head contribution is not needed and the motor not operating. To minimize wear in centrifugal pumps, the following guidelines should be followed (Paterson 2006):

- Discharge velocity less than 8 m/s (26 fps)
- Maximum impeller tip speed for all-metal pumps of 28 m/s (92 fps)
- Maximum impeller tip speed for rubber-lined pumps of 20 m/s (76 fps)
- Range of discharge flow/flow at best efficiency point of 60%–100%

Wear in pipes and line fittings and pipe material selection. Erosion of the walls of boreholes used to transport backfill underground is generally not considered a serious problem, though boreholes must be lined from the surface down to appropriately below the base of surface rock alteration, sometimes referred to as the base of complete oxidation. This is based on the usual situation where the oxidized/altered rock from the surface will be scoured by the fill flow, whereas the significantly more solid rock below will not. On the other hand, wear in elbows, tees, and other fittings and in pipes will result in the need for periodic replacement or selection of more appropriate lining materials. Consequently, the design engineer must consider whether to use

- Rubber-lined, heavy-duty (thick-walled), or standard pipes;
- Victualic, threaded, or flanged pipe couplings;
- Rubber-lined, built-up (heavy-duty), or standard bends, elbows, and tees;
- Heavy-duty rubber hose or rubber-lined pipe connections at horizontal takeoff points; or
- For long-term, high-tonnage applications, pipes and fittings with basalt or similar linings.

In general, wear is most severe at bends, elbows, and tees; however, wear will also occur in straight pipe, especially if the slurry is abrasive and contains angular particles. Wear rates depend on the density of the slurry, the diameter of the pipe, the flow velocity, and the maximum size and abrasiveness of the particles. Unfortunately, wear rates are rarely expressed in terms of these parameters but are more commonly given in terms of the tonnage handled by pipe prior to replacement. If line velocities are not excessive, the tonnages given in Table 13.6-2 can be expected before replacement becomes necessary.

The lack of data in Table 13.6-2 regarding the life of elbows and bends is because tees are much more commonly used for takeoffs because it is simpler to change the side of the tee that is blanked off than it is to uncouple a line to insert a bend or elbow. In stopes, distribution pipes can be either standard steel pipe or plastic pipe and should include tees and valves at 3-m (10-ft) intervals to facilitate even distribution of the fill. Wear is typically on the invert of the fill pipe, and pipe life can be extended significantly by rotating the pipe one-sixth of a revolution at regular intervals.

In multilevel mining, heavy-duty rubber hose connections are preferable to pipe connections at the levels. Only a single hose is required at a level even though there may be multiple branch lines. However, the connections on the ends of the hoses will be bolted flanges rather than victualic or threaded connections.

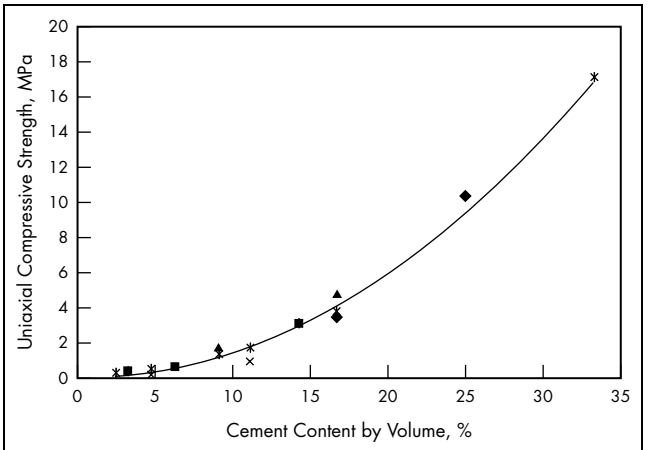
Backfill Plant Requirements

The first requirement in a typical backfill plant is a bank of hydrocyclones to remove excess water and fine particles from the tailings. The overflow from the cyclones (the fines and excess

water) is typically transported to a surface tailings impoundment for disposal. Many mines once operated on a 5-day week, whereas concentrators typically operate on a 7-day week, and in such cases it became necessary to provide a storage silo capable of holding backfill pouring requirements for 1 or 2 days. This silo is known as a repulper, because the backfill is allowed to drain until needed, at which time water is added at high pressure to the base of the tank to refluidize the fill.

The fill plant will also need transfer pumps and valving, and care should be taken to ensure that the capacities of the transfer pumps are sufficient. Transfer pumps should be able to handle a flow rate approximately 20% greater than the design flow rate for the system (solids plus water), because if the flow rate decreases below the critical value for sedimentation, the inevitable result will be the complete filling of the pipe with solids. Cleaning out a pipe that has sanded up is time-consuming and costly, particularly if the fill contains portland cement.

Current practice is more likely to have both mine and mill operating around the clock, thus eliminating the need for fill storage tanks and the complexities they involve.



Cemented Hydraulic Backfill System Design

Correctly prepared uncemented hydraulic fill is predominantly sand-sized and must behave as a sand, albeit on occasions a slow-draining sand. Consequently, it has no true cohesion or, until drained, no unconfined compressive strength. For some applications, such as fill placed against unmined rock that will be recovered later, it is often desirable that the fill be able to stand unsupported upon exposure. For such applications, it is customary (but on occasions not at all necessary and possibly detrimental) to add cement to the backfill.

Because cemented fill is the same fill material as the uncemented fill except for the cement, several of the design parameters for a cemented hydraulic backfill system are the same as for an uncemented backfill system. However, slurry solids content must be more carefully controlled, though pipeline velocities remain essentially the same. As is the case for uncemented fill, the tailings are deslimed with a typical D_{10} size of 74 μm (200 mesh). However, the cement provides fines to the mix and the drainage rate is typically somewhat slower than that for uncemented fill. This potential problem is in part negated for the following reasons: (1) portland cement consumes fill water during hydration, reducing the volume of water to be removed; (2) portland cement produces heat during hydration, reducing the viscosity of fill water, tending to increase dewatering rate; and (3) portland cement lubricates the flow so higher placement densities can be used, reducing the amount of water to be removed. In pipeline flow, portland cemented fill flows more uniformly than uncemented hydraulic fill, and this tends to reduce pipeline wear for similar placement rates—coarse fill particles have reduced access to pipeline walls. Optimum solids content for pipeline flow generally ranges from 68% to 72% solids by mass, and closer attention is given to control of this solids content. Costs considered, after portland cement is added to hydraulic fill, the fill operation moves from underground disposal of mining waste to preparation of a quality-controlled engineering material.

Cement Content Versus Strength and Deformation Properties

The strength of a cemented fill depends on the percentage of cement in the fill. Figure 13.6-1 shows the relationship between cement content and strength for several cemented mine backfills in Canada and Australia. Although Figure 13.6-1 shows the cement content as a volume percentage, it is best to express the cement content as a mass percentage of the total dry solids. The equation of the best-fit curve in Figure 13.6-1 is given by

Note: Symbols represent different mines. The mines are not identified because some of these data are from unpublished sources.

Figure 13.6-1 Backfill compressive strength as a function of cement content

$$C_o = 12.1\ P^{2.0448} \tag{13.6-2}$$

where

C_o = compressive strength in kilopascals (kPa) (multiply result by 0.145 to obtain strength in psi)
P = cement content in volume percent

Some mines have experimented with replacing part of the cement with fly ash or ground slag and/or similar pozzolanic materials. In the case of fly ash, there does not appear to be a significant difference in compressive strength for fly ash contents up to 20% of the cement content in fill with cement/tailings ratios between 1:10 and 1:30 by volume. In the case of ground slag, the uniaxial compressive strength increases compared to portland cement only, with the increase approximately proportional to the slag content.

Cement Content Versus Use

The amount of cement required in a cemented fill depends on the strength requirement and the use for the fill. Some examples are given in Table 13.6-3. These should be used for guidance and not adopted as standard. For example, use of cement in mucking floors may have advantages for movement of mucking equipment, but it prevents almost totally the downward flow of fill drainage water.

Freestanding Height

The freestanding height of cemented backfill depends on the compressive strength and density of the fill as follows:

$$H = 2C_o/\gamma g \tag{13.6-3}$$

where

H = freestanding height of the fill
C_o = uniaxial compressive strength of the backfill
γ = density of the fill

Table 13.6-3 Cemented fill cement/tailings ratio versus application

Application	Cement/Tailings Ratio
Bulk filling	1:30
Barrier against adjacent pillar, adjacent stope, or related structures	1:10
Mucking floors	1:6 to 1:12
Water-retaining bulkheads/barricades where no restriction of stope drainage must result—drain pipes through the strengthening plug	1:2

In practice, the known parameter in Equation 13.6-3 is the required freestanding height; the compressive strength necessary for the fill to stand unaided at that height is the unknown. For example, if the required freestanding height is 8 m and the specific gravity of the fill is 1.7, Equation 13.6-3 indicates that the required strength is 133 kPa (19.3 psi). From Figure 13.6-1, the strength corresponds to a backfill containing approximately 3% cement. Alternatively, for a compressive strength of 133 kPa, Equation 13.6-2 gives a cement content of 3.22%, which is equivalent to a cement/tailings ratio of 1:30.

Pump Requirements

Where there is extensive horizontal development on upper levels of a mine, the elevation head may be insufficient to support flow by gravity alone. In such cases, pumps will be necessary to transport the fill over all or part of the underground fill distribution system. Both positive displacement pumps and centrifugal pumps can be used for this application; however, rubber-lined centrifugal slurry pumps are considered a better choice. Pumps with dry glands, which minimize water handling requirements, are available. With centrifugal pumps, the slurry will flow through a pump even if it is not needed to supply head.

Backfill Plant Requirements

Backfill plant requirements are similar to those for uncemented fill, except for the need for a cement silo plus mixing tanks and feeders.

Cemented Rock Fill System Design

Cemented rock fill, as typical of modern practice, was developed at the Geco Division of Noranda Mines Ltd. in the early 1960s to provide support for stope walls that were prone to slough. By restraining stope wall rock, the fill reduced dilution and improved overall regional stability. A cemented rock fill system was developed at Mount Isa in Australia in the late 1960s, but the main reason for the rock fill component was to reduce the quantities of cemented hydraulic fill as portland cement was expensive in that part of Australia, being remote from cement suppliers and prone to disruption of supply during the wet season. In a cemented rock fill system, the main design function of the cemented hydraulic fill is to fill the voids in the broken rock.

Rock Fill Size Considerations

Rock fills should consist of coarse angular fragments of medium to high density, medium to high chemical stability, and high strength and abrasion resistance. Abrasion resistance can be tested using the Los Angeles abrasion test.

The rock fill can be modified to suit a particular application by optimizing the particle size distribution. A competent fill that will stand when exposed on a vertical face should have a low porosity. Fill should be appropriately graded with respect to particle size. The particle size distribution of a rock mass is often represented by the Gates–Gaudin–Schuhmann distribution:

$$P = (d/m)^n \tag{13.6-4}$$

where

P = cumulative percent finer than size d
d = particle size
m = maximum particle size

In the concrete industry, a densely packed fill material is obtained when the exponent, n, in Equation 13.6-4 is 0.5.

A major concern with rock fill is the extent of rock degradation from impacts during freefall passing underground from the surface or from degradation from particles grinding against each other during choke-fed passing. An impact test that was used successfully at Mount Isa in Australia (Kuganathan 2005) consisted of dropping samples of up to 300-mm (11.8-in.) boulders from a height of 16.5 m (54 ft) onto a piece of 16-mm (⅝-in.) thick manganese steel liner plate. A test was considered successful if 75% of the material recovered was coarser than 25 mm (1 in.). The first full-scale drop tests at Mount Isa involved dropping several tens of metric tons of surface-quarried rock about 530 m (1,600 ft) down a vertical shaft, with particle size analyses before and after.

Binder Placement

The stiffener in a cemented rock fill can consist of deslimed mill tailings fill, cemented deslimed mill tailings fill, paste fill, portland cement, fly ash or other pozzolan, or a combination of two or more of these. All of these binders are transported most easily by pipeline to be added to the rock fill as it enters the top or some more-appropriate location in the stope. Standardization of such practice is difficult and large stopes must be considered on a case-by-case basis.

Paste Fill System Design

With paste fill, the tailings become a high-density slurry with a solids content of 75%–80% by mass. The slurry acts as a viscous, Bingham solid, for which a critical shear stress must be exceeded before the material will flow. The critical shear stress for paste fills typically ranges between 250 and 800 Pa (0.041 to 0.116 psi) (Boger et al. 2006).

Because of the viscous nature of the paste and the large amounts of energy required to transport paste in the turbulent regime, it is customary to transport paste in the laminar flow regime (Paterson 2006). The drawback to laminar flow, however, is the potential for sedimentation and blockage in the pipeline, though paste fill, because of its tightly controlled production and relatively high pulp density, is less prone to settling than conventional deslimed mill tailings fill. Two other important attributes of paste fill are (1) the water is bound into the slurry, so that little drainage is required; and (2) the fact that fines removal from tailings may not be required.

Paste Particle Size Requirements

At least 15% of the particles in the paste should be finer than 20 μm (0.00079 in.) (Hassani and Archibald 1998).

In addition, it is customary to add from 3% to 6% portland cement or a mixture of portland cement and fly ash as a binder. If the tailings contain insufficient fines, it may be necessary to add fly ash or additional cement.

Pump Requirements

The critical issue for pumping the paste from the backfill plant to the mine stopes is the initial shear stress that must be overcome before the paste will flow (Abulnaga 2002):

$$P_{st} = 4\,\tau_0\,L/D_i \tag{13.6-5}$$

where
P_{st} = start-up pressure
τ_0 = initial shear strength of the paste
L = pipe length
D_i = inside pipe diameter

The initial shear stress to be overcome, or yield stress, can be measured by the vane shear test. Alternatively, it is becoming more common to estimate the yield stress from a slump test using the following relationship (Boger et al. 2006):

$$\tau_0/\rho g h = 0.5 + 0.5(s/h)^{0.5} \tag{13.6-6}$$

where
s = measured slump
h = height of the slump cylinder

Because of the viscosity and the density of the paste, positive displacement pumps are required. These pumps have the attribute that they can pump against any head up to the design head of the machine while the flow rate remains constant. These pumps should be fitted with pressure relief valves because they will continue to pump against blocked or closed pipes, which could result in a ruptured pipe or a damaged pump.

Pipe Wear

Few data are available regarding the wear of pipes transporting paste fill. However, because the paste moves as a viscous unit, it is expected that the wear rates are less than for conventional hydraulic fills. The wear can be checked in vertical sections of the pipelines using a three-legged caliper probe. It is recommended that readings be taken after 15,000 t (16,535 st) have been transported and thereafter at 50,000-t (55,116-st) intervals.

Backfill Plant Requirements

Components in a paste fill plant typically include tailings storage tanks with a 1-day live storage capacity; paste thickeners for reducing water content from 65% by mass to approximately 20% by mass; silos for cement (and possibly fly ash) storage; weightometer hoppers for tailings, cement, and fly ash (if used); mixers for blending tailings, fly ash, and cement (if used); and positive displacement pumps.

Pneumatic Stowing

Pneumatic stowing is often used in situations where hydraulic filling has significant drawbacks. Examples are situations where it is undesirable to handle the large quantities of water that drain off from the fill or where seams are thin and flat-lying so that hydraulic placement of fill tight to the roof is difficult to achieve. Pneumatic stowing has also been considered as a means of placing broken rock whose ore grade is too low for recovery by conventional means in order to extract a mineral by pressure or flood leaching.

Transport Considerations

For successful pneumatic stowing, the air velocity must be sufficient to move the solids. The air velocity at which the solids begin to move is the critical transport velocity. For vertical conveying, the critical transport velocity equals the terminal velocity, which is given by either Stokes' law or the Newton–Rittinger equation depending on whether the flow is laminar or turbulent. For pneumatic transport, the flow of both air and the solids is turbulent, and the terminal velocity is given by the Newton–Rittinger equation:

$$v_t = [4gD_i(\rho_s - \rho_a)/(3\rho_a C_d)]^{0.5} \tag{13.6-7}$$

where
v_t = terminal velocity
ρ_a = air density

For the fully turbulent regime, C_d has an essentially constant value of 0.44. The air density term in the numerator of Equation 13.6-7 can be ignored. For horizontal conveying, the critical velocity is approximately $0.7v_t$. For satisfactory flow, the air velocity should be four to five times the critical velocity.

Particle Size Distribution

The particle size distribution will affect the velocity necessary to transport the solids and the pipe size. To minimize the possibility of bridging of large chunks, the pipe diameter should be at least three times that of the largest chunk carried. As a practical matter, the maximum lump size should be 100 mm (4 in.) or less, with 75 mm (3 in.) preferred. Considered another way, typical stowing pipe diameters range from 150 mm (6 in.) up to 225 mm (9 in.). Consequently, the maximum lump size should preferably be less than 75 mm (3 in.), and ideally 50 mm (2 in.) or less. A smaller maximum particle size will also result in reduced velocity, power requirements, and pipe wear.

Feeder and Blower Considerations

A pneumatic stowing system has three basic components:

1. A hopper and feeder for the solids
2. An air supply consisting of compressed air from either a pipeline or compressor, or a rotary blower
3. An injection pipe and nozzle

The hopper should be large enough to contain a bucket load of broken material from a typical haulage vehicle. The discharge opening in the hopper should have a minimum dimension of at least three to six times the dimension of the largest piece being transported.

The feeder should be sized to handle the expected hourly throughput of the system. Three important considerations for the feeder, which is generally a rotary airlock type, are the number of vanes on the rotor, diameter of the airlock, and the rotor rpm. For a given flow rate in cubic meters per hour, better flow characteristics are obtained with a larger diameter airlock operated at a lower rpm. Six or eight vane models are available. In some applications, difficulties have been experienced with the eight-vane units.

Table 13.6-4 Estimated fill throughput through different types of pipe before replacement

Type of Pipe	Pipe Life, 1,000 m^3 of material passed
Standard Schedule 40 steel pipe	8 to 30
Twin-wall pipe	20 to 150
Steel pipe with abrasion-resistant basalt lining	200 to 1,500

Source: Adapted from Jerabek and Hartmann 1966.

Except for very large tonnage operations, low-pressure systems using positive displacement blowers provide satisfactory air quantities for stowing. These blowers are noisy and should be fitted with silencers. Injection pipes are typically 150–225 mm (6–9 in.) in diameter. Air velocities in the stowing pipe should exceed 20 m/s (65 fps), and the exit velocity in the nozzle should be about 40 m/s (130 fps) for optimum results. Stowing machines are available to place up to 280 m^3/h (367 yd^3/h).

Solids Loading and System Pressure Drop

An important parameter is the solids-to-air ratio by weight. For most stowing applications this ratio will range from 10 to 40. However, the actual value of the ratio for a given stowing operation will depend on the quantity and size of the solids to be stowed, given that with coarse material the velocity required to keep the solids in the air stream will be higher than for fine material.

The system pressure drop consists of the pressure drop due to the air in the system and the pressure drop due to the solids. The air pressure drop is given by the Darcy–Weisbach equation in the following form:

$$\Delta p_a = p_a^2 - p_2^2 = f\,(L/D_i)(V_a^2/2g)\gamma_{a1}p_a \qquad (13.6\text{-}8)$$

where
p_a = initial air pressure
p_2 = mine atmospheric pressure
f = friction factor = 0.016
L = pipe length
D_i = pipe internal diameter
V_a = pipe air velocity
γ_{a1} = specific gravity of mine air

Based on tests performed by Peter (1952), the total system pressure drop for a given solid/air ratio can be estimated from the following equation:

$$S = (0.2086 - 0.0001\,EQ)R_s + 1 \qquad (13.6\text{-}9)$$

where
S = ratio of system pressure drop to air pressure drop
E = electrostatic charge
Q = airflow rate, m^3/h
R_s = solids/air ratio by weight

Usually the equation shows the product of EQ in the direction of flow for determining the pressure drop. Thus, the presence of statically charged particles increases the pressure drop (Smeltzer et al. 1982). After the system pressure drop is known, the system power requirements can be determined.

Power Requirements

The power required to transport the solids is given by

$$P_b = RTQ\,\gamma_{a1}\ln((R_s\,\Delta p_a + p_2)/p_2) \qquad (13.6\text{-}10)$$

where
P_b = blower power
R = universal gas constant
T = absolute temperature (degrees K in metric units or degrees Rankine in English units)
Q = airflow rate
γ_{a1} = mine air density

Additional power will be required for the feeder as follows:

$$P_f = Q\,\gamma_{a1}\,D_f \qquad (13.6\text{-}11)$$

where
P_f = feeder power
D_f = feeder airlock diameter

It will be necessary in Equations 13.6-10 and 13.6-11 to include appropriate conversion factors to obtain the power in metric or English units.

Pipe Wear

Broken rock stowed pneumatically wears pipe rapidly, especially at bends. For this reason, standard Schedule 40 steel pipe should not be used. Heavy-duty (Schedule 80) pipe could be used; however, there are special multiwall pipes fabricated especially for stowing. Another option is pipes containing abrasion-resistant basalt pipe linings. Estimates of stowing pipe life for different types of pipe are presented in Table 13.6-4. Pipe life can be maximized by rotating the pipe one-sixth of a revolution at frequent intervals.

Flowable Fill System Design

Flowable fill is a self-consolidating, low-strength material used as an alternative to consolidated granular fill. It is an excellent solution for filling inaccessible areas such as abandoned mines and is used for this purpose by OSMRE and the Pennsylvania Department of Environmental Protection (PaDEP), among others. The mix proportions to provide 1 m^3 (1.31 yd^3) of the flowable fills used by these agencies are presented in Table 13.6-5.

Fly ash must conform in general to mineral admixture Class F but must have a moisture content not greater than 20% and a maximum loss on ignition of 6%. Black or brown fly ash will not be allowed unless certified lab results show the loss on ignition to be 6% or less. The sand must be 45%–80% finer than 1.19 mm (16 mesh) and approximately 10%–30% finer than 297 μm (50 mesh). The gravel must consist of hard, dense, durable uncoated gravel or crushed stone with a grain size distribution as follows:

Percent Finer, by Mass	Particle Size
100	19 mm (3/4 in.)
40–70	9.5 mm (3/8 in.)
0–15	4.76 mm (4 mesh)

Table 13.6-5 Flowable fill mixes for backfilling abandoned mines

Mix No.	Portland Cement, kg	Sand, kg	Gravel, kg	Fly Ash, kg	Water, L*
OSMRE No. 1	233	0	0	1,130	470
OSMRE No. 2	219	854	384	531	272
OSMRE No. 3	201	785	0	816	272
OSMRE No. 4	296	0	0	1,186	401
PaDEP	167	0	0	1,186	247

*Water contents may be modified from those shown to obtain sufficient slump for the mixture to flow.

Because flowable fill has a high slump by definition, gravity flow from the mixing tank will suffice for most applications. Other agencies that deal with abandoned mines may use other mixes.

Flowable Fill Equipment Requirements

Flowable fill is generally used to backfill abandoned mines. Consequently, it will generally not be possible to direct the flow of material from underground. Therefore, multiple access points from the surface are usually necessary, and storage silos and mixing equipment must be portable. Portable concrete batch mixers are readily available that can handle up to 153 m^3/h (200 yd^3/h). Portable silos for sand and fly ash storage can also be hired. Another option is to contract with a local concrete Ready Mix supplier, indicating the mix to be supplied.

OTHER CONSIDERATIONS

Remote Placement of Backfills

Backfilling of former mines as a subsidence-prevention measure is becoming increasingly common. In general, it will be necessary to provide multiple pour points to ensure the void will be as completely filled as possible. Similar to discharge from a stacker or conveyor, the solid discharge from a fill pipe will form a cone that is characterized by finer and finer particles as it moves away from the discharge point. The angle of repose of the cone depends on the solids percentage in the slurry—the higher the percent solids, the steeper the cone. Because a supply bore will become useless after the cone fills to the top of the opening, the spacing between supply borings depends on the height of the opening, as well as the percent solids in the fill.

Automated Systems

Because of the generally batch nature of filling and the need to change discharge locations during the course of backfill placement, not all facets of backfilling lend themselves to automatic operation. However, some portions of the cycle, such as starting and stopping of pumps and opening and closing of hopper gates, can be automated by means of interlocks, level controls, and other automatic controls. For example, the Manitoba Division of Vale Inco installed an automated fill pumping system at the Thompson mine in the 1960s. In theory, the valving on the discharge locations could be automated and interlocked with level switches placed below the discharges; however, the result would be a pouring system in the stope that would be significantly more difficult to install and dismantle.

Effect of Cemented Fill in Mill Feed on Processing Plant Recovery

When mucking on a fill floor, it is inevitable that some fill will be mixed with the broken ore. If the fill is uncemented, the only negative effect is some dilution. However, if the fill is cemented, there are likely to be unwanted effects on the concentrator circuit, especially in the case of a silver/lead/zinc ore. Specifically, the cement will significantly increase the pH of the process water because the pH of hydrous cement is approximately 10.5–11. In addition, the presence of calcium carbonate may chemically affect milling processes. Occasionally, the presence of cement will improve mill recovery percentages.

Heat Generation of Sulfide Backfills

Tailings containing pyrite and especially some forms of pyrrhotite readily oxidize, giving off heat and absorbing oxygen. As a consequence, it is not uncommon for the temperature in a stope to rise by 3°–5°C (5°–10°F) after the first lift of fill has been placed. However, the oxidation process may also result in additional cementing of the fill. Noranda took advantage of this at the Horne mine in Quebec when designing the hydraulic backfill system there in the 1930s (Patton 1957). One unfortunate consequence of this was loss of life by removal of oxygen from mine air. Also, it is reported that in the Kimberley mine in British Columbia, iron sulfides in placed rock fill increased fill temperatures to such an extent that fill behind bulkheads became molten.

SOURCES OF FURTHER INFORMATION

As indicated in the introduction, this chapter makes no claim for completeness. The following publications are aimed specifically at design of backfill systems:

- *Handbook on Mine Fill* (Potvin et al. 2005)
- *Paste and Thickened Tailings: A Guide*, 2nd ed. (Jewell and Fourie 2006)
- *Mine Backfill 1998* (Hassani and Archibald 1998)

These publications do not cover pneumatic stowing or flowable fill.

Numerous case histories of backfill systems can be found in the proceedings volumes of the International Symposia on Mining with Backfill that have been held approximately every 4 years since the first one was organized by Ed Thomas, the late Ken Mathews, Jack Barrett, and others at Mount Isa in Australia in 1973 under the auspices of the Australasian Institute of Mining and Metallurgy. Another source of case histories is the proceedings of the International Symposiums on Paste and Thickened Tailings that have been held since the 1990s, which have generally been published by the Australian Centre for Geomechanics.

ACKNOWLEDGMENTS

The author wishes to express his deep appreciation to Ed Thomas, an acknowledged authority on the design of backfill systems, for serving as technical reviewer for the chapter

and for providing input on backfill practices outside of North America. It has also been the author's great fortune to have known Ed since 1978 when Ed visited Elliot Lake, Ontario, where the author was involved in the design of a pillar extraction system using backfill.

CHAPTER 13.7

Cave Mining

Dennis H. Laubscher

INTRODUCTION

The expression *cave mining* will be used in this chapter to refer to all mining operations in which the ore body caves naturally after undercutting and the caved material is recovered through drawpoints. The term encompasses block caving, panel caving, inclined-drawpoint caving, and front caving. Caving is the lowest-cost method of underground mining, provided that drawpoint size and handling facilities are tailored to suit the caved material and that the extraction horizon can be maintained for the life of the draw.

The daily production from cave mining operations throughout the world (in 2008) was approximately 503 kt/d. Table 13.7-1 shows production broken down by layout.

Today, several open-pit mines currently producing in excess of 50 kt/d are examining the feasibility of implementing low-cost, large-scale underground mining methods. Several underground cave mines that produce high tonnages are planning to implement caving heights (or "dropdowns") of 500 m and at depths of 1,500 m. This will result in a considerable change in their mining environments. These changes will necessitate more detailed mine planning, rather than the simple projection of current mining methods to greater depths.

As more attention is directed to mining large, competent ore bodies with low-cost underground methods, it is necessary to define the role of cave mining. In the past, caving has been considered for rock masses that cave and fragment readily. The ability to better assess the cavability and fragmentation of ore bodies, the availability of robust load-haul-dump (LHD) machines, an understanding of the draw control process, suitable equipment for secondary drilling and blasting, and reliable cost data have shown that competent ore bodies with coarse fragmentation can be mined at a much lower cost using caving rather than with drill-and-blast methods. However, after a cave layout has been developed, there is little scope for change.

Aspects that have to be addressed are cavability, fragmentation, draw patterns for different types of ore, drawpoint or drawzone spacing, layout design, undercutting sequence, and support design. Table 13.7-2 shows some significant anomalies in the quoted performance of different cave operations.

It is common to find that old established mines that have developed standards during the course of successful mining in the upper levels of an ore body are resistant to change and do not adjust to the ground control problems that occur as mining proceeds to greater depths or as rock types change. Mines that have experienced continuous problems are more amenable to adopting new techniques to cope with a changing mining situation. Detailed knowledge of local and regional structural geology, the use of an accepted rock mass classification to characterize the rock mass, and knowledge of regional and induced stress environments are prerequisites for good mine planning. It is encouraging that these aspects are receiving more and more attention.

Table 13.7-1 Production per day obtained using different mine layouts in 2008

Mine Layout	Daily Production, kt
Grizzly	0
Slusher	3
Load-haul-dump machine	±500
Total	503

Table 13.7-2 Anomalies in quoted performance of caving operations

Quote	Explanation
96% of ore recovered for 100% mineral extraction	Underevaluation of ore body and dilution zone
Correct drawpoint spacing, but occurrences of 200% overdraw with 30% waste dilution entry	Highly irregular draw and underevaluation of dilution
15% dilution entry in spite of correct drawpoint spacing and uniform fragmentation	Drawpoints being drawn in isolation
Ore from lower 100 m of draw column still reporting in drawpoint, even though 260 m of ore has been drawn	Large range in fragmentation and irregular, high values in dilution zone

Dennis H. Laubscher, Mining Consultant, Bushmans River Mouth, South Africa

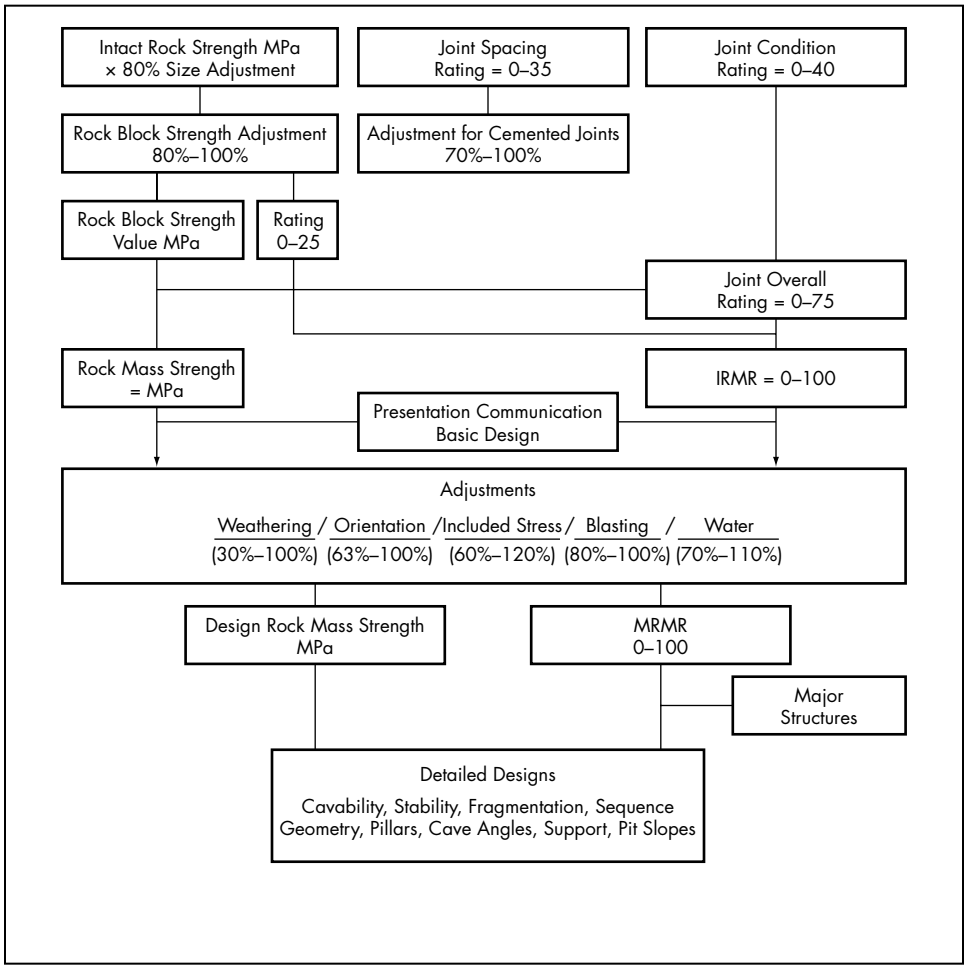

Figure 13.7-1 Flow sheet of MRMR procedure with recent modifications

The Laubscher rock mass classification system provides both in-situ rock mass ratings (IRMRs) and rock mass strength. Such a classification is necessary for design purposes. The IRMR defines the geological environment, and the adjusted or modified rock mass ratings (MRMRs) consider the effects of the mining operation on the rock mass. Figure 13.7-1 is a flow sheet of the MRMR procedure with recent modifications. The reader is encouraged to read the chapter "The IRMR/MRMR Rock Mass Classification for Jointed Rock Masses" by Laubscher and Jakubec (2001). The ratings describe in detail cavability, subsidence angles, failure zones, fragmentation, undercut-face shape, cave-front orientation, undercutting sequence, overall mining sequence, and support design.

FACTORS AFFECTING CAVING OPERATIONS

The 25 parameters that should be considered before implementing any cave mining operation are set out in Table 13.7-3. The parameters in bold are a function of the parameters that follow. Many parameters are uniquely defined by the ore body and the mining system and are not discussed further. The parameters considered later are common to all cave mining systems and need to be addressed if any form of cave mining is contemplated.

Cavability

Monitoring many caving operations has shown that two types of caving can occur—stress and subsidence caving. However, it is better to use the terms *vertical extension* to mean upward propagation of the cave and *lateral extension* to mean the propagation of the cave as a caved block is expanded.

Vertical extension caving occurs in virgin cave blocks when the stresses in the cave back exceed the strength of the rock mass. Caving can stop when a stable arch develops in the cave back. The undercut must be increased in size or the boundaries weakened to induce further caving. High horizontal stresses acting on steep dipping joints increase the MRMR. This was the situation in block 16 at the Shabanie mine in Zimbabwe. A stable back was formed when the undercut had a hydraulic radius of 28 and the MRMR was 64. When block 7 (adjacent to block 16) caved, the horizontal confining stress was removed, which resulted in a reduction in the MRMR to 56 in block 16. At this point, caving occurred.

Lateral extension caving occurs when lateral restraints on the block being caved are removed by mining adjacent to the block. This often results in a large stress difference, leading to rapid propagation of the cave and limited hulking.

Table 13.7-3 Parameters to be considered before implementation of cave mining

Cavability	**Primary Fragmentation**	**Drawpoint/Drawzone Spacing**
Rock mass strength (rock mass rating [RMR]/MRMR)	Rock mass strength (RMR/MRMR)	Particle size of ore and overlying rock
Rock mass structure-condition geometry	Geological structures	Overburden load and direction
In-situ stress	Joint and fracture spacing, and geometry	Friction angles of caved particles
Induced stress	Joint condition ratings	Practical excavation size
Hydraulic radius of ore body	Stress or subsidence caving	Stability of host rock mass (MRMR)
Water	Induced stress	Induced stress
Draw Heights	**Layout**	**Rock Burst Potential**
Capital	Particle size	Regional and induced stresses
Ore-body geometry	Drawpoint spacing and size	Variations in rock mass strength, modulus
Excavation stability	Method of draw—gravity or LHD	Structures
Effect on ore minerals	Orientation of structures and joints	Mining sequence
Method of draw	Ventilation, ore handling, drainage	
Sequence	**Undercutting Sequence (pre/advance/post)**	**Induced Cave Stresses**
Cavability: poor to good or vice versa	Regional stresses	Regional stresses
Ore body geometry	Rock mass strength	Area of undercut
Induced stresses	Rock burst potential	Shape of undercut
Geological environment	Rate of advance	Rate of undercutting
Rock burst potential	Ore requirements	Rate of draw
Production requirements	Completeness of undercut	
Influence on adjacent operations	Shape (lead, lag)	
Water inflow	Height of undercut	
Drilling and Blasting	**Development**	**Excavation Stability**
Rock mass strength	Layout	Rock mass strength (RMR/MRMR)
Rock mass stability (drill-hole closure)	Sequence	Orientation of structures and joints
Required particle size	Production	Regional and induced stresses
Hole diameter, lengths, rigs	Drilling and blasting	Rock burst potential
Patterns and directions		Excavation size (orientation and shape)
Powder factor		Drawpoint
Swell relief		Mining sequence
Support	**Practical Excavation Size**	**Method of Draw**
Excavation stability	Excavation stability	Fragmentation
Rock burst potential	Induced stress	Practical drawpoint spacing
Brow stability	Caving stresses	Practical size of excavation
Timing of support: initial, secondary, and production	Secondary blasting	Gravity or mechanical loading
	Equipment size	
Rate of Draw	**Drawpoint Interaction**	**Draw-Column Stresses**
Fragmentation	Drawzone spacing	Draw-column height
Method of draw	Critical distance across major apex	Particle size
Percentage hangups	Particle size	Homogeneity of ore particle size
Secondary breaking/blasting	Time frame of working drawpoints	Draw control
Seismic events		Draw-height interaction
Air blasts–drawpoint cover		Height-to-short-axis base ratio
		Direction of draw
Secondary Fragmentation	**Secondary Blasting/Breaking**	**Dilution**
Rock, block shape	Secondary fragmentation	Ore-body geometry
Draw height	Draw method	Mining geometry
Draw rate, time-dependent failure	Drawpoint size	Particle size distribution
Rock block workability and strength	Gravity grizzly aperture	Range of particles, unpay ore and waste
Range in particle size, fines cushioning	Size of equipment and grizzly spacing	Grade distribution of pay and unpay ore
Draw control program	Ore handling system, size restrictions	Mineral distribution in ore
		Drawpoint interaction
		Secondary breaking
		Draw control (techniques, predictions)
		Draw markers
Tonnage Drawn	**Support Repair**	**Ore/Grade Extraction**
Level interval	Tonnage drawn	Mineral distribution
Shut-off grade	Point and column loading	Method of draw
Drawpoint spacing	Brow wear	Rate of draw
Dilution percentage	Floor repair	Dilution percentage
Controls	Secondary blasting	Cutoff grade to lant
Redistribution		Ore losses
Subsidence		
RMR/MRMR		
Height of caved column		
Minimum and maximum spans		
Major geological structures		
Depth of mining		
Topography		

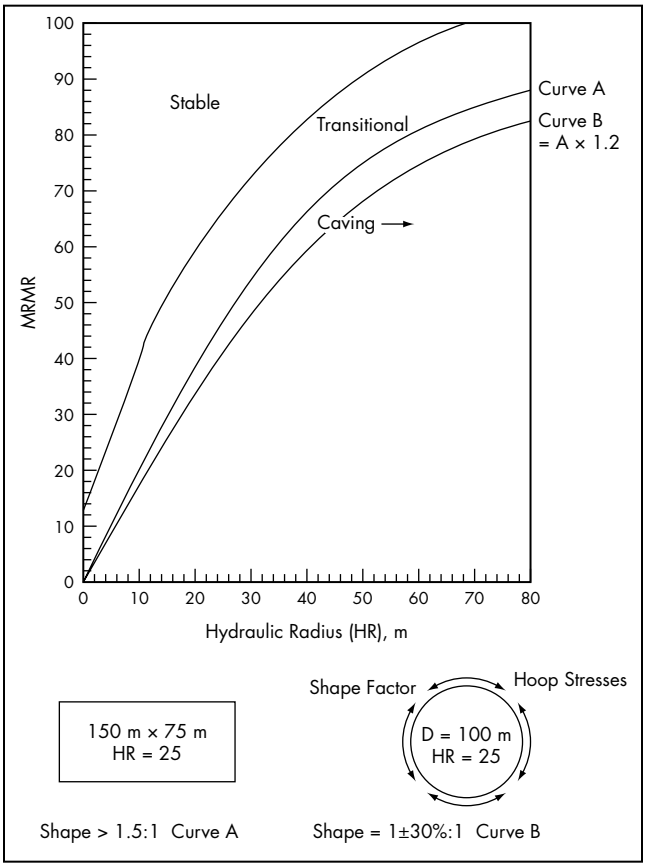

Figure 13.7-2 Stability diagram based on worldwide experience

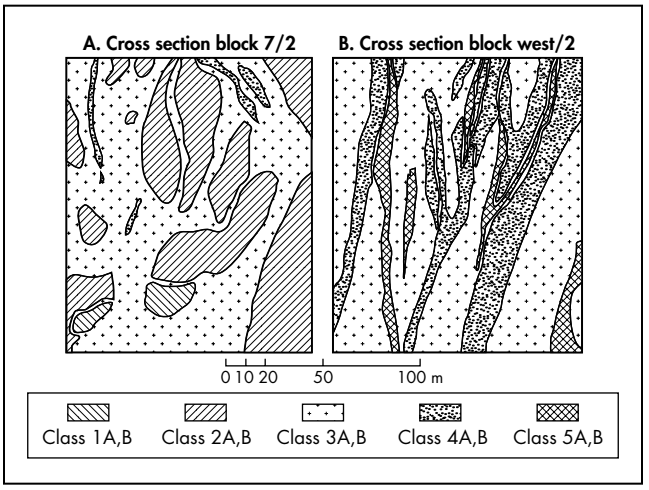

Figure 13.7-3 Geomechanics classification data

Figure 13.7-2, based on a worldwide experience base, illustrates caving and stable situations in terms of the hydraulic radius (area divided by perimeter) for a range of MRMR values. An additional curve has been added to account for the stability that occurs with equidimensional shapes.

All rock masses will cave. The manner of their caving and the fragmentation need to be predicted if cave mining is to be implemented successfully. The rate of caving can be slowed by control of the draw since the cave can propagate only if there is space into which the rock can move. The rate of caving can be increased by a more rapid advance of the undercut, but problems can arise if an air gap forms over a large area. In this situation, the intersection of major structures, heavy blasting, and the influx of water can result in damaging air blasts. Rapid, uncontrolled caving can result in an early influx of waste.

In conventional layouts, the rate of undercutting (RU) should be controlled so that the rate of caving (RC) is faster than the rate of damage (RD) due to abutment stresses. Thus, RC > RU > RD.

However, in areas of high stress, the rate of caving must be controlled to maintain an acceptable level/amount of seismic activity in the cave back. Otherwise, rock bursts can occur in suitably stressed areas (pillars and rock contacts). As advanced undercutting will be used in these situations, damage to the undercut and production levels will not be a problem.

The stresses in the cave back can be modified to some extent by the shape of the cave front. Numerical modeling can be a useful tool for helping an engineer determine the stress patterns associated with possible mining sequences. An undercut face that is concave toward the caved area provides better control of major structures. In ore bodies having a range of MRMRs, the onset of continuous caving will be in the lower-rated zones if they are continuous in plan and section. This effect is illustrated in Figure 13.7-3B, where the class 5 and 4B zones are shown to be continuous. In Figure 13.7-3A, the pods of class 2 rock are sufficiently large to influence caving, and cavability should be based on the rating of these pods. Good geotechnical information, as well as information from monitoring the rate of caving and rock mass damage, is needed to fine-tune this relationship.

Particle Size Distribution

In caving operations, the degree of fragmentation has a bearing on

- Drawpoint spacing,
- Dilution entry into the draw column,
- Draw control,
- Draw productivity,
- Secondary blasting and breaking costs, and
- Secondary blasting damage.

The input data needed to calculate the primary fragmentation and the factors that determine the secondary fragmentation as a function of the caving operation are shown in Figure 13.7-4.

Primary fragmentation can be defined as the size distribution of the particles that separate from the cave back and enter the draw column. The primary fragmentation generated by subsidence caving is generally more coarse than that resulting from stress caving. The reasons for this are (1) propagation of the cave occurs more rapidly, (2) the rock mass disintegrates primarily along favorably oriented joint sets, and (3) there is little shearing of intact rock. The orientation of the cave front or back with respect to the joint sets and the direction of principal stress can have a significant effect on the primary fragmentation.

Secondary fragmentation is the reduction in size of the original particles as they move through the draw column. The processes to which particles are subjected determine the size distribution that reports to the drawpoint. A strong, well-jointed

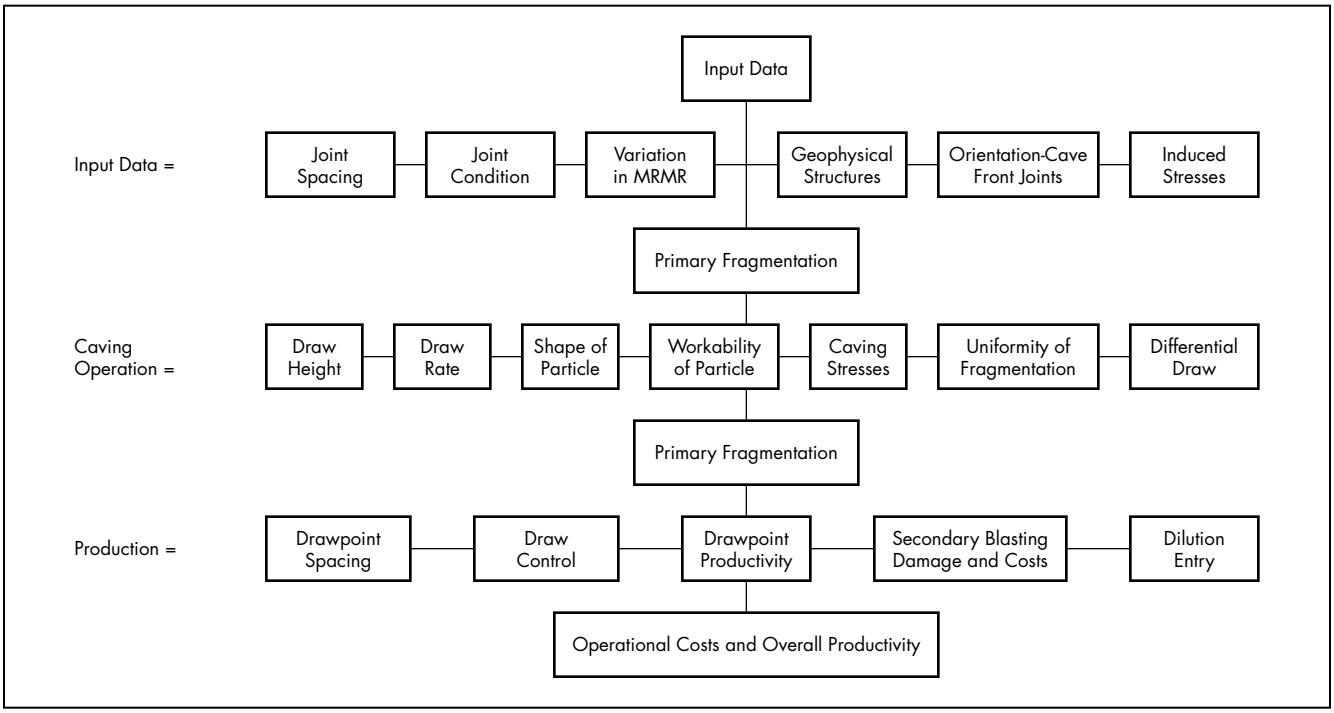

Figure 13.7-4 Input data for calculation of fragmentation

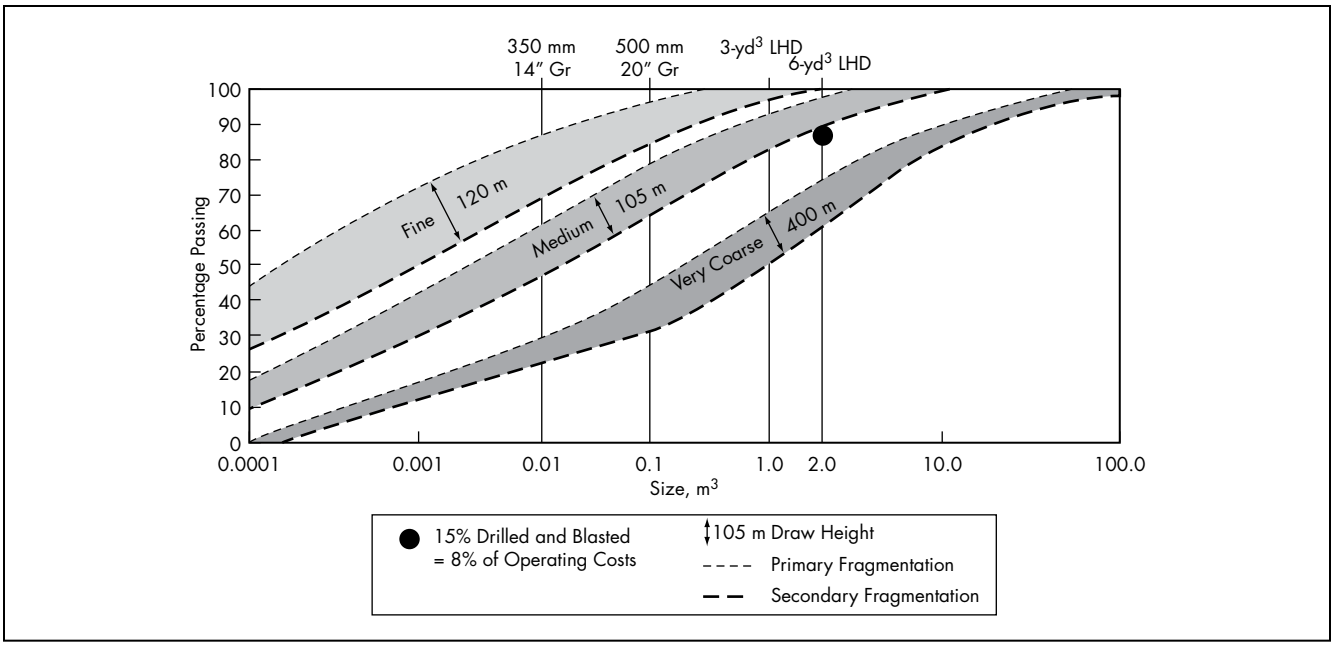

Figure 13.7-5 Size distribution of cave fragmentation

material can result in a stable particle shape at a low draw height. Figure 13.7-5 shows the decrease in particle size for different draw heights and coarse (less jointed) to fine (well jointed) rock masses. A range of RMRs will result in a wider range of particle sizes than that produced by rock with a single rating. This is because the fine material tends to cushion larger blocks and prevents further attrition of these blocks. This difference is illustrated in Figure 13.7-3B, in which class 5 and class 4 material is shown to cushion the larger primary fragments from class 3 material. A slow rate of draw results in a higher probability of time-dependent failure as the caving stresses have more time to work on particles in the draw column.

Fragmentation is the major factor determining drawpoint productivity. Experience has shown that 2 m^3 is the largest block that can be moved by a 6-yd^3 LHD machine and still allow an acceptable rate of production to be maintained. In Figure 13.7-6, the productivity of a layout using 3.5-, 6-, and

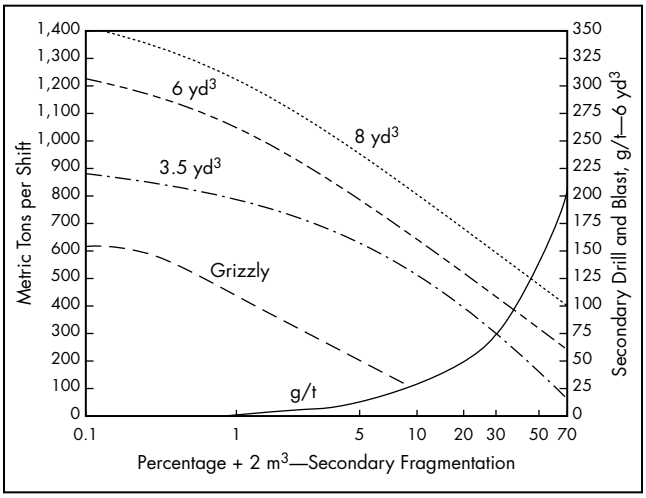

Figure 13.7-6 LHD productivity on a round trip of 100 m with 60% utilization

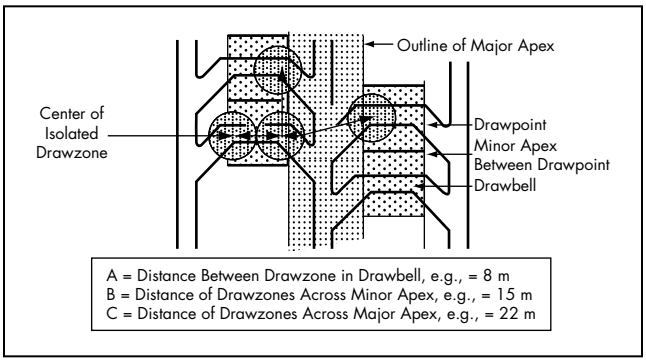

Figure 13.7-7 Maximum and minimum drawzone spacing (isolated drawzone = 10 m, area of influence = 225 m^2)

8-yd^3 LHD machines loading to a grizzly is related to the percentage of fragments larger than 2 m^3. The use of secondary explosives is based on the amount of oversized rock that cannot be handled by a 6-yd^3 LHD.

A computer simulation program has been developed for predicting primary and secondary fragmentation. The results obtained from this program are confirmed by underground observations.

Drawzone Spacing

Drawpoint spacings for grizzly and slusher layouts reflect the spacing of the drawzones. However, in the case of LHD layouts with a nominal drawpoint spacing of 15 m, drawzone spacing can vary from 18 to 24 m across the major apex (pillar), depending on the length of the drawbell. This situation occurs when the length of the drawpoint crosscut is increased to ensure that an LHD machine is straight before it loads. In this case, the major consideration (optimum ore recovery) is compromised by incorrect use of equipment or a desire to achieve ideal loading conditions. The drawzone spacings for 30-m center-to-center production drift spacings are shown in Figure 13.7-7, with the critical distance being across the major apex. The length of the drawbell can be increased from 8 to

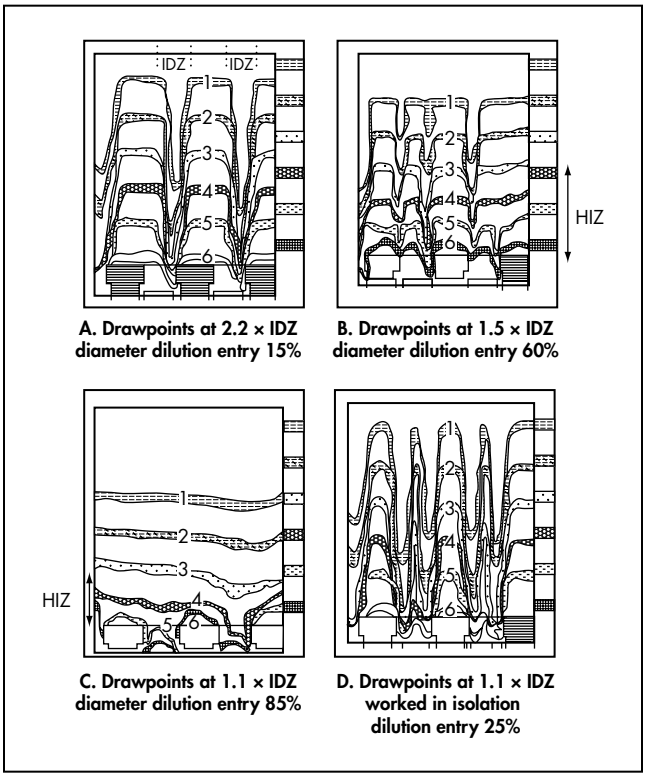

Figure 13.7-8 Results of three-dimensional sand-model experiments

10 m and the production drift spacing to 32 m without affecting the major apex spacing. Interaction in the drawbell will still occur.

Sand model tests have shown a relationship between the spacing of drawpoints and the interaction of drawzones. Widely spaced drawpoints develop isolated drawzones with diameters defined by the fragmentation. When drawpoints are spaced at 1.5 times the diameter of the isolated drawzone (IDZ), interaction occurs. Interaction also improves as drawpoint spacing is decreased, as shown in Figure 13.7-8. The flow lines and the stresses that develop around a drawzone are shown in Figure 13.7-9. The sand model results have been confirmed by observation of the fine material extracted during cave mining and by the behavior of material in bins. The question is whether this theory, which is based on IDZs, can be wholly applied to coarse material, where arching (spans) of 20 m have been observed. The collapse of large arches will affect the large area overlying the drawpoint, as shown in Figure 13.7-10. The formation and failure of arches leads to wide drawzones in coarse material, so that drawzone spacing can be increased to the spacings shown in Figure 13.7-10.

The frictional properties of the caved material must also be recognized. Low-friction material can flow greater distances when under high overburden load, and this can mean wider drawzone spacings. It is therefore logical to expect that when a line of drawbells is drawn, this creates a large low-density zone. Similarly, when lines of drawbells are drawn on alternate shifts, good interaction will result. The draw program at the Henderson mine in Colorado (United States) broadly follows this pattern.

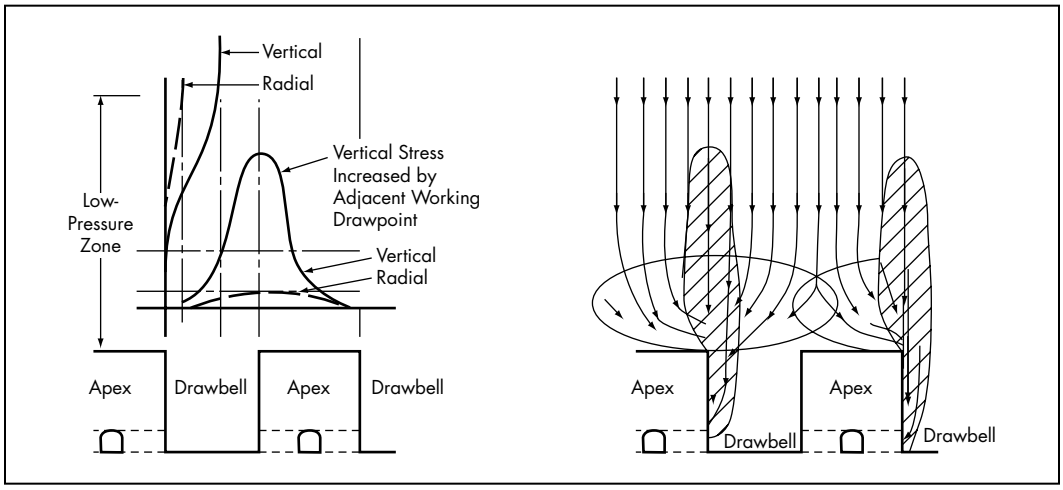

Figure 13.7-9 Flow lines and inferred stresses between adjacent working operations

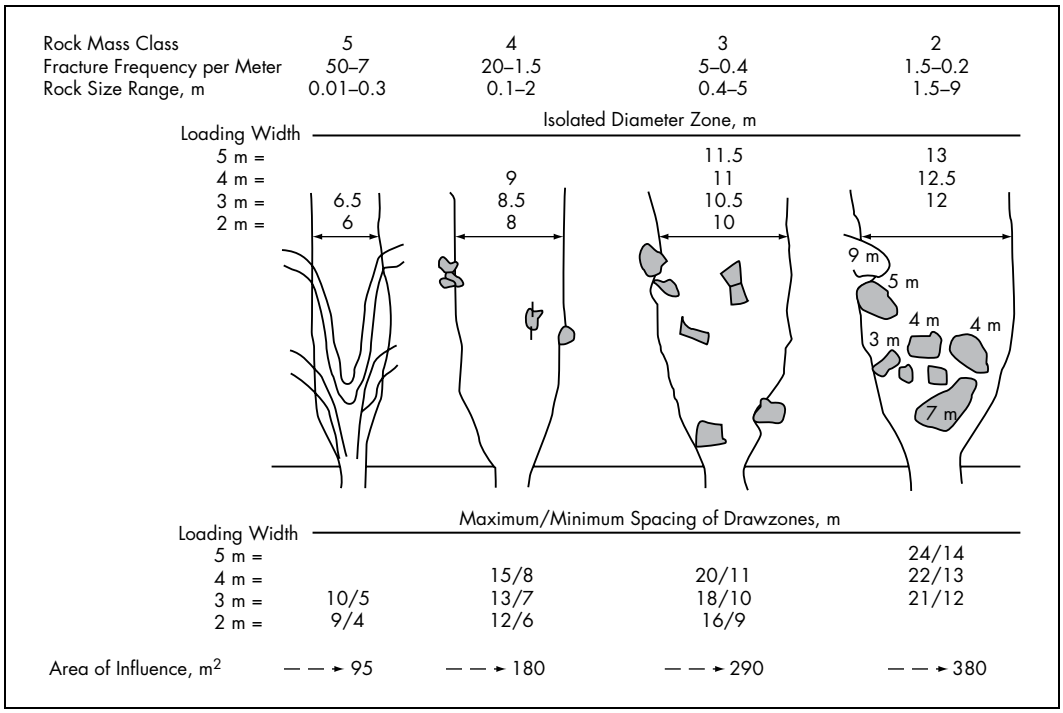

Figure 13.7-10 Maximum/minimum spacing of drawzones based on isolated drawzone diameter

Three-dimensional model tests need to be continued to establish some poorly defined principles, such as the interaction across major apexes when the spacing of groups of interactive drawzones is increased. Numerical modeling could possibly provide the solutions for the draw behavior of coarsely fragmented material.

Draw Control

Draw control requirements and applications are shown in Figure 13.7-11 and Table 13.7-4, respectively. The grade and fragmentation in the dilution zone must be known if sound draw control is to be practiced. Figure 13.7-12 shows the value distribution for columns A and B. Both columns have the same average grade of 1.4%, but the value distribution is different. The high grade at the top of column B means that a larger tonnage of waste can be tolerated before the shutoff grade is reached.

In LHD layouts, a major factor in poor draw control is the drawing of fine material at the expense of coarse material. Strict draw control discipline is required so that the coarse ore is drilled and blasted at the end of the shift in which it reported in the drawpoint.

It has been established that the draw will angle toward less dense areas. This principle can be used to move the material overlying the major apex by creating zones of varying density through the differential draw of lines of drawbells.

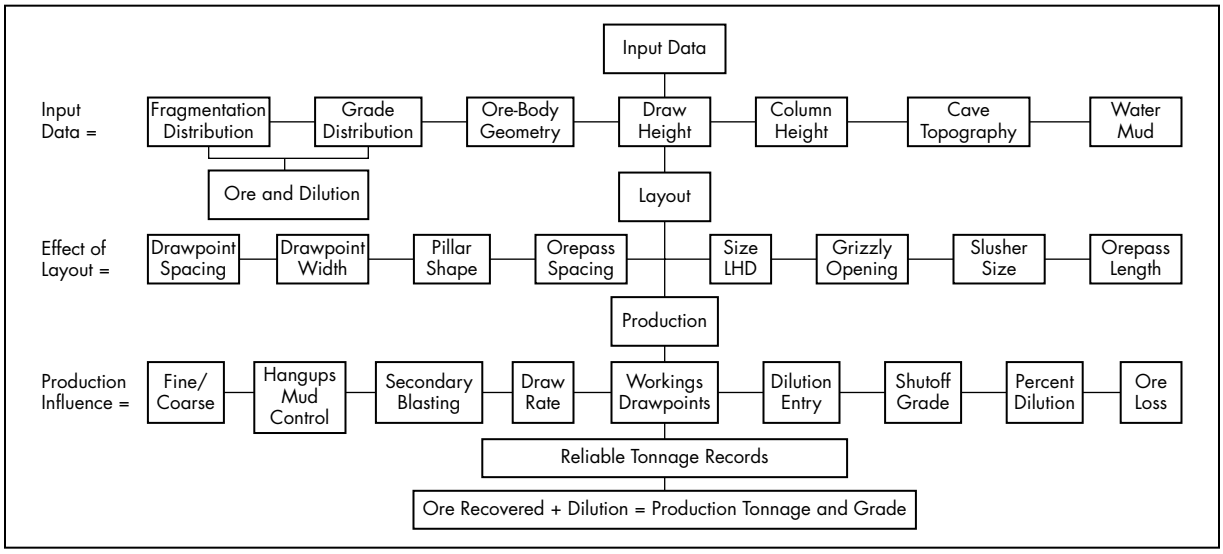

Figure 13.7-11 Draw control requirements

Table 13.7-4 Draw control applications

Objective	Application
Reduce dilution	Calculation of tonnage
Improve ore recovery	Recording of tonnages produced
Avoid damage to pillars	Controlling draw

Dilution

For the purposes of block caving, the *percentage of dilution* is defined as the percentage of the ore column that has been drawn before the waste material appears in the drawpoint. It is a function of the amount of mixing that occurs in the draw columns. Mixing is a function of

- Ore draw height,
- Range in fragmentation of both ore and waste,
- Drawzone spacing, and
- Range in tonnages drawn from drawpoints.

The range in particle size distribution and the minimum drawzone spacing across the major apex will give the height of the interaction zone (HIZ). This is illustrated in Figure 13.7-13. There is a volume increase as the cave propagates so that a certain amount of material must be drawn before the cave reaches the dilution zone. The volume increase, or swell factors, is based on the fragmentation and is applied to column height. Typical swell factors for fine, medium, and coarse fragmentation are 1.16, 1.12, and 1.08, respectively.

A draw control factor is based on the variation in tonnages from working drawpoints (Figure 13.7-14). If production data are not available, the draw control engineer must predict a likely draw pattern. A formula based on the above factors has been developed to determine the dilution entry percentage:

$$\text{dilution entry} = (A - B)/A \times C \times 100$$

where

A = draw-column height (H) swell factor
B = height of interaction
C = draw control factor

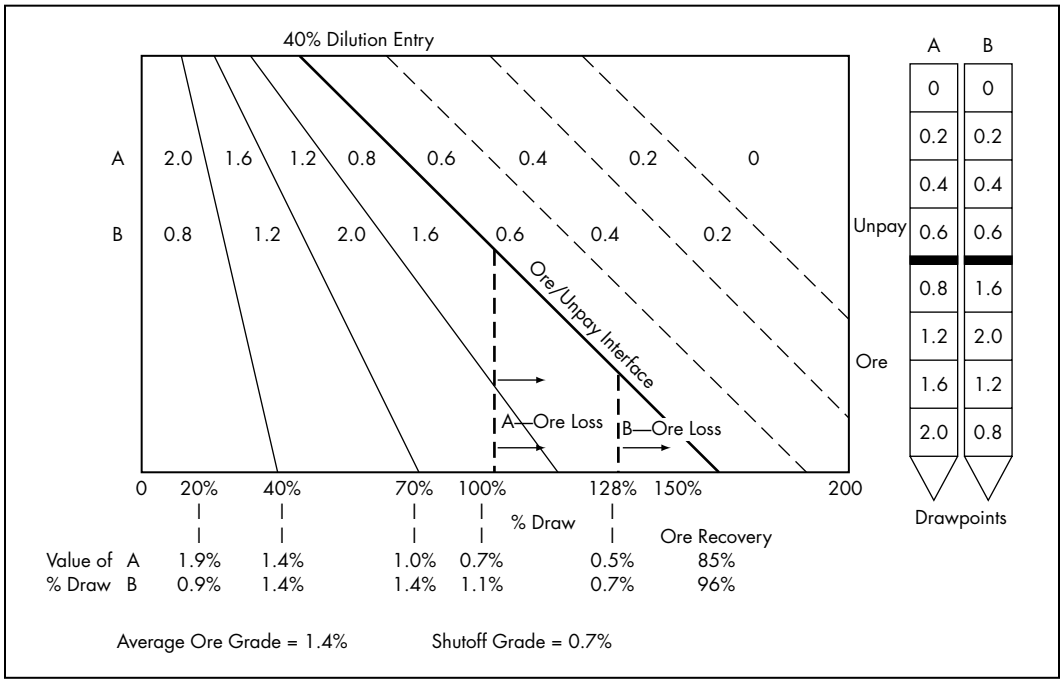
The graph for dilution entry was originally drawn as a straight line, but underground observations show that where the dilution occurs early, the rate of influx follows a curved line with a long ore "tail" (Figure 13.7-15). Figure 13.7-16 shows that dilution entry is also affected by the attitude of the drawzone, which can angle toward higher overburden loads.

Layouts

Eight different horizontal LHD layouts and two inclined drawpoint LHD layouts are used at various operating mines. An example of an inclined drawpoint LHD layout is shown in Figure 13.7-17. The El Teniente (Chile) and Henderson mine layouts are shown in Figures 13.7-18 and 13.7-19, respectively. Numerical modeling of different layouts showed that the El Teniente layout was the strongest and had several practical advantages. For example, the drawpoint and drawbell are on a straight line, which results in better drawpoint support and flow of ore. If there is brow wear, the LHD can back into the opposite drawpoint. The only disadvantage is that the layout does not have the flexibility to accommodate the use of electric LHD machines as does the herringbone layout.

A factor that needs to be resolved is the correct shape of the major apex. It is thought that a shaped pillar will assist in the recovery of fine ore. Also, in ore bodies characterized by coarse fragmentation, there is less chance that stacking will occur (Figure 13.7-20). The main area of brow wear is immediately above the drawpoint. If the vertical height of the pillar above the brow is small, failure of the top section will reduce the strength of the lower section and result in aggravated brow wear.

More thought must be given to the design of LHD layouts to provide a maximum amount of maneuver room within a minimum size of drift opening. Thus, larger machines can be used within the optimum drawzone spacings. Another aspect that needs attention is LHD design, that is, to reduce the length and increase their width. Although the use of large machines might be an attraction, it is recommended that caution be exercised and a decision on machine size be based on a correct assessment of the required drawzone spacing in terms of fragmentation. The loss of revenue that can result from dilution



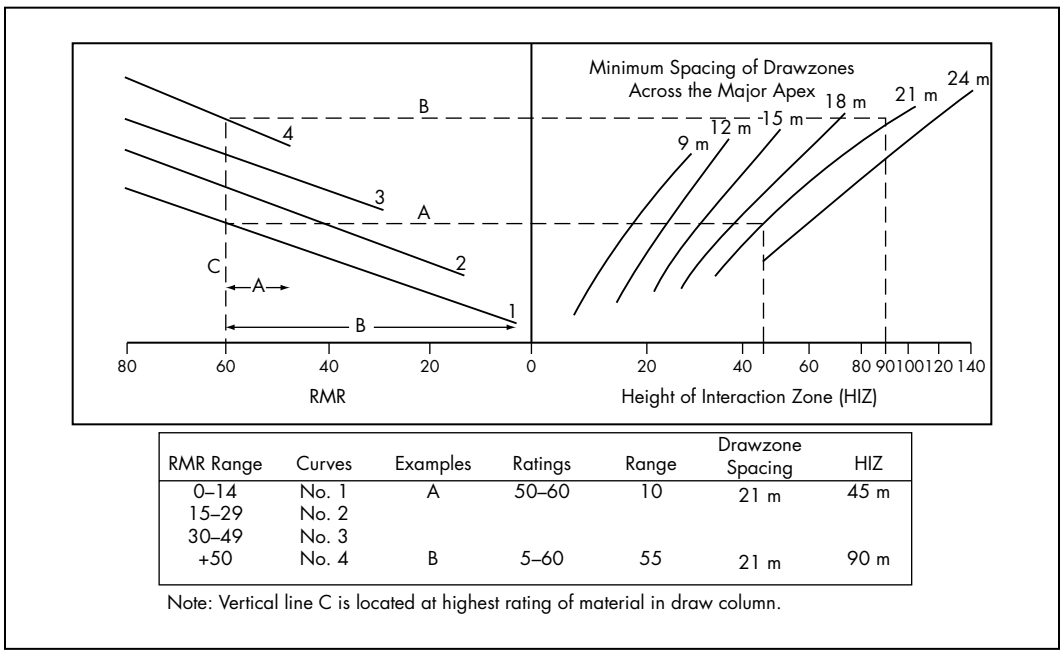


Figure 13.7-12 Grade analysis

RMR Range	Curves	Examples	Ratings	Range	Drawzone Spacing	HIZ
0–14	No. 1	A	50–60	10	21 m	45 m
15–29	No. 2					
30–49	No. 3

Note: Vertical line C is located at highest rating of material in draw column.

Figure 13.7-13 Height of interaction zone

far exceeds the lower operating costs associated with larger machines.

Undercutting

Undercutting is one of the most important aspects of cave mining because not only is a complete undercut necessary to induce caving, but the undercut method can reduce the damaging effects of induced stresses.

The normal undercutting sequence is to develop the drawbell and then to break the undercut into the drawbell, as shown in Figure 13.7-18. In environments of high stress, the pillars and brows are damaged by the advancing abutment stresses. The Henderson mine technique of developing the drawbell with long holes from the undercut level reduces the time interval and extent of damage associated with post-undercutting. To preserve stability, the Henderson mine has also found it

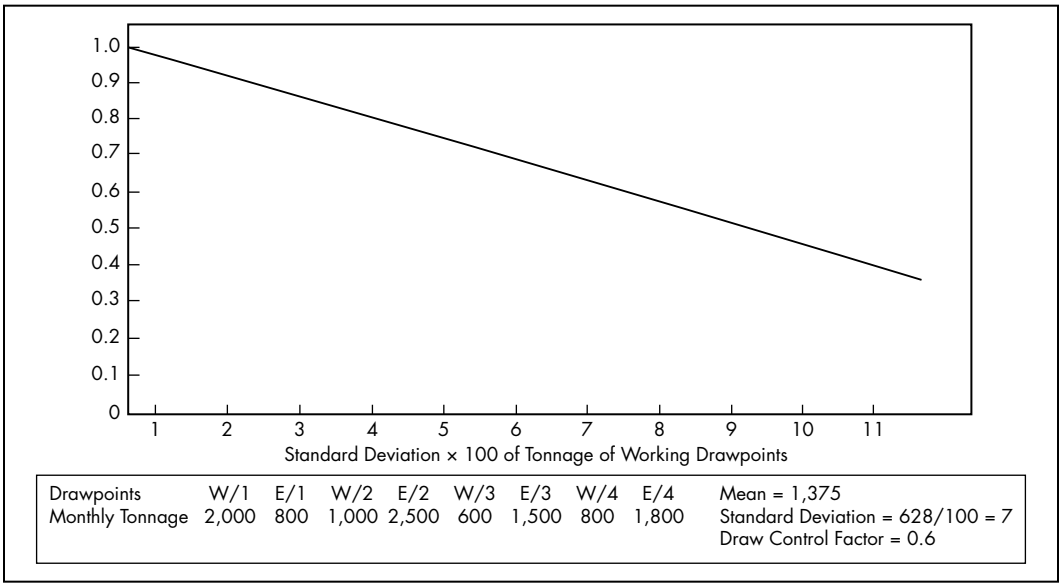

Figure 13.7-14 Draw control factor

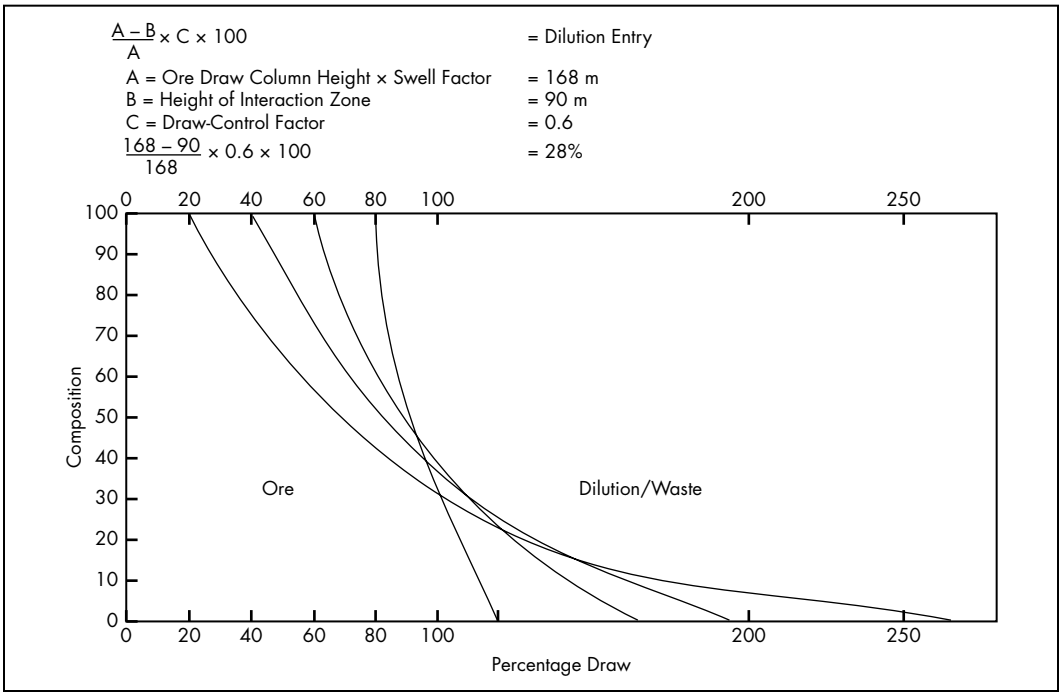

Figure 13.7-15 Calculation of dilution entry

necessary to delay the development of the drawbell drift until the bell must be blasted (Figure 13.7-19).

The damage caused to pillars around drifts and drawbells by abutment stresses is significant and is the major factor in brow wear and excavation collapse. Rock bursts also occur in these areas. The solution is to complete the undercut before development of the drawpoints and drawbells. The "advanced undercut" technique is shown in Figure 13.7-21.

In the past, the height of the undercut was considered to have a significant influence on caving and, possibly, the flow of ore. The asbestos mines in Zimbabwe had undercuts of 30 m with no resulting improvement in caving or fragmentation. The long time involved in completing the undercut often led to ground control problems. Good results are obtained with undercuts of minimum height, provided that complete undercutting is achieved. Where gravity is needed for the flow of blasted undercut ore, the undercut height needs to be only half the width of the major apex. This results in an angle of repose of 45° and allows the ore to flow freely.

Support Requirements

In areas of high stress, weak rock will deform plastically and strong rock will exhibit brittle, often violent, failure. If there is a large difference between the RMR and MRMR values,

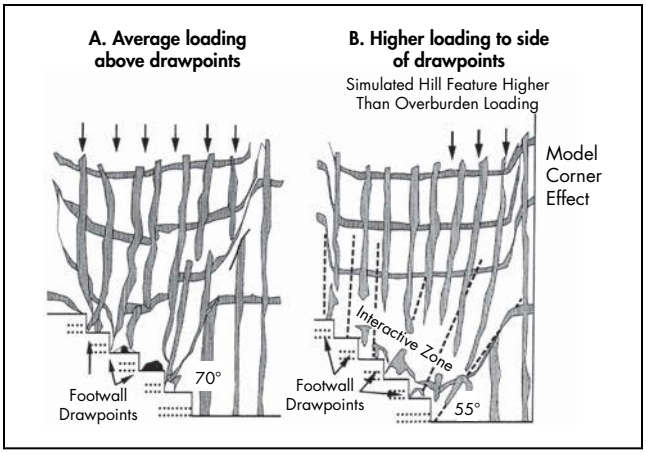

Figure 13.7-16 Inclined drawpoint layout showing effect of different overburden loading (three-dimensional sand-model experiments)

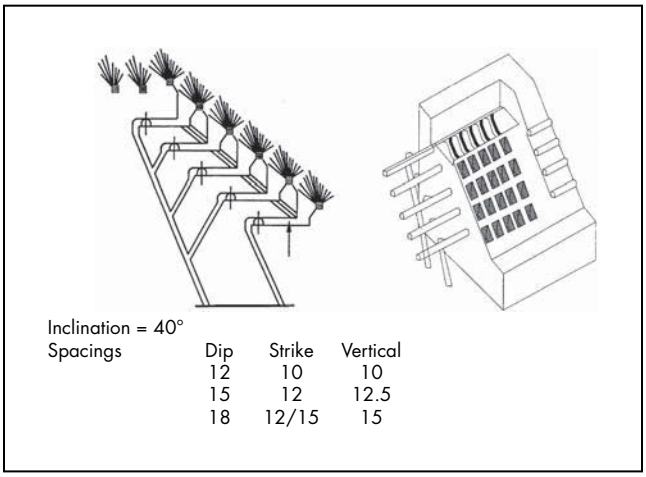

Figure 13.7-17 Inclined drawpoint LHD layout

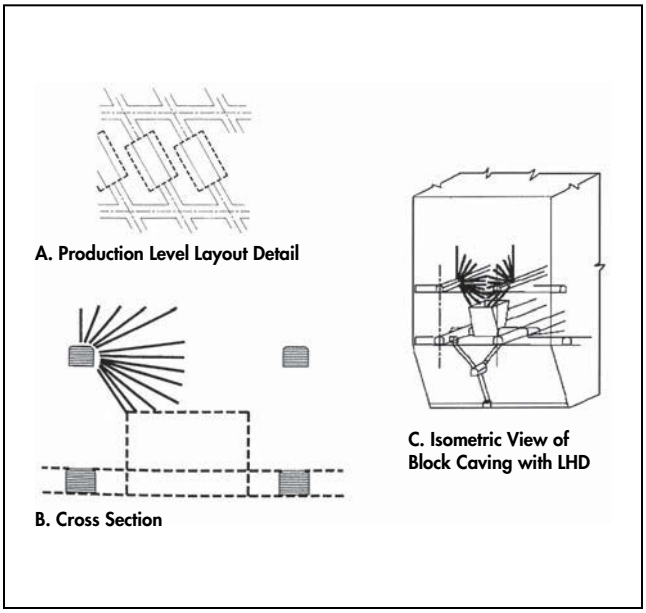

Figure 13.7-18 LHD layout at El Teniente

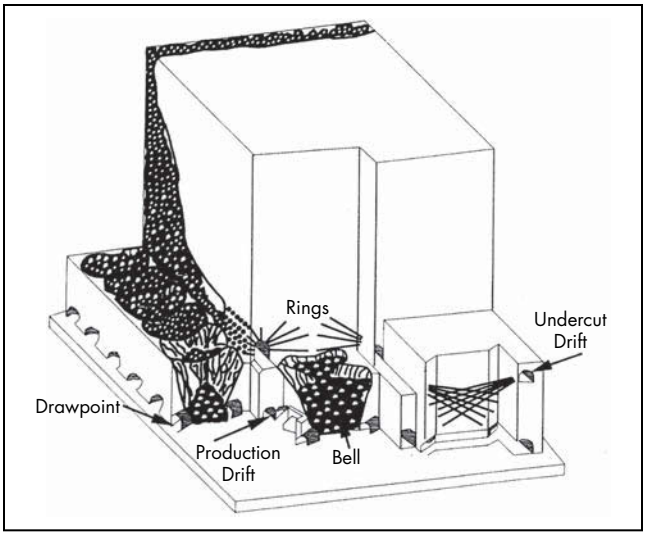

Figure 13.7-19 Isometric view of panel cave operation at the Henderson mine

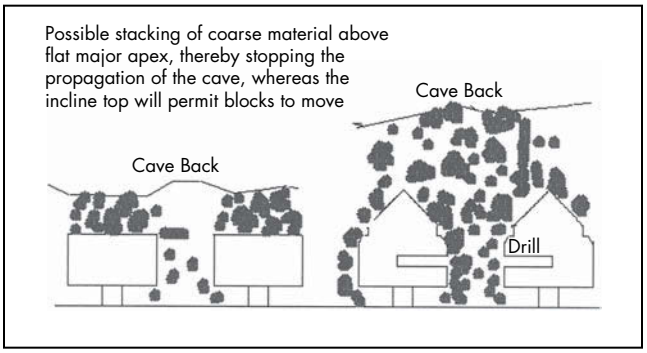

Figure 13.7-20 Effect of shape of major apex

yielding support systems are required. This is explained in Figure 13.7-22.

Prestressed cables have little application in underground situations unless it is to stabilize fractured rock in a low-stress environment. The need to constrain the rock laterally and for lining surfaces such as concrete cannot be too highly emphasized. Support techniques are shown in Table 13.7-5. The use of cable bolts in brows is common practice, but often these bolts are not installed in a pattern that takes into account joint spacing and orientation. Cable bolts should not be installed in highly jointed ground, as the bolts do not apply lateral restraint to the brow and serve only to hold blocks in place.

CONCLUSIONS

Cavability can be assessed provided accurate geotechnical data are available and geological variations are recognized. The MRMR system provides the necessary data for an empirical definition of the undercut dimension in terms of the hydraulic radius. Numerical modeling can assist an engineer in understanding and defining the stress environment.

Fragmentation is a major factor in assessing the feasibility of cave mining in large, competent ore bodies. Programs are being developed for predicting fragmentation, and even the less sophisticated programs provide good design data. The economic viability of caving in competent ore bodies

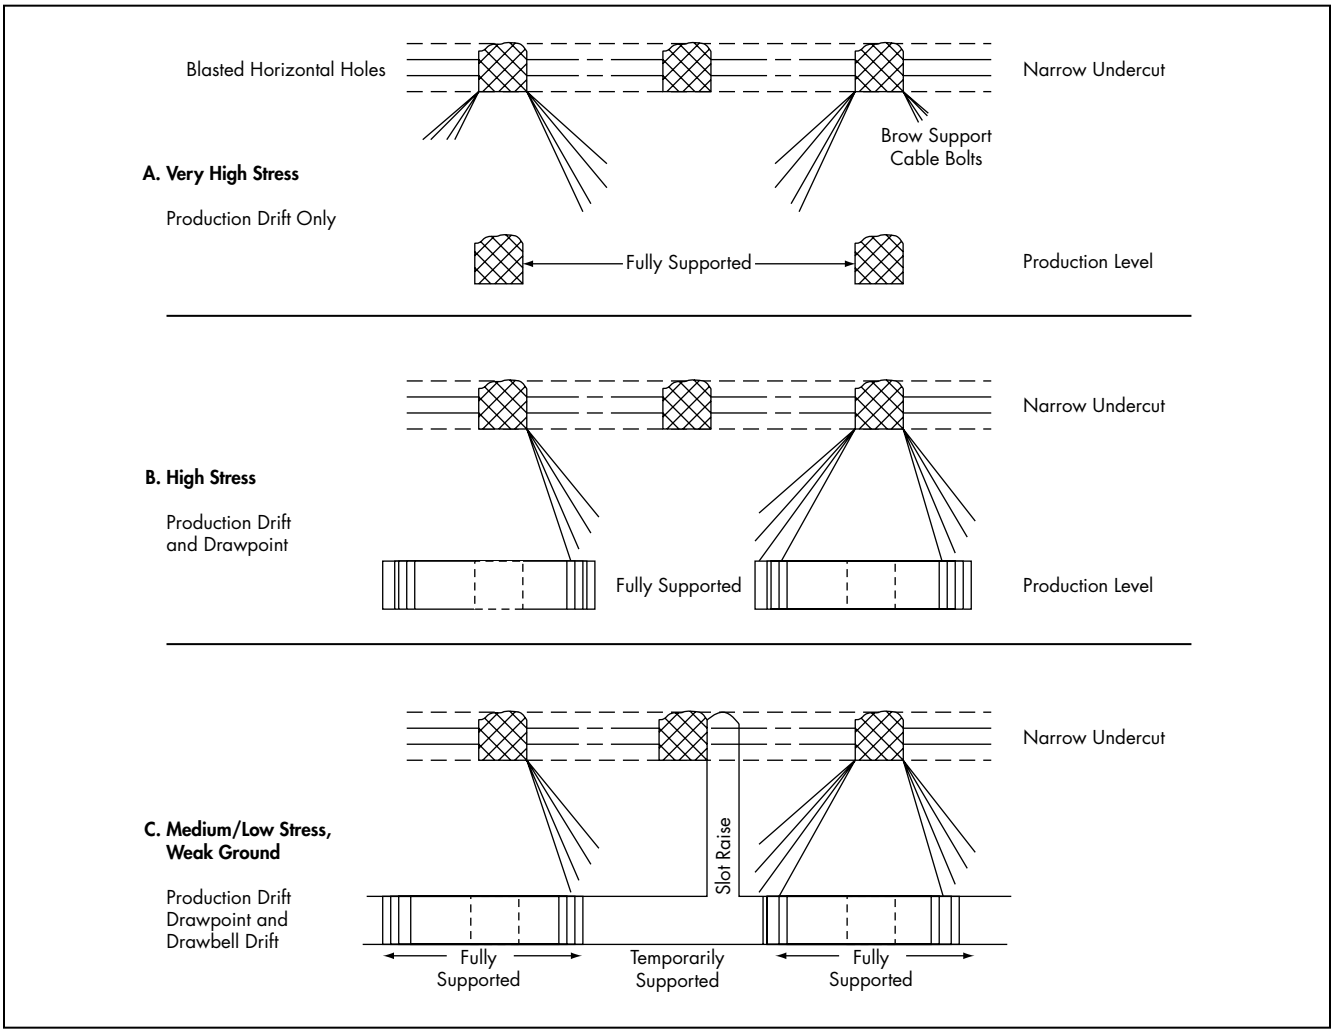

Figure 13.7-21 Different sequences of advanced undercutting RMR

is determined by LHD productivity and the cost of breaking large fragments.

Drawpoint and drawzone spacings for coarser material need to be examined in terms of recovery and improved mining environments. Spacings must not be increased to lower operating costs at the expense of ore recovery. The interactive theory of draw and the diameter of an isolated drawzone can be used in the design of drawzone spacings. Complications occur when drawzone spacings are designed on the basis of primary fragmentation and the secondary fragmentation is significantly different.

The drawpoint is the only control that the operator has once caving has started. The drawpoint should be commissioned as soon as possible after the ore body is undercut. It is therefore essential that every effort is put into ensuring the stability of the drawpoint. The support system must be designed for the rock mass strength and draw height. When it is planned to draw high column heights, the extra expense of ensuring drawpoint integrity is essential. Major drawpoint repairs in a horizontal layout tend to disrupt the draw pattern and can lead to column loading.

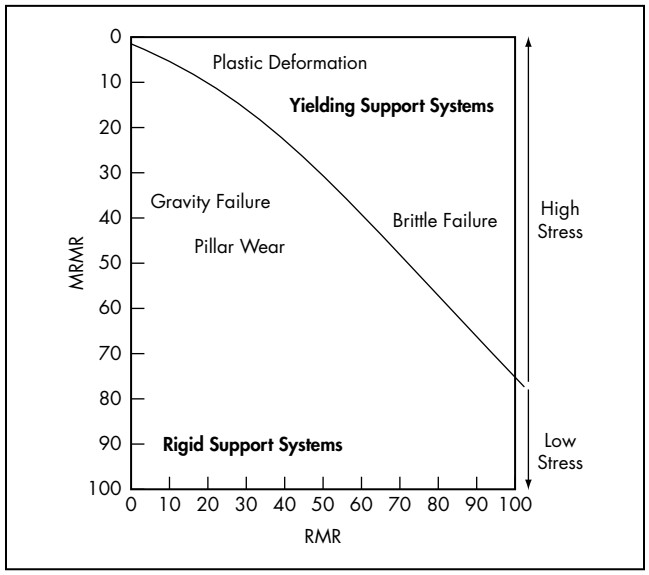

Figure 13.7-22 Support requirements for caving operations

Table 13.7-5 Support techniques

Support Element	Low Stress	High Stress
Bolts		
Length	1 m +(0.33 W × F)	1 m+(0.5 × F)
Spacing	1 m	1 m
Type	Rigid rebar	Yielding (e.g., cones)
Mesh	0.5 mm × 100 mm square	0.5 mm × 75 mm or 50-mm aperture
Deep-seated support	Cables, 1 m + 1.5 W	Steel ropes, 1 m + 1.5 W Long cone bolts
Shotcrete linings	Mesh-reinforced shotcrete	Mesh-reinforced shotcrete
Arches	Rigid steel arches Massive concrete	Yielding steel arches Reinforced concrete
Surface restraint	Large washers (triangles) Tendon traps	Large plate washers Yielding tendon traps
Corners	25-mm rope, cable slings	25-mm rope, cable slings
Brows	Birdcage cables from undercut level Inclined pipes	Birdcage cables from undercut level Inclined pipes
Repair	Grouting Extra bolts, cables, plates, straps, and arches	Grouting Extra bolts, ropes, plates, straps, and yielding arches

Notes: W = span of tunnel. F is based on MRMR = 0–20:F = 1.4; MRMR = 21–30:F = 1.3; MRMR = 31–40:F = 1.2; MRMR = 41–50:F = 1.1; MRMR = 51–60:F = 1.05; MRMR = >61:F = 1.0.

Block caving has advantages over large open pits in environmentally sensitive areas. The crater is much smaller and if necessary can be filled with waste rock even during drawdown. When the operation is completed, the rehabilitation costs will be considerably less than with a large open pit.

ACKNOWLEDGMENTS

This chapter, taken from SME's 2001 publication *Underground Mining Methods*, presents an update of the technology of cave mining. Although it is not possible to quote other references because the bulk of the data supporting the contents of this chapter have not been published, the basic concepts are known to mining engineers. However, it is appropriate to acknowledge the contributions from discussions with the following individuals in Canada, Chile, South Africa, and Zimbabwe: R. Alvarez, P.J. Bartlett, N.J.W. Bell, T. Carew, A.R. Guest, C. Page, D. Stacey, and A. Susaeta. The simulation program for the calculation of primary and secondary fragmentation was written by G.S. Esterhuizen at the University of Pretoria in South Africa.

CHAPTER 13.8

Longwall Mining

Stephen L. Bessinger

INTRODUCTION

Longwall mining is a technique that evolved from a largely manual method in which rows of individual roof props supported the roof along a long face. The ore was broken from the face, first by drilling and blasting, and later by mechanical means powered by pneumatic, hydraulic, or electrical energy. Ore loading was done by hand shoveling into a conveyor or rail cars at the face. This method was labor intensive, lacked productivity, and exposed workers to significant hazards. Since then, technology evolution has produced spectacular improvements, motivated by the need for improved safety and productivity, as well as reduced labor and production costs. This evolutionary process has resulted in modern longwall systems, which are the focus of this chapter. The configuration and major components of a modern longwall are shown in Figure 13.8-1.

The shearer traverses the face, excavating the ore within a defined extraction height. The mined material is loaded onto the armored face conveyor (AFC) by the shearer and is transported to the main belt conveyor system via the stageloader. The stageloader normally has an integral crusher to provide suitably sized material for conveyor belts. The shields advance sequentially, following the shearer to hold up the roof directly above the face equipment and advance the AFC to repeat the cutting cycle. The excavated area behind the shields is allowed to collapse, which limits the roof load that the shields must support and starts a process that may create surface subsidence. High-capacity longwall mining systems depend on the breaking action of a machine to mine the ore. As such, modern longwalls are used to produce ores that can be mechanically cut or broken without explosives.

High-capacity longwalls mainly produce coal, but examples also exist in trona, potash, and phosphate rock. The potential is being investigated to apply longwall technology to platinum and gold-reef deposits with equipment adapted to the requirements of stronger rocks.

LONGWALL APPLICATIONS

Longwall mining has evolved mostly in response to coal-mining applications. Because many coal mines yield a relatively low-value product, particularly when coal is used for electric power generation, the output of the longwall must be a sustained stream, with low cost on a unit-of-production basis. The desirable image often suggested is that of a *coal faucet*, which can be opened or closed as needed. Embedded in the image is the ability to adjust the flow to desired levels. It should be the goal of those involved in the design, operation, and maintenance of a modern longwall to fulfill the goals of sustainability and productivity suggested by the coal faucet image. It is notable that health and safety considerations are intrinsically interwoven into longwall design and operating concepts because they are fundamental elements of sustainability and success. It is customarily accepted that longwall mining is the safest and most productive mining method that can be applied to soft rock deposits.

Longwall systems are serially dependent processes. This is because all of the associated equipment that supports longwall operation must function simultaneously, at the capacity of the longwall, to permit its operation. This dependence is a particular issue for the outby ore transport method, typically conveyor belts. Frequently shortfalls in outby conveyor belt performance are the most limiting constraint on longwall performance. The important point is that the success of the longwall system depends on the success of each of its constituent components, not just the machinery composing the longwall. This principle extends even to mine development activities that create the panel where the longwall will operate in the future.

Longwalls are typically designed for specific considerations related to the target deposit. Notable among these considerations are those described in the following sections.

Deposit Depth

Longwall mining has been applied to deposits with very shallow depth of cover, perhaps less than 50 m in a few cases and up to 1,600 m at the other extreme. Applications in the 100–600-m depth are common for longwall coal mines, especially in the United States and Australia. The loads on longwall roof supports (shields) are largely independent of depth of cover. Shield loads are more related to the extraction height and the

Stephen L. Bessinger, Engineering Manager, BHP Billiton–San Juan Coal Company, Farmington, New Mexico, USA

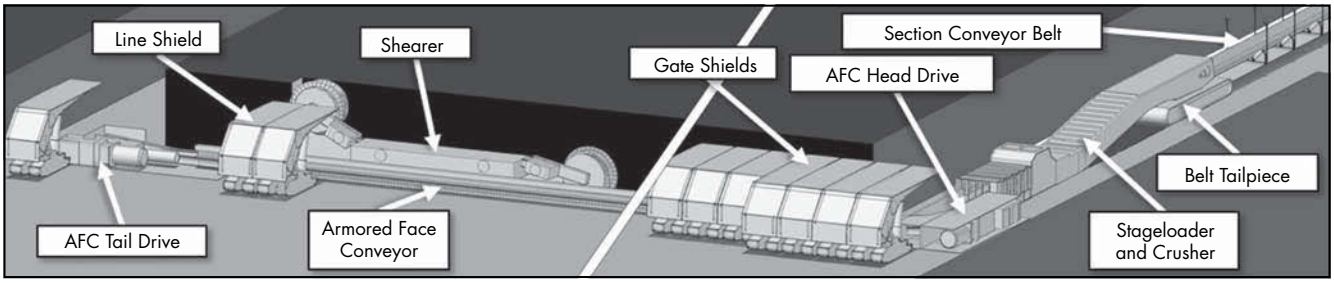

Figure 13.8-1 Major components of a modern longwall

strata overlying the ore bed (seam) than to any other factor. Mining-induced stresses on the face (front-abutment load) and gate road pillars (side-abutment load) are depth related. Not only must gate road pillars demonstrate expected stability, but the roof, in conjunction with the primary and secondary supports, must also be stable. Floor lift (floor heave) is frequently encountered at increased depth or with weak materials in the floor (i.e., under clay, fire clay, or claystone) (Peng 2006).

Deposit Dip

Most longwall mining systems are applied where the inclinations along the longwall face or the panel axis are low, less than 8.5°. Although longwalls are being used at much steeper inclinations, these are not consistent with high productivity. Steeply inclined longwalls also require special adaptations to stabilize the face against downhill creep, shield toppling, and product transport issues. Steep-seam, gate road development is also problematic. Steep, thick seams offer more opportunity for success but are still difficult.

As conveyor belt inclination increases, so do the issues in its operation, up to a practical limit and depending on the material being conveyed. For run-of-mine (ROM) coal, this limit is in the 15° range (CEMA 1997). This value can be even less, possibly 12°, if the material conveyed is wet. The wet condition can arise when production volumes diminish but water application is unchanged. In another case, large volumes of water can be transported by a submerged AFC onto the conveyor belt system. Importantly, operation of either conveyor belts or AFCs is easier when material flow is uphill. Numerous difficulties arise when conveying material down an appreciable grade, which far overwhelms any energy benefits that might be realized (Evans 1993).

The relative layout of the face and progression of panels in the mining sequence with respect to dip is important because of concerns about water migration, methane accumulation, and toppling of face and rib materials.

Deposit Thickness

Longwall systems are typically applied to laterally extensive tabular deposits with limited variation in ore thickness. After the ore thickness and its variation are characterized within the area to be mined, a nominal mining height will be defined. Practical minimum and maximum mining heights are defined by critical equipment sizes and operating envelopes. The longwall has little flexibility in extraction of material within the bounds of a panel and will cut through any area of the panel, extracting at least its minimum operating height. The only alternative is to bypass undesirable areas within the panel by withdrawing the longwall equipment and reinstalling it outside the undesirable area. This is a costly and time-consuming process, chosen only after considerable planning and reconnaissance. Where ore thickness is greater, the longwall can extract up to the maximum cutting height of the shearer or near the fully extended height of the shields. Caution must be used when approaching the fully extended height of the shields to avoid a condition where the shields fail to apply and maintain full loads into the roof without roof failure.

Mining equipment technology has the consequence of defining mining height in the following approximate intervals of deposit thickness (T).

- Thin: $T < 1.75$ m
- Moderate: $1.75 \text{ m} < T < 3.75$ m
- Thick: $3.75 \text{ m} < T < 7.25$ m
- Very thick: $T > 7.25$ m

Thin seam systems have historically applied longwall plow technology but have not achieved the productivity of thicker-seam, shearer-based applications.

Most modern, high-capacity longwalls operate in the moderate height category—from 1.75 to 3.75 m. Optimum height is generally agreed to be in the 2.5–4.0 m range for single-pass longwalls.

Above 3.75 m and up to approximately 7.25 m mining height, the thick category, is the upper limit of single-pass longwall capability. In this range, normal longwall equipment requires numerous adaptations to perform successfully until it reaches a practical limit at approximately 7.25 m.

Above 7.25-m extraction thickness, longwall technology is forced into several alternatives: multilift longwall or top coal caving. On a worldwide basis, as very thick coal seams extracted by surface mining extend to depths beyond economic limits, underground mining methods will be required that offer high resource recovery, such as longwall top coal caving.

Deposit Uniformity

Ideally, a tabular deposit well suited to longwall mining would exhibit uniformity in the ore bed/coal seam as well as the adjacent roof and floor. Unfortunately, examples of such ideal conditions are few. Generally, discontinuities result from structural or depositional origins but may also be the result of post-depositional events.

Structural geologic disturbances normally involve folding and faulting. Gentle inclinations induced by folding can be considered as previously described in the discussion on dip. However, if the gentle dips of a broad syncline, anticline, or monocline go over approximately 8.5° as a trend, this may limit applicability of the longwall. Expectations of high productivity may decline as the inclination steepens from 8.5° up to 15°.

Aside from overall inclination, the rate of change of inclination becomes a constraint, as the AFC, shearer, and shields

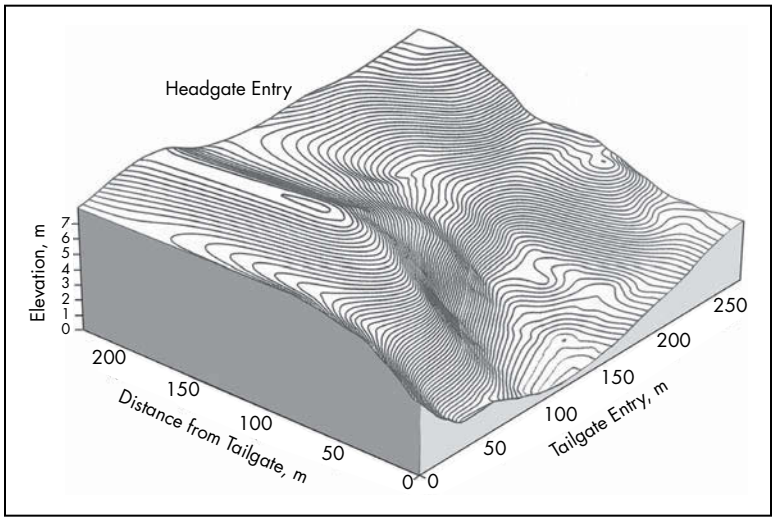

Figure 13.8-2 Disturbed seam topography

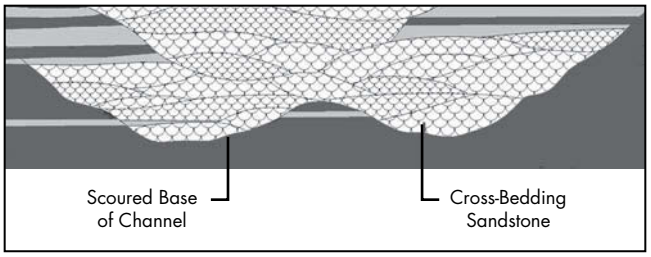
all have different concerns in this regard. As an example, if the radius of curvature of seam topography gets short, and the shearer is able to follow it, the AFC may have less vertical articulation than required to follow the changed topography and bridge, forming a span that is not supported by the floor. Thus, the AFC would only be supported by the connections that hold adjacent pan sections together (*dog bones* or *dumb bells*). By the AFC's own weight, or with the additional weight of the shearer, the AFC connections may fail or the pan structure may fail. This can cascade into an AFC system failure, such as a "chain wreck" where AFC chains break, flights are damaged, and main drive sprockets may fail. Such incidents may take hours to days to repair and cost in the hundreds of thousands of dollars in direct and lost-opportunity costs. They also create avoidable safety hazards.

In an alternate case, shields can lift their bases off the floor during cyclic advancement if their canopies become "iron bound" with adjacent shields because of a short radius of curvature in extraction profile. This condition can result in a suspended shield, which can fall to the floor unexpectedly and be a safety hazard. Of course, all of these problems are created when the equipment is asked to do something that was never intended by the original equipment designer or, conversely, was not identified as a performance requirement in the acquisition specifications. Figure 13.8-2. shows a disturbed area that was successfully mined with a longwall but not without impact to productivity.



Another structural geology concern is fracturing or faulting. An example might be fracturing along the axis of local bed flexure, which can adversely affect roof control or cause elevated gas or water inflows. Notably, fractures/faults parallel to hillsides exist in some areas and may complicate logical panel layouts beneath a ridge line. Faulting may be present with or without appreciable folding. Strata displacements may be normal faults, and total displacements may be distributed across one or more discrete fault traces within a short distance. This is generally a manageable issue so long as the local displacement is not too large. Because these features are preferably traversed at an acute angle to the face, grading roof, and floor into and out of the feature makes operating through local offsets feasible—up to double the mining height in displacement. This will introduce an adverse impact to ROM product quality and overall productivity. Obviously, proximity of faults on a single face is problematic, as is the case where faults, still at acute angle to the face, exhibit enduring persistence. Both of these cases may require revised ROM quality and productivity estimates.

Then there are those cases where the fault is at a shallow angle with the face line or possibly even parallel to the face at worst case. This scenario can have seriously negative impacts to productivity and may lead to premature face recovery or even threaten the loss of equipment. If such a feature is suspected, it should be approached with caution after careful risk assessment and with a plan of mitigating actions in place. If such a feature is first recognized as it emerges onto the face, it is certainly appropriate to make efforts to evaluate it and implement a mitigation strategy before exposing a large proportion of the face to the hazard. It has frequently been the case that a longwall could "outrun" a local adverse roof condition; however, that is not true for faults parallel or at shallow angle to the face.

In the case of most structural faulting, the ground stresses within one block of the fault may not be equivalent to the stresses in others. Although normal faulting is at some risk in this regard, it is particularly problematic in thrust faults. The stress differential between blocks in a thrust-faulted scenario can result in some blocks having extremely difficult ground control issues compared to others.

Depositional discontinuities develop in response to conditions present at the time that the mineral deposit formed. These discontinuities commonly arise in conjunction with sand channels above or below a coal seam or as scours (also termed *faults* or *wants* in some locales) where they erode and replace the coal seam. Figure 13.8-3 depicts sand channels as they may commonly occur in coal-bearing strata.

In near proximity to these features, it is possible to have elevated stresses and differential compaction surfaces. These glassy smooth discontinuities (slickensides) are weak in tension and can constitute a hazard to roof control. Where large thicknesses of coal occur over a short stratigraphic interval, compactional features can exist as faults, with displacements mostly confined in near proximity to the seam and having normally short lengths, perhaps less than 250 m. Compactional faults are not normally the source of great concern.

Source: Adapted from Papp et al. 1998.
Figure 13.8-3 Sand channel in coal strata

Sand channels above the mining horizon can lead to increased shield set load and yield load requirements and should be evaluated accordingly. Where these features might be encountered at a shallow angle to the face, opportunities to avoid the condition are initially preferred. When near-seam sand bodies are strong and stiff, in conjunction with significant depth, the possibility of sudden strain energy release in response to mining can be a concern.

Another variation of depositional discontinuity occurs when soft sediments are injected into or across the coal seam. These are not usually large or strong, so they represent more of a threat to ROM quality and local ground control as opposed to sustainability (Moore 1940).

In a similar fashion, it is occasionally the case that igneous materials can be injected into coal-bearing strata, forming lenticular or vertically crosscutting dikes. In various locations around the world, including South Africa, Australia, and the western United States, these igneous dikes can be a serious obstacle to longwall operation. Where these bodies are narrow, perhaps less than 1.0 m wide, they are often sufficiently contaminated by entrained debris that they do not achieve strength beyond the limits of mechanical cutting by a shearer or continuous miner. However, when encountered as thicker bodies, typically a stronger core requires other means to penetrate it. In South Africa, this material is identified as dolerite and forms dikes off of sills intruded into the coal-bearing strata. The dolerite dike material can be more than 140 MPa compressive strength (Papp et al. 1998). It is also the case that post-depositional events can lead to the formation of natural coke, or a natural burn can produce coal loss with only residual coal ash.

It is safe to assume that all of forms of rock-mass nonuniformity noted will have a negative impact on longwall operation. As such, it is useful to identify any geologic features at the planning stage. Although reconnaissance drilling and detailed geologic mapping are customary, various geophysical methods can be applied to search for the different discontinuity types. Satellite imagery, magnetic or seismic surveys, and electromagnetic tomography are a few of the methods used. Unfortunately, these methods are not universally useful, and choice of method deserves careful attention. It is common to find that none of the methods are particularly informative for any specific site.

Strata Gases

Characterizing the gases and quantities that might be encountered during longwall development or subsequent longwall mining is important when striving to achieve the coal faucet concept. If acceptable atmospheric conditions cannot be continuously maintained where people work and travel, the longwall is at risk of being idled during periods where excursions beyond acceptable limits occur. In the United States, concern is emerging for atmospheric safety in the mined-out areas (gob or goaf) behind the longwall or in sealed adjacent areas.

Several gases have prominent impacts on longwall design and operation worldwide. These include those described in the following paragraphs.

Methane

Methane (CH_4) is common in coal mines to varying degrees and may be encountered in most sedimentary strata. Coal seams have long been recognized as likely reservoir rocks for methane, but it is increasingly recognized that other porous and permeable near-seam rocks can be significant sources of methane liberation. This is particularly true when the in-situ rock mass is fragmented by mining-induced caving. Higher CH_4 liberation rates in new longwall gobs result from creation of smaller particles than existed in the undisturbed rock mass. Release of lithostatic stress also lends to increased production rates of methane in caved material. Not only does the methane fill the void space of rock porosity at some reservoir pressure, it can be chemically adsorbed by coals. It is also common for fractures or faults to be charged with fluids.

Occasionally the rock stress augmented with interstitial fluid (gas) pressure can be greater than the unconfined rock strength, which results in one mechanism of *outburst* when rock failure occurs. Not only can this create atmospheric inundations from the escaping gas, it can result in violent ground control hazards. Such events are known in a few U.S. and Australian coal mines.

Lastly, the most notable hazard of methane in the mining environment is its explosibility when mixed with atmospheric oxygen in certain ratios. As one step to avoid this hazard, most longwall face equipment is designed, tested, and certified to be explosion proof or intrinsically safe. Explosion-proof equipment will not allow an ignition within the enclosure to propagate outside it. Intrinsically safe components rely on the principle that methane–oxygen mixtures will not ignite below certain initiation energy thresholds, and they ensure that such energy is never available, even during component failure conditions.

Carbon Monoxide

Carbon monoxide (CO) can be adsorbed on coal and naturally occurring or it can be a product of partial combustion of hydrocarbon fuels or coal. This gas primarily represents a health hazard, but can be explosive in relatively high levels when mixed with atmospheric oxygen.

Aside from its human toxicity, it is often an indicator of combustion, spontaneous combustion in some coals, or may result from fire or explosion. Longwall mines with spontaneous combustion propensity may monitor the CO production rate from the longwall as an early indicator of an evolving thermal event.

Carbon Dioxide

Carbon dioxide (CO_2), a common strata gas, may be present along with methane or may be a dominant constituent. In some Australian cases, high-pressure CO_2 resides in localized areas of the coal seam and requires specialized control measures to manage the hazards of outbursts. CO_2 is also a product of full combustion of coal and hydrocarbons. As such, it can be

one of several gases monitored to detect evolving combustion events, spontaneous combustion in particular. Graham ratio, Jones-Trickett ratio, and CO/CO_2 ratio, as well as CO production rate, may be used to detect the onset or monitor progression of a combustion event (SIMTARS 1999).

Hydrogen Sulfide

Hydrogen sulfide (H_2S) is primarily recognized in the mining environment for its toxic effects on humans. It is also a concern in longwall mining for its corrosive effects on metals and its participation in unexpected steel failures.

H_2S can dissolve in still water and be released when the water is disturbed. The aqueous mechanism can bring it in direct contact with metals, such as bronze or steel in longwall components, and result in metal sulfide formation and the liberation of free hydrogen (H_2). Because H_2 is not normally a strata gas but is known to be an indicator gas in combustion events, this can explain its existence without the presence of a thermal event.

H_2S can be a metabolic product of sulfate-reducing bacteria. These bacteria are naturally occurring and can form microscopic colonies beneath which high concentrations of H_2S can exist, perhaps up to 4,000 ppm. This can create overwhelming corrosive or metallurgical effects while atmospheric levels remain low.

Other Gases and Vapors

On occasion, other gases and vapors may naturally occur. Low molecular weight hydrocarbons can exist in gas or liquid phases in sedimentary strata. Their combustibility and quantity may be reason for concern in some instances.

In most cases, the regulatory body that has jurisdiction over mining health and safety for a specific location will have statutory guidelines for safe and legal levels of the noted gases. In order to be successful and sustainable, a longwall system must be designed to accommodate safety and statutory compliance in order to avoid production outages associated with gas level excursions above allowable limits.

Water

In many areas, water is associated with the coal seam or near-seam strata. It may also be associated with overlying or updip workings and fracturing or faults. In any event, its management is reason for careful planning because of its generally negative impacts to longwall development and operation, as well as the typically negative impact it can have on ground control. Where swelling clay minerals are present in the rock, the matrix may decompose when the clay minerals hydrate and swell. The slake-durability test is one measure of a rock's behavior when exposed to moisture. When swelling clay minerals are present, the rock typically performs poorly in slake durability.

Siltstone, mudstone, claystone, and fireclays are often the operating floors for longwall development sections or the longwalls themselves. The often present water, coupled with the duty as a roadway for rubber-tired equipment, turns these floors to mud, sometimes hundreds of millimeters deep. In the immediate headgate or tailgate entries, this can mean that the belt tailpiece and stageloader are resting on mud and may even invite floor heave, which requires clearance before equipment advance. It also can mean that gate shields may unreliably advance or be unable to create the intended load into the roof, leading to a deterioration of roof control in the headgate or tailgate. This same principle can leave standing support such as props, cans, or cribs with an inadequate foundation upon which to create resistance to roof deformation. Water management, or the failure to manage it, is often a reason that longwall productivity falls short of its full potential.

Spontaneous Combustion

Spontaneous combustion is a condition where slow oxidation of a combustible substance leads to heat evolution and increasing temperature until the material reaches a point where combustion starts and spreads to adjacent fuel. Some coals, particularly those with lower rank, exhibit a propensity toward spontaneous combustion (Cliff et al. 2004). It is a particular concern when spontaneous combustion heatings or thermal events take place in a longwall gob (goaf), where they can be difficult to locate and identify, and even more difficult to access and extinguish. Such events typically cease production in the affected portion of the mine until, in the best case, the event ends or, in the worst case, causes loss of life and assets.

As serious as this scenario is, an even worse one is possible where methane is present in combination with a coal prone to spontaneous combustion. In that case, atmospheric oxygen in combination with explosive methane levels can be ignited by a small spontaneous combustion ignition source, resulting in an explosion and fire. In such an event, multiple fatalities and loss of assets are possible.

Because responsible mine operators are committed to a *zero-harm* philosophy, effective controls must be offered to preclude the possibility of a spontaneous combustion event or an explosion and fire. The mitigating strategy for all of these concerns is the long known *fire-triangle* concept for fuel, oxygen, and ignition source. Considering the fire triangle, it becomes immediately evident that in a spontaneous-combustion-prone coal mine, the only component that may be subject to control is oxygen. Thus, the choice of bleederless longwall ventilation, explained later, can effectively exclude oxygen from the gob (goaf) and mitigate the hazard.

As with any underground fire, the issue is only partially getting the fire extinguished, which usually entails oxygen deprivation, but also dissipating the residual heat resulting from combustion so that the event will not simply resume if oxygen becomes available again. This is also why early detection and intervention are key components to a spontaneous combustion control plan. But the most important element is a strong focus on prevention (Mitchell 1996).

Roof and Floor Strata

One of the advantages of a longwall mining system is that it can accommodate a wide range of roof conditions. Gate road stability issues aside, stabilizing the longwall roof is actively done by the shields. The shield must immediately stabilize the near-seam roof when it is initially set against the roof after it is advanced, referred to as *set load*. The set load required to stabilize the roof is a function of site-specific conditions and parameters of the face cross section. The set load produced by the shield is derived from the emulsion system pressure available to the shield during setting, the major stage diameter of the leg, and its resulting area. Set pressure applied to leg area and derated, to account for leg inclination (angle to vertical) functionally defines set load created by the shield. To be successful, set load required to stabilize the roof must be less than the vertical thrust created by the shield at setting. Subsequently, the shield must stabilize the roof throughout the time when the

shearer cuts past it, adding a web depth to the span, and ultimately as adjacent shields are lowered away from the roof as they are advanced. Loads also arise from face deterioration and span enlargement to the degree that it occurs in response to development of front-abutment loads from web to web. If the shield resists this load and the roof remains stable, the result is the end-cycle load required to support the ground. In concept, this should be at or below the yield capacity of the shield.

This yield load is calculated in a manner similar to that of set load, except that instead of system setting pressure, the opening pressure for the leg yield valve must be considered. With set load and yield load independently defined, it is possible to create some of the popularly discussed ratios such as set-to-yield ratio, yield capacity/linear length of face, and set or yield capacity/area of supported roof. Although these terms are frequently discussed as design factors, they are, in fact, only outcome statistics to the actual equilibrium that must be successfully established. They also have limited comparability over a range of possible operating heights, because only the vertical component of the leg load primarily contributes to roof stability. The horizontal force component is mostly resolved within the shield by the lemniscates links.

Because the interaction of the roof and the roof support (shield) has been described, and the need for stability is clear, the factors leading to loads arising from the roof must be characterized. Roof loads on shields increase with increasing distance along the face from either gate road up to a maximum load specific to any site. Distances greater than that effectively only expand the number of mid-face shields exposed to that maximum load. It is not prudent or practical to attempt to select shields in the design process for any load less than the maximum load experienced for the specific installation. Certainly, using outcome statistics or rules-of-thumb to size shield capacity is poor practice and risks the possibility that an entire longwall will fail to perform as intended. Should this be the case, available solutions may require premature equipment replacement or acceptance of undesirable operating performance.

Evaluating the factors that contribute to roof loading on the shields, it is clear that both site-specific and face cross-section factors are contributory. Site-specific factors include

- Seam thickness (extraction height),
- Near-seam strata (type and thickness),
- Seam and nearby strata material properties,
- Caving behavior of strata,
- Seam inclination,
- Natural and mining-induced fractures, and
- Previous mining above or below the seam.

In concept, the overlying rock collapses into the void created by mining. As the intact material fragments and caves, with particles rotating and translating into the void, its volume bulks to fill the void, largely in inverse proportion to particle size. This process continues until little enough void space remains between the rubble and the uncaved rock that further displacement of the overlying rock takes place through particle translation but with little rotation. Eventually, even the downward translation reaches equilibrium with the resistance created by the underlying compacted rubble. Thus, the weight of rock overlying the longwall can be supported across three areas:

1. Unmined face ahead of the longwall (front-abutment load)
2. Longwall roof supports
3. Rubble material of the gob

The area depicted in Figure 13.8-4 graphically shows the region of rock that must be stabilized by the roof supports (shields). In consideration of the loading process described, it is evident that the loading of longwall roof supports has little impact from mining depth. It also becomes evident that overlying roof materials that cave as small particles from thin layers can lead to smaller caving heights before particle rotation is diminished and consequently to lower shield loads and thus lower shield capacity requirements. Conversely, thicker and stronger overlying beds can impose much larger loads on roof supports, especially if they are close to the mining horizon. Another consideration is that stiff roof rocks, typically strong as well, can require high set loads to stabilize them. Further, they can lead to extreme cases of periodic weighting, where strong beds can act as cantilevered loads, imposing successively greater loads on the roof supports until the cantilever fails. Such strong beds can be multiple within the caving horizon and cause superimposed effects of periodic loading. Figure 13.8-5 shows an example of how this variation might look for an example longwall application (Barczak and Garson 1986). Wind blasts originating in the gob often coincide with the caving of thick, strong beds, or the first cave of a new longwall panel.

In some instances a cantilevered bed failure results in the release of stored energy and in a “bump” or “bounce.” This mining-induced seismicity can be damaging to equipment and hazardous to personnel. In general, mining-induced seismicity is often associated with strong rock or coal and significant depth. High overburden stress coupled with mining layouts that may act as stress concentrators can lead to mining-induced seismicity originating at elevations ranging from beneath the mining horizon and extending upward to the surface. High-flow yield valves on shield leg cylinders can afford protection against equipment damage at moderate convergence rates in a periodic weighting event, but only purpose-designed rockburst protection can prevent damage to shields during a bump where a large convergence can occur suddenly.

Face cross-section factors that affect loads imposed on the shields include

- Geometry of the shields, shearer, and AFC;
- Depth of cut (web); and
- Sequence state in cutting cycle.

Because of these factors, coupled with geologic variation that takes place on scales smaller than the area mined by a set of roof supports within their service life or even within the course of a panel, it is not surprising that the loads imposed on shields vary over a range at any installation. Figure 13.8-6 shows the cumulative probability distribution of loads required to stabilize the longwall roof.

These curves can be numerically modeled for a proposed longwall face cross section and strata section, and are site specific for every individual application. Models of this type have shown good correlation with data collected from pressure monitoring on equipment in service. As discussed previously, the set load curve is derived independently of the yield load curve.

It can be observed that in the region above approximately 96% cumulative probability (CP), providing additional support load into the roof offers diminishing returns. Using this method to select roof support capacity leads to selection of

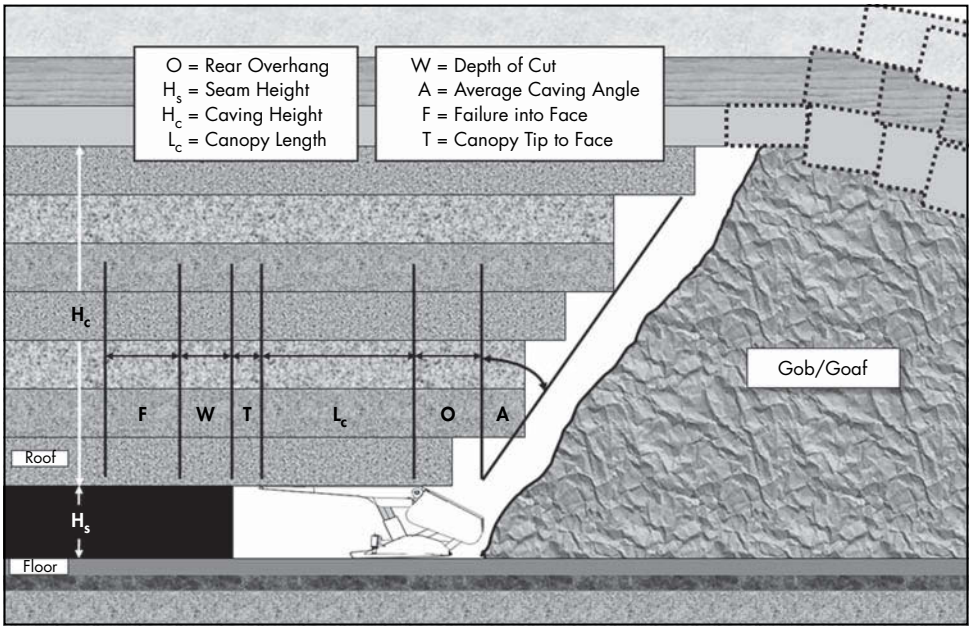


Figure 13.8-4 Conceptual loading model for longwall shield capacity evaluation

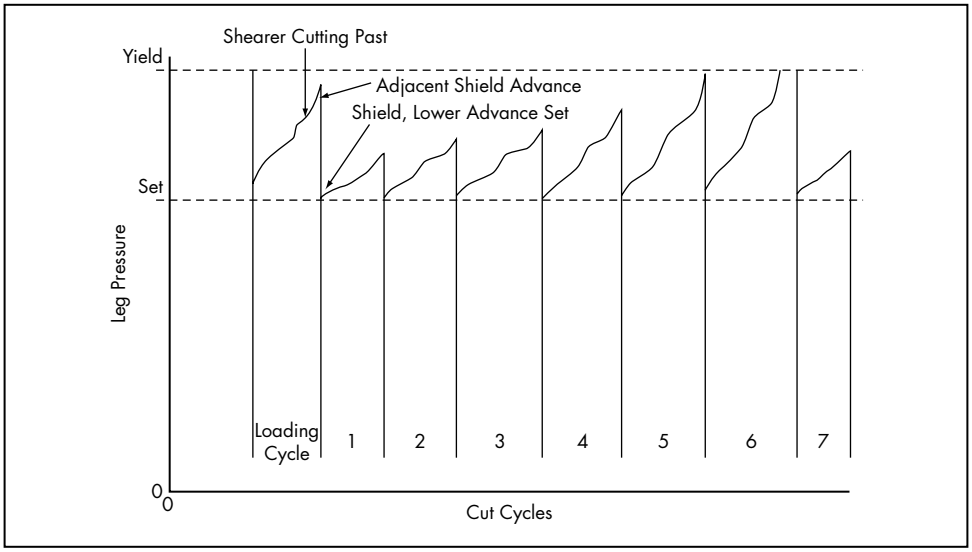

Figure 13.8-5 Periodic weighting behavior of a longwall roof

supports that control loads from the roof in the 91%–96% CP range. This leaves a 4%–9% incidence of yielding. In most cases, yielding events will be of brief duration, and equilibrium will be reached by sharing load onto adjacent shields. Selection of capacity in the higher end of the range, 93%–96% CP, allows for some deterioration in performance, as equipment ages, without creating performance problems.

Choice of supports larger in capacity than 96% CP of the roof loads that will arise offers higher cost, greater weight, reduced travelway dimensions, and elevated emulsion system demands with little perceptible benefit. However, because the probability distribution is nonlinear, selecting capacity much below 91% CP leads to an excessive occurrence of shield yielding and onset of roof damage companion to the more severe yielding events.

Notably, potential shields for any application should be evaluated at different heights (leg cylinder inclinations) to verify that they will be adequate for any mining height condition they may experience in service. Excess debris should not be allowed to accumulate on top of the roof canopy or beneath the base, as this material can be compacted and may allow excess roof convergence and damage to arise before enough support resistance is generated to create equilibrium. This is especially true for strong, stiff roof materials such as competent sandstones near the roof line in some coal mines.

Specific Energy of Cutting

The productivity of a mechanized cutting process for rock is largely a function of the material's specific energy of cutting, which depends on the type of cutting being applied. Shearers

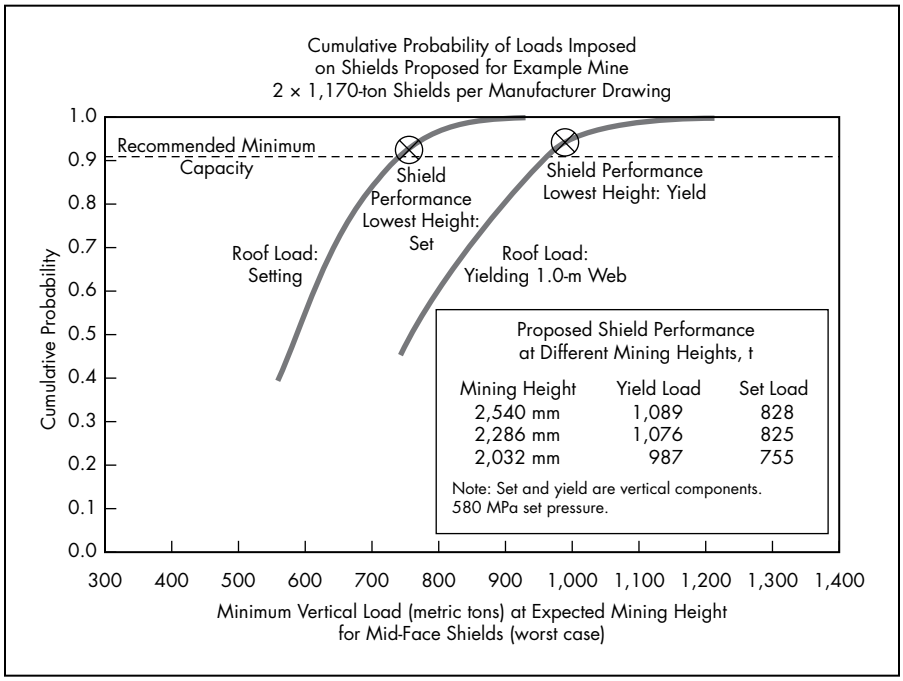

Figure 13.8-6 Example of site-specific stochastic longwall roof-loading evaluation

are different from drum-type continuous miners, which are yet different from longwall plows. While shearers and continuous miners work against forces related to compressive strength of the material being cut, plows primarily work against the tensile strength of the material, which is typically much weaker than the compressive strength. Particularly with respect to shearers, the cutter motor power used to produce a resultant quantity of ROM ore over a period of time defines the specific energy of cutting for the material (kilowatt-hour per metric ton [kW·h/t]). This assumes that the cut material can be cleared so that product accumulation does not impede the process. This measure is useful for the purpose of production process design and management but is not as pure a parameter as the name might suggest.

The load applied to the material to be cut can alter this value and is a benefit for the longwall system. When the front-abutment load has fully evolved, after the start of mining in a panel, this load is usually large enough to "soften" the face and reduce the energy required to produce a quantity of material. Until the front abutment fully develops, cutting will be more difficult than after it exists. The apparent softening can also be noted as abutment load varies in periodic weighting cycles and when production resumes after a stoppage of sufficient duration to allow significant stress redistribution.

The addition of work done by the abutment stress is also advantageous to creation of a larger product size distribution and lower fugitive dust production on a milligram/cubic meter/metric ton basis. Interestingly, the cutting bits deeper in the web do more work and produce a smaller size distribution of product than the bits shallower in the web. This smaller-sized product may be significant in dust production, which can become airborne. The possibility of improved machine utilization and proportionately reduced dust production exists with adoption of increased web depth. In the transition of web depths from 0.76 m to as much as 1.07 m, this appears to have been true.

Specific energy of cutting for various materials being cut by shearing machines ranges from 0.05 kW·h/t for easily cut coals to 1.3 kW·h/t or more for some very hard cutting sandstone and igneous dike materials.

Where very difficult cutting is expected for an extended duration, specially designed *rock drums* are used in lieu of normal production drums. These rock drums are designed with closer bit spacing and more bits per line in the drum lacing to accommodate the heavier cutting demands. The style of bits may also change between radial and conical cutting bits to offer improved longevity and performance.

Typically, high-capacity longwalls operate well when they encounter materials in the 0.05–0.45 kW·h/t range.

Abrasivity

When considering a longwall mining application, the abrasivity of the product to be mined and conveyed is of concern. Most wear on the AFC and beam stage loader (BSL) is related to the tonnage of material that has been conveyed across the systems. As an approximation to the wear that might be expected in a particular application, standardized laboratory tests have been developed that are also used by the electrical generation industry, which has similar concerns as mining about abrasive wear to equipment within its facilities. In high-level summary, sacrificial blades are rotated through a mass of the rock material of interest for a predetermined time. At the end of the test, the weight of material lost by the sacrificial blades is determined and reported. This weight loss ranges from only 8 mg Fe in a trona specimen to more than 1,300 mg Fe in a severely abrasive coal and sandstone ROM product. Typical values range from 200 to 900 mg Fe, which roughly correlates with wear of 0.5 to 2.5 mm of deck-plate thickness reduction per million metric tons of production. Unacknowledged in these values are the corrosion processes, which can certainly influence the outcome in service. Improved results can be achieved by use

of abrasion-resistant steels where the corrosion environment will not provoke premature failures (Ludema 1996).

Mine Layouts

Having identified most of the important site-specific considerations that might have to be addressed by a successful mine design, the general mine layouts can begin to be discussed.

Historically, advancing and retreating longwall layouts have been the subject of much discussion worldwide. In the advancing system, the longwall setup room is close to the main or submain entry set, and the longwall mines away from these entries into undeveloped reserves. In the process, support is constructed to constitute one or more gate roads behind the longwall face. Mining continues until a designated extent is reached or conditions force face recovery. The fact that artificial roadways have to be maintained in the gob adds significant cost and labor to this technique. As cost and productivity benchmarks have evolved across the industry, the elevated costs and lower productivity of advancing faces have generally seen these operations cease or transition to retreating longwall layouts. Only in unusual circumstances or where historic precedent dictates are advancing faces operated. At present, all of the world-class longwall installations are retreating faces. This trend can be expected to continue into the future.

Retreating longwall layouts may be of two types: conventional or punch (highwall) type. Figure 13.8-7 shows a conventional retreating longwall layout with a mined-out panel adjacent to the active longwall. The entries of the previous panel's headgate (main gate) transition into becoming the tailgate for the active face. The active longwall face mines progressively from the setup room at the far (inby) end of the developed panel and is eventually recovered as it enters its intended recovery position. The recovery position of the face is shown by the line that coincides with the near (outby) extent of the mined-out panel. Optional recovery chutes may be used to aid free equipment recovery.

The punch (highwall) longwall is largely similar, except that instead of developing a main or submain entry set from which gate roads are driven, the gate roads are developed directly off a surface-mined box cut or highwall. Punch longwalling is attractive because it eliminates the need to develop and maintain long-term underground workings in the form of mains and submains entries. It also lends itself well to the transition from surface mining to underground mining that confronts many mine operators as the depth and production costs of remaining reserves increase.

Gate roads for retreating longwalls are typically formed with two- to four-entry developments. Although single-entry and dual-entry gate roads are common outside the United States, dual-entry gate roads are an exception in the United States. In the interest of worker safety in a fire or explosion emergency, U.S. mining law generally requires a minimum of three-entry developments in coal mines to accommodate separated intake (fresh air), return (exhaust), and conveyor belt entries.

In cases where it is safer to have a dual-entry development than the statutory minimum of three entries, a variance may be granted by regulatory enforcement authorities based on a demonstrated diminution-of safety-argument. U.S. mine operators have succeeded in the diminution-of-safety argument where adverse geotechnical conditions threaten worse consequences than the reduction of number of entries. Companion to the grant of such a variance are additional controls to safeguard against the hazards envisioned during statute development.

Often, especially in the United States, three- or even four-entry developments are used for gate roads. The motivation for creation of more development length, in total, than is minimally required to sustain longwall operation should be carefully considered. It is ordinarily desirable to minimize the ratio of development costs per longwall metric ton produced. It is also desirable for time value of money considerations to associate as closely in time as possible the expenditure of costs that provide future benefits with realization of those benefits. In the pursuit of these principles, it is common for longwalls to be operated in geometric succession, with the headgate of the prior panel being used as the tailgate of the current panel and so forth, until some predefined extent is reached.

Often this extent is the aggregation of a group of panels to form a *district*. The number of panels in a district is variable, typically based on ventilation or geotechnical considerations. When managing the constraints of a large district eventually becomes difficult enough, mine operators prefer the development of the incrementally additional gate road, which is required to develop the first panel in a new retreating longwall district. Frequently, districts are sealed upon completion, removing them permanently from the worked and traveled portion of the mine. Mine operators are then largely relieved of the burden to maintain access for inspection and ventilation of such a sealed district, but access must be maintained to inspect the final seals where the district meets with active mine workings, and the seals themselves must be maintained in adequate condition.

Accumulations of water, explosive atmospheres, or spontaneous combustion events can be reasons for concern, even in sealed and otherwise abandoned areas. Relatively recent changes to U.S. regulatory requirements for seals and monitoring atmospheres in sealed areas address these concerns.

On occasion, it can be necessary to isolate overburden stress effects between the current longwall panel and the prior panel with a barrier pillar. Where panels are mined at depth with thick, stiff beds in the overlying strata, failure to adequately support the stiff strata can channel vertical stresses toward the current panel. This elevated stress can result in mining-induced seismic activity in the strata section, with possible events in excess of 3.5 on the Richter scale. These events can be damaging to equipment and hazardous to personnel, particularly when seismic activity originates at or near the face location. At a lesser scale, stiff coal subjected to large stresses can fail suddenly and result in the expulsion of material from the face toward the longwall travelway, creating a hazard to personnel.

Longwall gate-road development is characteristically "just in time" to avoid delaying production activity on the longwall. The degree to which the development is ahead of the needs of the longwall in time is often referred to as *float time*.

Some ventilation plans require the next adjacent longwall to be developed in order to implement the ventilation plan. More commonly, this is not the case, and float times are in the 6-to-50-week range. This allows adequate time to withdraw the development equipment and stage longwall-move supplies and equipment prior to the onset of a longwall move. However, it does not impose unnecessary "hang time" on the gate road, as deterioration of conditions can begin soon after development in some settings. It also associates the cost

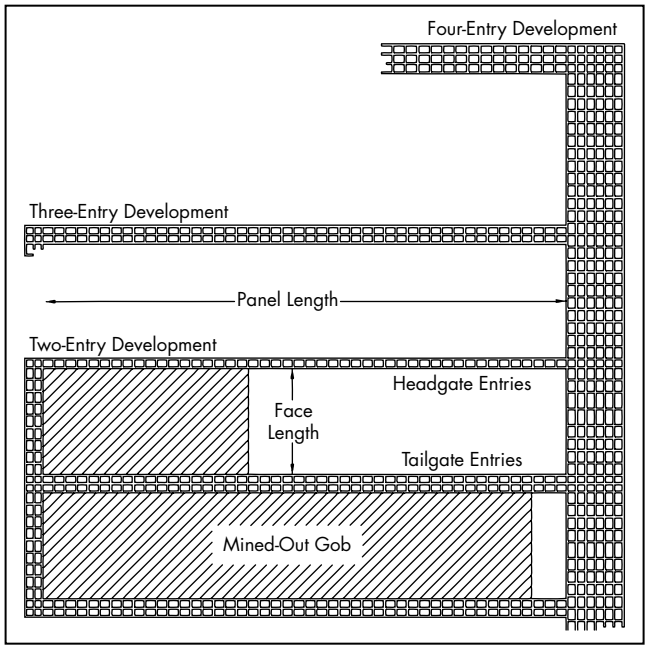

Figure 13.8-7 Fully retreating longwall layout

of such development in time, closer to the future benefits expected to arise from it. For many mine operators, the longwall move actually starts with emplacement of portions of the new face prior to completion of mining in the current panel. Such equipment might include: tailgate gate shields; AFC and BSL; a new or rebuilt shearer; electric power and control equipment; and emulsion-pumping equipment, controls, and tank. The amount of equipment preinstalled depends on arrangements specific to any mine operator. In general, shorter production outages occur with increased amounts of equipment preinstalled in the new longwall panel.

Gate road development itself is done with continuous miners and one of the several face haulage mechanisms available. Figure 13.8-8 shows the general layout of a three-entry gateroad development section with a continuous miner and battery coal haulers. The section depicted uses a place-changing method of operation where a continuous miner mines a cut and then changes places to mine a cut in another entry or crosscut. When the continuous miner has withdrawn, a separate machine installs roof bolts and possibly wire mesh or roof straps to roof and rib or roof trusses, if necessary.

Roof bolting progresses from where support was installed on the prior sequential cut in that working place to the face of the cut. After a cut is fully supported, the roof bolter is withdrawn and the cut is ready for auxiliary activities that may be necessary before the continuous miner returns to make its next cut in that working place. As this process is successively applied to entries and crosscuts, the entry set is advanced. Cuts may range from as little as 3.0 m to more than 12.0 m. In good roof conditions, the cut depth may be limited to the depth attainable without exposing personnel to unsupported roof or airborne contaminants.

Short cuts have a decidedly negative impact on the productivity of place-changing mining methods, as a disproportionately great amount of working time is lost to place changing. As depicted, ventilation is provided by section fans.

The coal haulers transport the mined product to a conveyor belt for ultimate clearance from the working section. It is common for the conveyor belt to be equipped with a feeder breaker. The feeder breaker has a limited amount of surge capacity, allowing coal haulers to unload quickly, but also meters product through a breaker and onto the conveyor belt at rates that optimize belt system performance. This is particularly the case where multiple sections all discharge onto a shared conveyor belt.

Place-changing operations are typically applied in relatively good roof conditions and often have better productivity than the alternative—in-place continuous miners. These in-place continuous miners, also called bolter miners, install roof bolts, mesh, straps, and even roof trusses in parallel with the mining cycle. Thus, roof support is installed close to the face, and the roof has minimal opportunity to deteriorate before additional support is implemented to augment its natural integrity. Also, this method minimizes the number of times that the bolter miner is moved between working places, thereby minimizing damage to potentially weak floors.

Historically, seriously flawed weight distribution on bolter miners led to worse floor damage than place-changing machines, even though machine travel was less. Recognition of this problem has allowed it to be mitigated on modern machines.

Aside from mining and bolting, section operations are much the same between in-place and place-changing systems. Some mine operators use loading machines between bolter miners and the coal haulers. The loading machine allows the bolter miner to discharge product into a small surge pile on the floor, behind the bolter miner. The machine loads from this surge pile into coal haulers as they become available and decouples the continuous miner from producing and loading only when a coal hauler is on station and ready to receive product. The use of a loading machine also caters to an often noted deficit of bolter miners, which is cleanup in-cut.

As a general principle, bolter miner productivity is less than place-changing operations when a reasonably long cut, perhaps greater than 6.0 to 7.5 m, is available. However, if cut depth falls below this range or if ground control is unacceptable in the cut depth available, a bolter miner system may become the preferred option. Current bolter miners have the ability to sump and bolt simultaneously. This has a notably favorable impact on productivity when compared to earlier style bolter miners, which could only cut as much as was available with the machine frame stationary when drilling and bolting activities were ongoing.

Additional concerns for gate road design are entry and crosscut span, crosscut angle, and spacing. Gate road entries must serve several purposes, including the following:

- Provide adequate cross section for ventilation
- Provide access of personnel and materials
- Transport and installation of longwall equipment
- Installation of the longwall section conveyor belt
- Temporary locations for emulsion-pumping equipment and electrical power and controls
- Retreat of the longwall in normal operation

Standing roof support is restricted to only those areas where it does not obstruct necessary machine travel. In the longwall conveyor belt entry, supplemental support may be installed as a precaution because there is little opportunity to add remedial support after the belt is commissioned.

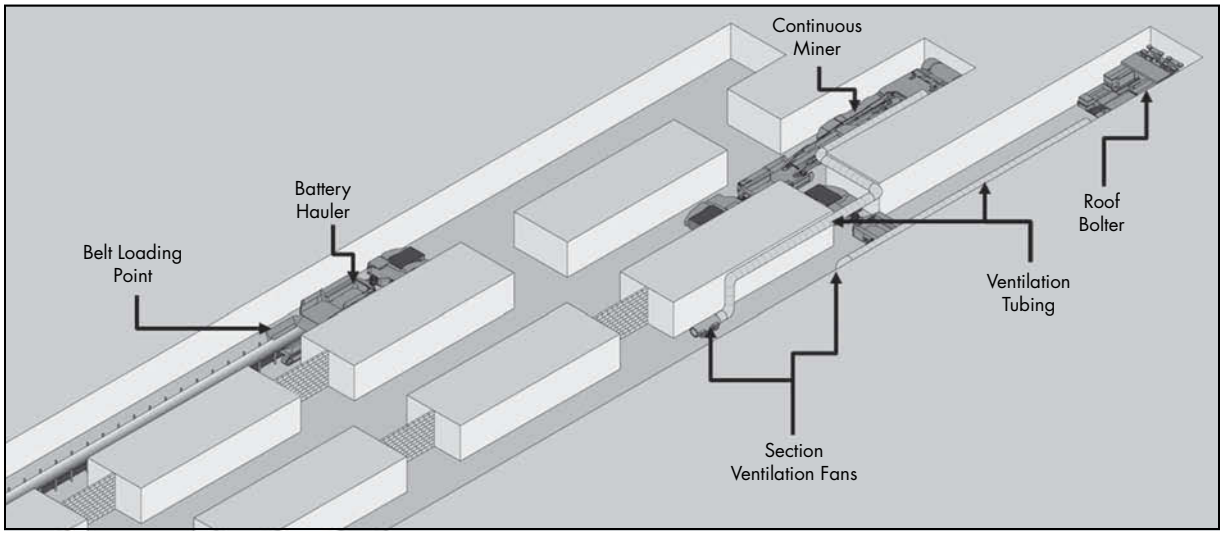

Figure 13.8-8 Three-entry gate road development with place-change mining

Four distinct regimes of increasing loading are applied to gate roads, aside from the first and last panels of a district:

1. Initial development
2. Adjacent to a single longwall gob (headgate)
3. Intermediate to adjacent longwall gobs (active tailgate)
4. Longwall gobs on both sides, well behind (inby) the face

The primary roof-support system controls the ground in the first and second stages, but supplemental support is commonly applied prior to use as a tailgate for the active longwall. This support is typically installed in the immediate tailgate entry and crosscuts before it reaches third-stage loading, and, where practical, it may even be installed at the time of development. Commonly used materials include wooden cribs (4-point or 9-point), cans, steel props, and pumpable cribs.

The alternative of right-angle intersection of crosscuts to main entries versus inclined is a balance of considerations between the convenience of access afforded by inclined intersections and the propensity of acute-angled corners to deteriorate with consequent enlargement of the intersection sum-of-diagonals (SoD). Increasing SoD often correlates with decreased stability of intersections. Floor stability and horizontal stress direction can influence the optimal intersection design.

The result of entry spacing and crosscut spacing is pillar size. The correct selection of pillar size for longwall gate roads is an involved discussion, beyond the scope of this chapter. In general, bigger pillars are more desirable from a stability perspective, but the unrecoverable reserves lost to gate road pillars, the increased development footage, and prolonged development time is not desirable. Long pillars are favorable to gate road development, but wider pillars are not. This is because development along panel length is useful to the purpose of completing panel development, but distance spent on crosscuts is not. Access to the longwall face for heavy maintenance is enhanced by shorter crosscut spacing.

Face Length and Panel Length

The choice of longwall face length is a balance of the initial capital cost committed to acquire longwall equipment versus the benefits of improved productivity, production cost savings, and additional reserve recovery for a wider longwall face. The decision is also limited by the capabilities of existing equipment, although capabilities have steadily improved over time. In subsidence-sensitive areas, wider faces can cause mine plans to be offset further from sensitive surface structures and sterilize additional reserves in the process, a cost weighed against recognized benefits.

As the industry-wide dedication to zero harm redefines acceptable hazards to ever diminishing severity and frequency, a conflicting prospect emerges as mining conditions tend to become increasingly adverse and present increased hazards. The cumulative result is an increased amount, and cost of development footage required to sustain longwall operations. Consequently, increased longwall face length is attractive. For most site-specific circumstances, an optimum longwall face length can be defined. Often there is a broad optimum in net present value terms—between 300 m of installed equipment length and up to perhaps 475 m in other cases. Present technology allows face length up to approximately 500 m with high productivity. Common face lengths range from 250 to 425 m. Achieving maximum lengths implies the use of the largest AFC chains and highest-rated electric motors and AFC gearboxes available.

Longwall panel length is an issue constrained by

- Ventilation system limitations,
- Timing considerations to avoid production outages,
- Longwall equipment longevity,
- Property constraints, and
- Reserve extent.

At some point, excessive ventilation pressure losses and insufficient air quantities dictate a practical limit to the length of a gate road development or may constrain longwall operation. Alternatively, the time required to complete a long development may compare unfavorably with the rate at which an active longwall is retreating. Yet another consideration is whether the longwall equipment can retain the required availability levels as it wears through continued service, although durability of the constituent equipment elements of the longwall has been improving through time. It is not unreasonable to expect shields, AFC drives, and frames to serve through the longest panels. AFC sprockets can be reversed or replaced during planned

maintenance intervals, as can chains, flights, and chain connectors. Shearing machines have longevity on par with the longest panels (highest tonnages) but can also be repaired as subcomponents, or a replacement shearing machine can be implemented during mining of a panel more readily than undertaking a complete longwall move (panel transfer). With this, contemporary longwall panels range from 1,850 to 4,600 m in length, with contained panel tonnages up to 11 million metric tons of coal.

Thin Seams

Most of the discussion so far has been focused on the most common high-productivity longwall variation: single-lift longwall in the 1.75- to 3.75-m extraction height range. However, thin ore deposits, typically with higher value, such as coking coals, are of interest. Thin seams are also a topic where they overlay other coal seams but must be extracted first to prevent their sterilization by undermining. Historically, thin coal seams were extracted with low-productivity shearing machines and longwall plow systems. Low-seam shearing machines of the past are hopelessly obsolete compared to current expectations. Periodic attempts are made to make low-seam shearers practical, as a number of mining projects worldwide reside at the edge of viability and would be successful if only better productivity were available. Shearers in low seams are constrained by factors such as

- Motor size (diameter and power),
- Vane depth of drums and loading performance,
- Clearance (shearer tunnel and ranging arm),
- Length and height limits (traversing undulations), and
- Operator ability to travel at tram speed of the shearer.

While efforts continue to solve the low-seam shearer issues, progress has been made in the modernization of longwall plow systems. Figure 13.8-9 shows a longwall plow. Instead of cutting the coal with a shearer, the coal is cut by a plow body captivated on the AFC and drawn from gate to gate on a dedicated chain driven by motors on each face end. Since the plow cuts only a fraction of the web of a shearing machine, normally 100 to 140 mm but up to 250 mm on the highest-capacity installations, multiple transits of the face are required to achieve equivalent production to one pass with a shearer. In contrast, the plow speed may be more than 10 times that of typical low-seam shearers, so plows offer attractive potential in deposits too low for shearers, provided that conditions are favorable (Gluckauf GmbH 1985).

Favorable conditions for a plow-type longwall include

- Strong, continuous roof and floor rock;
- Ore that plows readily and parts cleanly from roof and floor;
- Ore horizon with little thickness variation and limited undulations; and
- Ore free of intrusions, faults, or dikes.

Roof falls in the tailgate or on the face can be serious obstacles to a plow. Replacement of a significant section of the extracted horizon with sandstone through faulting or washout can be equally problematic.

The history of plow-type longwalls is extensive in Europe, where almost every conceivable condition has been confronted by plowing, but not always to successful outcomes in modern terms. The seam conditions that make plow application attractive in a modern context are limited compared to the totality of potential low-seam reserves worldwide. At present, only a few plow-type longwalls compete with shearer-based longwalls for the same markets.

Thick Seams

Unlike thin seams, thick-seam longwall has great potential worldwide. Single-pass longwall designs up to 7.25 m high have been proposed with installations more than 6.5 m high in service. A variety of issues require adaptation of the designs of these high installations, including

- Shearer steering into/out of the face,
- Structural integrity of AFC to bear heavy shearers,
- Face operator travelways and safety,
- Slab development or persistence,
- Face spalling ahead of the shield tips,
- Shield capacity and resulting weight, and
- Potential worst-case AFC starting capability.

The production history of many of these installations bears testimony to the success of designers and mine operators in overcoming the numerous challenges arising from thick-seam operation. At any period of time, some of these high faces appear in the ranks of the world's most productive longwalls.

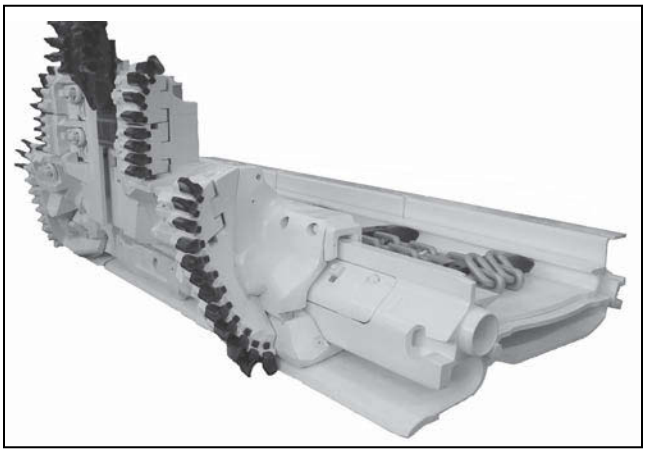
Interest is intensifying in longwall extraction of even thicker seams than 7.25 m, but there is an accompanying recognition that single-pass longwall is not the solution. To extract very thick coal seams, the longwall top coal caving (LTCC) technique is being developed. Two major variations of the LTCC method exist. In one, the face cross section is much like a conventional shearer-based system with a single AFC. An original pass is made as customary, at a convenient height, and then a special purpose caving chute integrated into the shield canopy is lowered so that material caving from above the shield is channeled into the AFC. When product quality or caving conditions dictate, the chute is retracted, and successive chutes are opened along the face. The process is repeated until the majority of the available product has been drawn. At this point, additional undercutting is conducted with the shearer in preparation for successive drawing of caved material.

Alternatively, another technique of LTCC uses an AFC, both ahead of the shields as expected but also behind them under a powered flipper used to allow or preclude caved coal introduction onto the rear AFC. Figure 13.8-10 shows a typical installation in cross section.

Potential exists for more new LTCC installations worldwide than the total number of modern high-productivity longwalls currently in service in North America. Today, LTCC installations exist in China and Eastern Europe with considerable expansion of the technique possible there, as well as significant prospects for introduction to Australia and possibly even the Americas. The LTCC technique could require adaptation to conform to statutory requirements in countries where the technique has not previously been practiced.

Multiseam Longwall

On occasion thick seams are extracted by single-lift longwall operations conducted in a coordinated sequence, with the upper longwall progressing ahead of the lower longwall in an interlocked sequence. Though this method has examples in the field, coordinated operation of independent longwalls can be difficult. Thin interburden is more problematic than thicker interburden, as are joints or fractures that transect the interval between the seams. Thin or low-shear-strength interburden, as well as jointed interburden, can transmit stress between



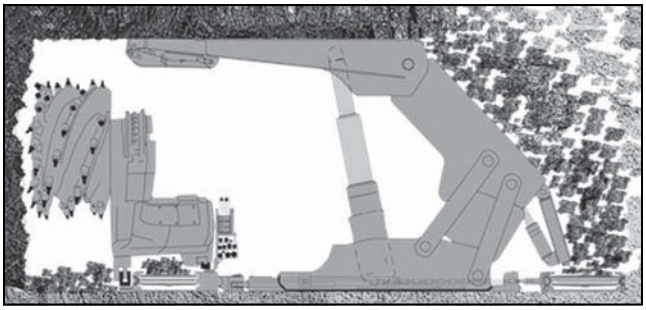


Figure 13.8-9 Longwall plow

Courtesy of Joy Mining Machinery.

Figure 13.8-10 Top coal caving with rear AFC

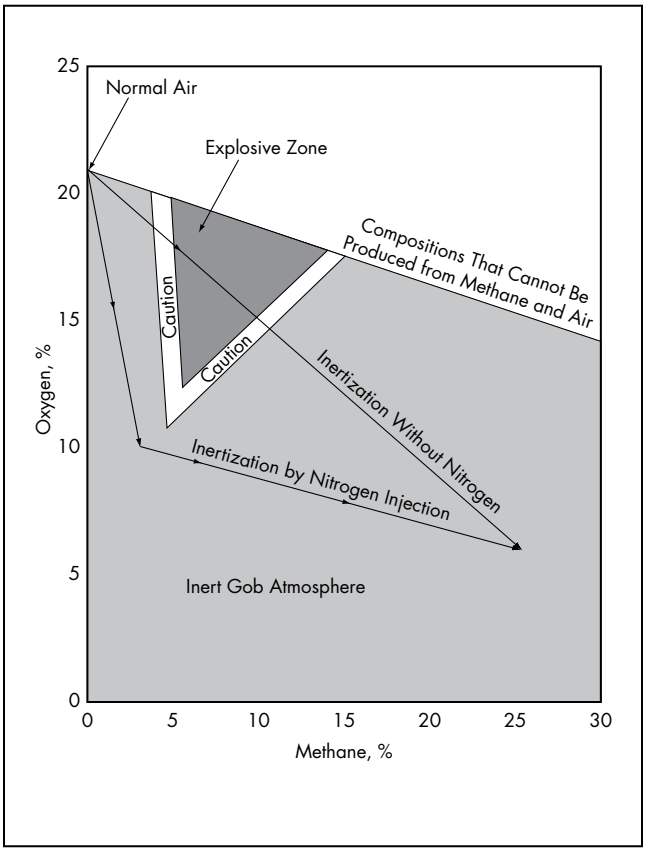

Figure 13.8-11 Coward's triangle

mining horizons more directly than horizons separated by even a modest thickness of strong, stiff interburden. High stresses are often transmitted from one horizon to another where strong structures surrounded by high-extraction workings in one horizon are approached by workings in the other horizon. In general, multiseam operations are more focused on extraction of independent seams at appreciably separated intervals of interburden and time. Often the earlier workings are not executed with anticipation of modern longwall mining in the future, thus making mine planning an exercise in mitigating interseam interactions.

Longwall Ventilation

Ventilation of longwall mining systems seems to exhibit nearly endless variety in the exact details of worldwide plans (AusIMM 1986; Kennedy 1999). Taken at a broader level, longwall ventilation falls into two general categories with very different mechanisms (MSHA 1996). To introduce these principles, some basic attributes of methane and air mixtures should be clearly understood. Figure 13.8-11 shows Coward's triangle (Coward and Jones 1952). Other representations of the explosion hazard are popular in various locations around the world, but the chemistry and physics of the matter are universal. Thus, other representations describe the same physical behavior.

Two principal regions are represented in Figure 13.8-11. The upper portion of the figure describes compositions that cannot be formed from methane and air and is therefore irrelevant. Below these naturally impossible compositions of methane and air is the region of naturally possible mixtures. These possible mixtures include two major subdivisions: inert mixtures and explosive compositions. The inert mixtures will not explode if exposed to a potential ignition source and occur as fuel-lean or fuel-rich compositions with respect to the explosible compositions. The explosible compositions exist within Coward's triangle shown in the approximately 5%–15% methane range and approximately 12%–21% oxygen range. The zone depicted around the triangle is an arbitrary safety margin. This physical behavior of methane and air mixtures being an absolute principal, two approaches to avoid the explosion hazard exist. One is to provide fresh air to dilute methane to a fuel-lean state. If such a state can be maintained without fail, it renders an acceptably safe condition. Paramount to this strategy is that the fuel-lean (oxygen-rich) atmosphere cannot transition from a respirable state, required where people work and travel, to a fuel-rich (oxygen-deficient) state, which is likely to occur in the unventilated gob. Where the respirable mine atmosphere transitions to an unventilated gob atmosphere, particularly after mine workings are sealed, it becomes impossible to guarantee that the reducing oxygen level and increasing methane level will not cross through the region of explosible compositions without active intervention. This case is described by the upper trajectory line in Figure 13.8-11. If even a small energy source above the intrinsic safety threshold is available to ignite the explosive composition, a violent event will result in proportion to the volume of gas mixture ignited (SIMTARS 2001). If coal dust becomes airborne secondary to a typical methane explosion, a much more energetic and violent event can arise (Burrows 1989). This mechanism has repeated itself many times worldwide, often with disastrous outcomes. Application of incombustible dust (rock dust or stone dust) to areas where

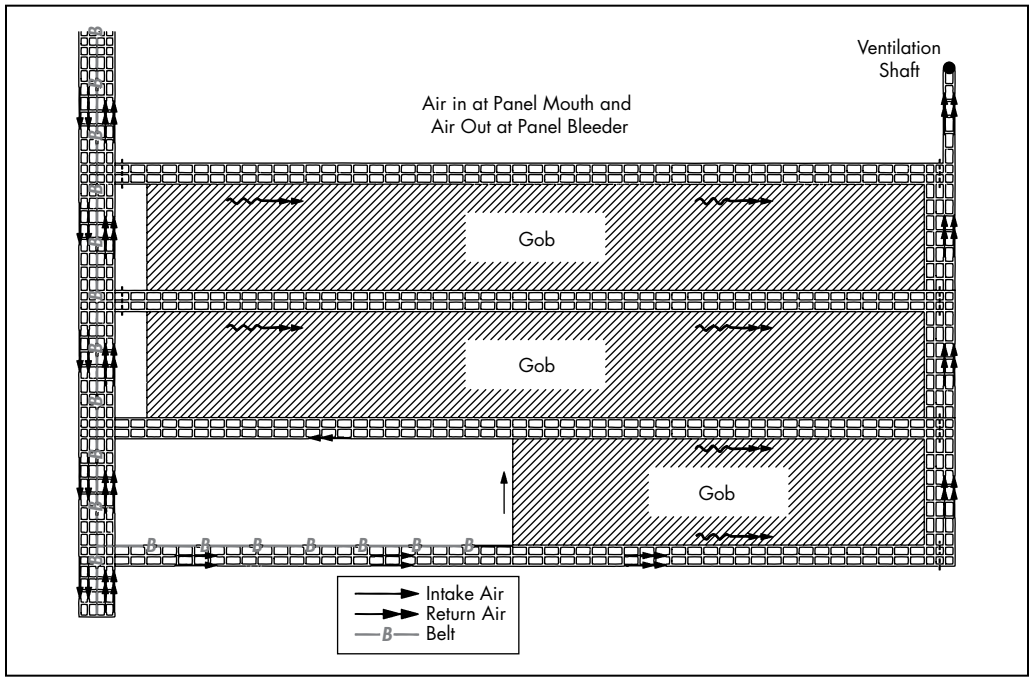

Figure 13.8-12 Typical flow-through bleeder system

coal dust can accumulate is effective in mitigating this dust explosibility hazard.

An alternative mitigation strategy for the explosion hazard involves the deliberate exclusion of oxygen from gob atmospheres, followed with forced inertization if necessary to depress oxygen levels below those where an explosion hazard can exist, regardless of methane concentration. This is represented by the lower trajectory line in Figure 13.8-11, which is actively controlled by inert gas injection and never crosses the region of explosion hazard, Coward's triangle. Periodic atmospheric monitoring, followed by application of the inertization process as necessary, can prevent explosible methane–oxygen compositions from being created by already inert atmospheres where introduction of new oxygen is possible.

With this in mind, the two major strategies of longwall ventilation are bleeder and bleederless ventilation systems. A conceptual flow-through bleeder longwall ventilation system is shown in Figure 13.8-12.

In this system, fresh (intake) air is supplied through the headgate entries and splits at the headgate to ventilate the longwall face. An adequate volume is allowed to flow behind (inby) the face at the headgate to ventilate the perimeter of the gob. Along the face and at the tailgate, air is allowed to "bleed" into the gob and tailgate to ventilate the methane to fuel-lean levels. This is the most common ventilation system used in the United States. It is notable that because atmospheric compositions are uncertain where they cannot be monitored and controlled in the bleeder-ventilated gob inby the longwall and in the adjacent abandoned gobs, any potentially persistent ignition source such as spontaneous combustion or intermittent source of ignition energy such as lightning is reason for concern.

The major alternative to bleeder ventilation of longwalls is bleederless ventilation. The bleederless longwall ventilation system is depicted in Figure 13.8-13.

The notable differences between the bleederless and bleeder ventilation systems are that in the bleederless system seals are built in headgate crosscuts immediately inby the face in order to progressively seal the gob and exclude oxygen as the longwall retreats. If concerns exist about atmospheric compositions in the gob or if oxygen invasion could stimulate spontaneous combustion, the added feature of forced inertization, as discussed previously, can be an effective risk-mitigation strategy. Gases such as nitrogen, CO_2, or even oxygen-depleted air can be used for safely inertizing mine atmospheres. The exhaust gas from combustion processes, such as gas turbine engines, can potentially be a source of oxygen-depleted gas mixtures for inertization.

To prevent oxygen inflow into sensitive gobs, pressure balancing is often applied to minimize pressure differentials across seal lines and minimize introduction of new oxygen to a gob. An alternative technique is the use of *balance chambers*, as depicted in Figure 13.8-14. In this method an initial seal is built to separate the atmospheres, and then another seal is built outby the initial seal, becoming primary. Inertization gas delivery pipes penetrate both seals to allow inert gas delivery to the sealed area and the space between the seals. If the seals have reasonable integrity, the space between the seals can be elevated to a low positive pressure, and the small leakage volume that occurs is either into the gob, the mine airway, or both. The net effect is to prevent oxygen ingress into the sealed area at low total inert gas expenditure. Sudden change in inertization gas consumption can be an early indication of deterioration in seal performance.

A valuable tool to monitor the composition of mine atmospheres in critical areas is a *tube-bundle* system. With this equipment, atmospheric samples are drawn from critical locations underground through dedicated individual tubes to analysis equipment located at the mine surface. This allows sampling of areas where electrical sensors might be prohibited

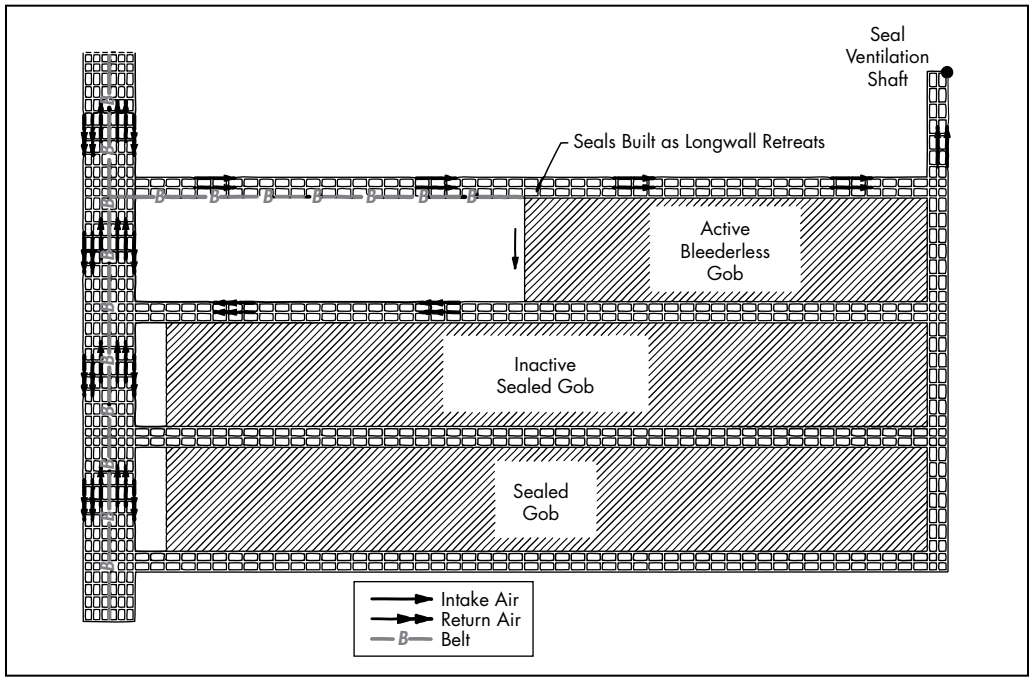

Figure 13.8-13 Bleederless longwall ventilation

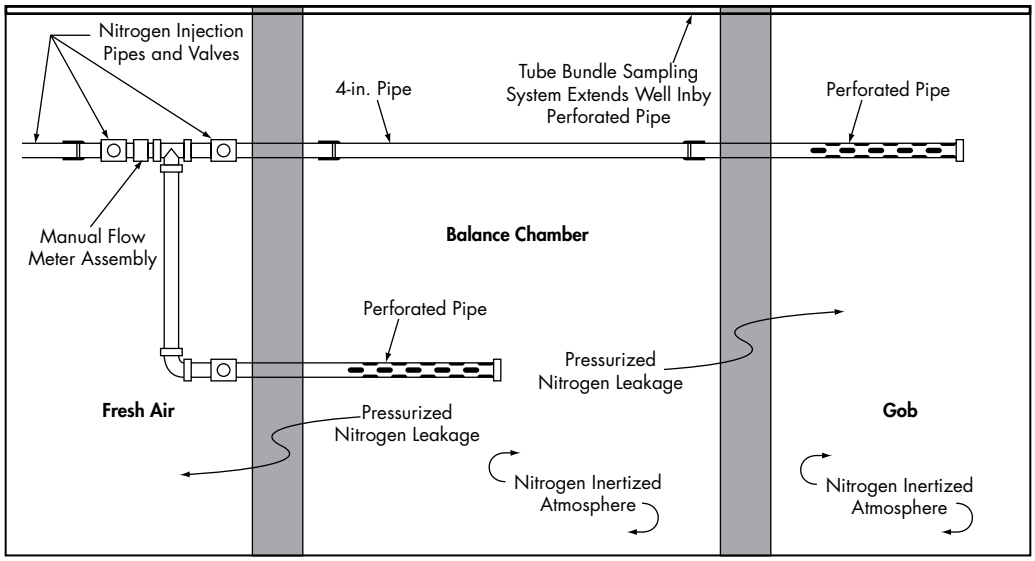

Figure 13.8-14 Inertized balance chamber

and sampling continuation in the event that electrical power is removed, as is the case in many mine emergencies.

An addition to the controls inherent in either of the ventilation systems described, gob ventilation boreholes (GVBs) can be used to assist the ventilation system by extracting gob atmosphere, predominantly methane, before it enters the ventilation system. GVBs are often centrally located in a longwall panel when the intention is to intercept methane evolved from broken strata before it enters a bleeder ventilation system. These holes, drilled from the surface in advance of mining, are often spaced at larger intervals than GVBs intended to control expansion volumes in a bleederless ventilation system. The location of GVBs is typically along the periphery of a panel, where void space is connected to workings at seam level, when the intention is to control barometric expansion volumes, as in bleederless ventilation systems.

Diurnal barometric pressure variation occurs daily, with the barometer falling as the atmosphere warms with duration and intensity of solar exposure and rises as night falls when the atmosphere cools and air density increases. Random barometric pressure variations are related to weather systems. The actual barometric pressure is a function of both effects and can be predicted for a surface location with good overall accuracy. Operation of GVBs in response to barometric pressure variation,

alternating with inert gas injection, can control evolved methane and prevent oxygen invasion into progressively sealed gobs, as in bleederless systems, or other sealed areas.

Although GVBs are typically drilled vertically from the surface, an alternative method applies medium radius drilling technology to postmining methane drainage. The wells start with a vertical collar followed by a build section where the well is steered to a horizontal position. The horizontal lateral is located in a stable horizon above the longwall panel. Holes up to 1.6 km in length, producing approximately 1 m^3/s of methane, have been achieved.

An alternative to GVBs drilled from the surface is an array of cross-measure boreholes drilled at upward inclination from the seam horizon. Such cross-measure holes can drain methane prior to mining and be used later to a similar effect as GVBs when caving behind the retreating longwall opens a communication between the holes and the larger gob. Gas captured by the holes can be collected by an underground piping system and directed to a borehole to the surface without entering the mine ventilation system.

Horizontal boreholes, originating in-seam or turning into the seam from vertical wells to the surface, can be progressed in-seam for more than 1 km to drain methane in advance of mining. These holes have proven to be highly effective for methane drainage but must be planned carefully, as they can later present hazards that must be mitigated before mining progresses through them.

CONTEMPORARY ISSUES

Improving the health and safety of miners by reducing their exposure to hazards has been a major motivation in the steady progress of mining mechanization. Longwall mining as it exists today is the product of this ceaseless effort. Greater productivity and resource recovery are realized, while the incidence of injuries and accidents continues to decline as a trend. Few would dispute that longwall mining is, by far, the safest and most efficient underground soft-rock mining method.

Although many concerns have been addressed with great success, others have persisted. Coal workers' pneumoconiosis, more commonly called "black lung," is a chronic disease which investigators have correlated to respirable dust exposure in the coal industry. Black lung is often debilitating in its advanced phase and may lead to death. Most coal-producing countries worldwide acknowledge this hazard and have occupational health limits for respirable coal dust exposure intended to prevent workers from contracting the disease. Not all dust is deemed hazardous but only the submicrometer (<10-μm size particles) fraction of dust is believed to contribute to black lung. Because longwall mining results in large production, it is not surprising that increased amounts of dust can also result, with respirable dust being a fraction of the total.

Depending on the regulatory strategy applied, this can lead to different conclusions. One strategy is based on environmental exposure. This assumes that a worker will not benefit from any personal protective equipment and that safety is produced only by maintaining environmental levels below disease thresholds. This strategy does not give innovation or technology an opportunity to contribute solutions unless it impacts the environmental exposure as opposed to the respiratory exposure. However, personal protective equipment such as airstream helmets offers demonstrated effectiveness, and automation technology has the potential to remove workers from most dust exposure. Personal dust exposure management is now more feasible than ever, with the demonstration and introduction of personal dust monitors. Seemingly, the optimum solution to the problem of dust exposure would apply the best available technologies, crediting the benefits in realistic terms, to create incentive for continued progress in longwall technology.

Another issue of modern underground mining is related to surface subsidence. The most damaging aspect of mining-induced subsidence is the zone that connects undisturbed surface with areas subjected to near maximum vertical displacement. This boundary varies from a few meters to a few hundred meters wide and commonly wraps around the perimeter of the subsided area. The condition is exaggerated when subsidence takes place years after active mining and may continue for a protracted period of time. It is also worsened when small land areas are subsided, a few hectares per instance, leading to a greater proportion of subsided land area being subjected to the most damaging end outcome (Kratzsch 1983; SAIMM 1982). These situations, often acting in combination, make compensation for damage to surface assets difficult, because the mine operators may no longer have a corporate presence or the ability to pay for reparations years or even decades after the fact (Peng 1992).

The development of longwall mining has brought relief to these concerns. As modern longwall panels have gotten wider and longer, the proportion of subsided land area permanently subjected to the most damaging boundary conditions has decreased. Also, unlike the subsidence of smaller individual areas, the subsidence develops to its maximum level in close alignment with predictions and generally does so in a period of weeks to months after active mining by longwall methods. Thus, all stakeholders are in a better position, both in terms of damage and timing, to make such reparations as may be appropriate.

Longwall mining has been extensively applied to urban and suburban areas in Germany, Poland, and the United Kingdom to mine under a tremendous variety of structures, including public buildings and residences, industrial facilities, roads, bridges, railroads, pipelines, and power lines, to successful outcomes. Longwall mining has also been used worldwide to mine under rivers, lakes, and oceans successfully. With the worldwide knowledge base for mitigation of subsidence damage to surface structures, many alternatives can often be applied to minimize damage to surface assets or repair them effectively.

As longwall mining transitions from rural to suburban areas in the United States and Australia, it has vocal critics. The arguments put forward derive from many origins but generally do not suggest a better method to extract the resource but rather oppose the extraction all together or dispute the value of the damages that might be created or the ability to bring about acceptable reparations.

CONCLUSION

When longwall systems are properly selected and operated, the results can be spectacular and sustainable. These installations make longwall mining look easy. In reality, successful selection and operation of longwall systems are based on attention to detail and a commitment to continuous improvement. These pursuits require much effort and rely on a capable staff as much as the equipment composing a longwall mining system.

Success also depends on a close collaboration between mine operators and technology suppliers, often as a strategic

alliance. Both parties must begin with the end goal in mind, which has to be attainment of safe production and profitability for both partners. Mine operators and technology suppliers must recognize their stake in the shortfalls as much as the successes, constantly being prepared to contribute investments in time and money in pursuit of continuous improvement. This is especially important in consideration of the long-term nature of the relationship created by long equipment service life and large capital investments.

Continuous improvement is necessary to meet the evolving expectations of stakeholders to the overall production process. These stakeholders expect the result of zero harm as it applies to health and safety of employees, local communities, and the environment. They also expect improving productivity and diminishing costs, even in consideration of future mining conditions that typically are more adverse than past or present conditions.

For all of these reasons, success at longwall mining is exclusively a result of organizations with aligned purpose, detailed planning, and controlled execution leading to sustainable results on the part of a wide diversity of involved stakeholders.

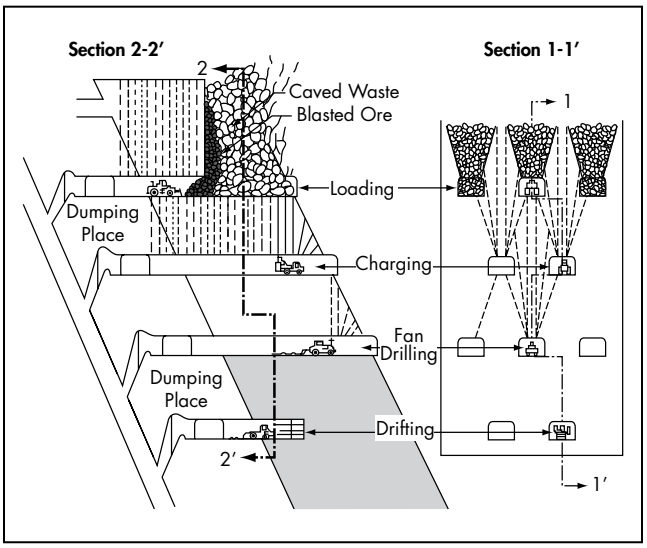
CHAPTER 13.9



Sublevel Caving

Geoff Dunstan and Gavin Power

Sublevel caving is a top-down mining method allowing earlier production than sublevel stoping with less upfront development than traditional block caving. In large-scale operations it has the potential to be a *factory method* (meaning highly repetitive) with the cost and capacity benefits associated with high production, moderate development requirements, and maximum use of automated equipment (Bull and Page 2000). In smaller mines it can be used as a selective method with lower production rates, where the capacity benefits are less evident. Horizontal slices of in-situ ore are progressively blasted and extracted, with blasted ore and caved rock filling the void created by ore extraction (Figure 13.9-1). Dilution can be managed and minimized by disciplined draw control. As this process progresses, caving propagates upward to create surface subsidence.

Originally, sublevel caving was used in weak ground that would collapse when the timber supports were removed. After a supported drift was pushed across the ore body from an access or perimeter drift, the supports would be individually removed in a retreating fashion. As each support was removed, the ore would cave—thus the name sublevel cave—and be slushed out to the perimeter drift. The next support would not be removed until the amount of diluting material became excessive. Overall, the method was slow and combined poor ore recovery with high dilution.

Later applications of the method saw it applied in relatively competent ore bodies with weak hanging walls in order to facilitate the caving process and avoid the creation of large voids. The stronger ground required drill-and-blast to take the role of the support removal, so in this version of the method it is no longer the ore that caves but the host rock above and immediately adjacent to the ore. With the introduction of drill-and-blast, sublevel caving could be utilized in ore bodies with footprints too small for natural cave development and/or dipping geometry unfavorable for block caving. In recent times, the method has been applied to ore bodies with strong hanging walls where cave assistance techniques have been used as required.

Figure 13.9-1 Schematic of sublevel caving mining

Current applications of the method are accessed by decline(s) and have sublevels established on approximately 20- to 35-m vertical intervals, far greater than the early applications of the method, due largely to advances in drilling and blasting technologies. A perimeter drift is driven along (transverse layout) or perpendicular (longitudinal layout) to the strike of the ore body and is generally offset approximately 20 m from the ore–waste contact. Some mines develop the perimeter drift in ore and recover it after production is completed from the drifts. The perimeter drift is developed to access the production drifts for ore transportation, services, and ventilation. The production drifts are spaced between 12 and 30 m on horizontal centers. To enable optimal coverage for drilling and to allow for the downward flow of caved material, they are staggered between the levels (Figure 13.9-2).

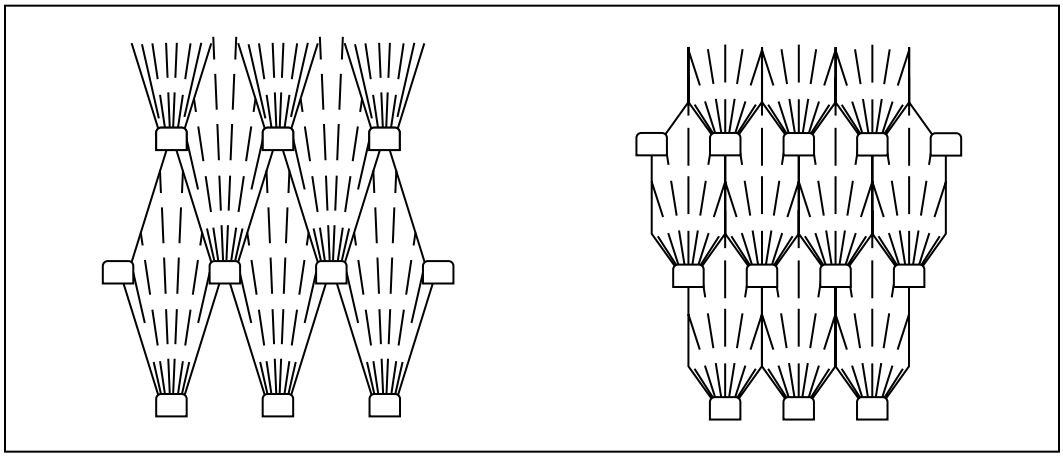

Figure 13.9-2 Sectional view of sublevel caving ring options

Over the years, the ratio of development-to-production ore has increased from approximately 1:3 to as high as 1:10.

The production ore extraction process commences by placing either a slot drift on the far ore–waste contact or placing individual slot raises at the end of each production drift. The slot drift will have a slot raise at one end and a series of parallel rings, generally on 2- to 3-m burden, the width of drift reaching up to the level above. Once the slot has been opened, to create adequate expansion room for the first production rings, some *slashing* rings will start the production rings in the drifts until the production rings reach full height. The production rings will usually be angled forward by 10° to 20° from vertical to assist the breakage and flow of the ore in the confined blasting environment and to help maintain geotechnical stability at the brow. The production ring burden is generally between 2 and 3 m. The production rings drill up through the pillar between the production drifts on the level above, as shown in Figure 13.9-2.

The layout of the method requires secondary ventilation to be forced into the production drifts throughout both the development and production phases of the level. Load-haul-dump (LHD) machines are used to extract the ore from the fired rings and transport it back to either stockpiles or ore-passes located on the perimeter drift.

As the initial level is opened, only the swell material from the blast (approximately 40%) is excavated, because caving will likely not be initiated until production on the level is well advanced. The extraction ratio of ore increases to a nominal value of approximately 80% to 100% over the subsequent two or three levels. The reduction in the early draw rates is designed to minimize the likelihood of air blast until the overlying cap rock and/or hanging wall starts to break up and flow. In addition, the reduced draw builds up a blanket of ore above the active drifts, which can assist in minimizing the impacts of dilution in a blind cave, as well as protecting the drifts when the sublevel caving is commenced directly below an open pit.

Operational sublevel caving practice varies widely, and consequently tonnage and mineral recoveries are also variable from operation to operation. Overall tonnage extraction rates for large-scale sublevel caving mines will be approximately 80% to 120% of the blasted tonnage for approximately 65% to 95% of the total ore-body mineral content. Of the rock drawn from each fired ring, approximately 15% to 25% will be dilution. More dilution comes at the end of each individual ring's life, and varying practices mean that dilution results also vary from site to site (Power and Just 2008).

When extracting the ore body, strict operational rules are required to ensure the method's success. Only after the upper level has been retreated a safe distance, somewhere between one and two times the sublevel interval, can the level below be commenced. Within the level, the production rings need to be brought back in a planned sequence (managing the lead–lag between adjacent production drifts) to minimize the impact of stress and explosive damage on neighboring drifts.

APPLICATION OF SUBLEVEL CAVING

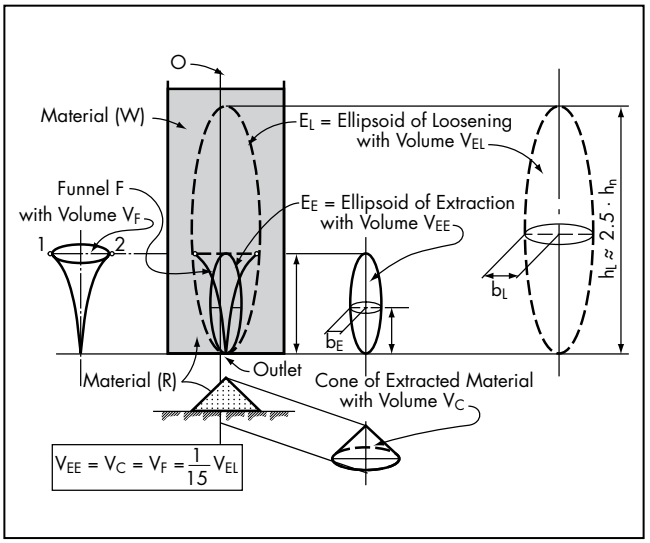
The suitable ore-body characteristics that lead to the successful implementation of the sublevel caving method include

- Cavable overlying host rock,
- Relatively large ore-body footprint or a relatively weak hanging wall to initiate and propagate caving,
- Steeply dipping and relatively uniform ore body,
- Reasonably uniform grade distribution,
- Disseminated ore body with a low-grade zone around the sublevel caving production area to minimize the impact of waste dilution,
- Competent ore body to minimize the excavation support requirements and improve drift availability to enable continuous production, and
- Visually different ore and waste properties.

Although sublevel caving can be successfully applied to ore bodies missing some of these characteristics, any such omissions generally lead to increased operational complexity (Power and Just 2008).

GRAVITY FLOW

The sublevel caving method relies on the gravity flow process to get the ore to the drawpoint. As a result, gravity flow has been a focus of sublevel caving research for many years.



Gravity flow in the sublevel caving environment is unique in a number of ways:

- The effects of blasting produce differential fragmentation within the ring, both vertically and laterally.
- Draw occurs from drawpoints on multiple levels, laterally offset, resulting in multiple stages of flow.

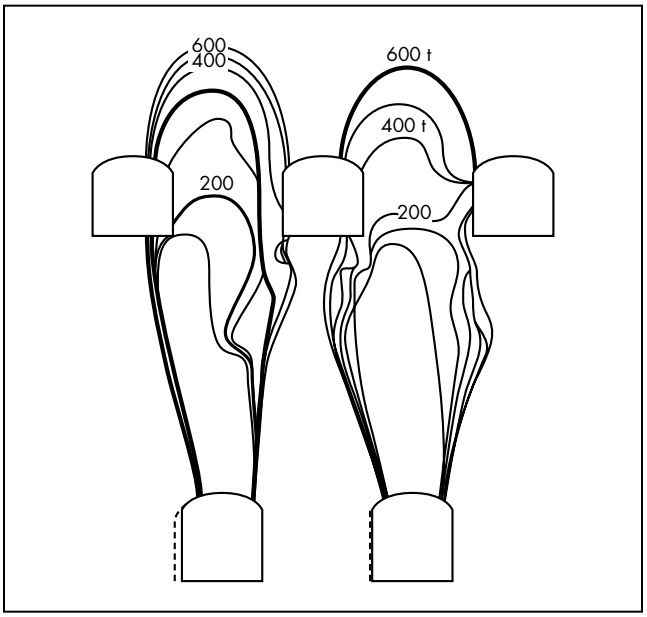
Source: Kvapil 1992.

Figure 13.9-4 Example of idealistic flow analysis derived from analysis of physical models

- Each individual ring is subject to unique factors, including geological structure, drill-and-blast inconsistencies, and differing draw patterns.

As in other fields of research, the gathering of information on flow has been a gradual process, with successive workers building on the data and theories of past workers. Early studies of gravity flow focused on small-scale, glass-fronted physical models and over time expanded to larger three-dimensional (3-D) models such as shown in Figure 13.9-3. These models involved the drawing of broken rock from geometrically scaled and well-controlled environments, so that the resulting movement and extraction zones could be studied in detail and accurately measured.

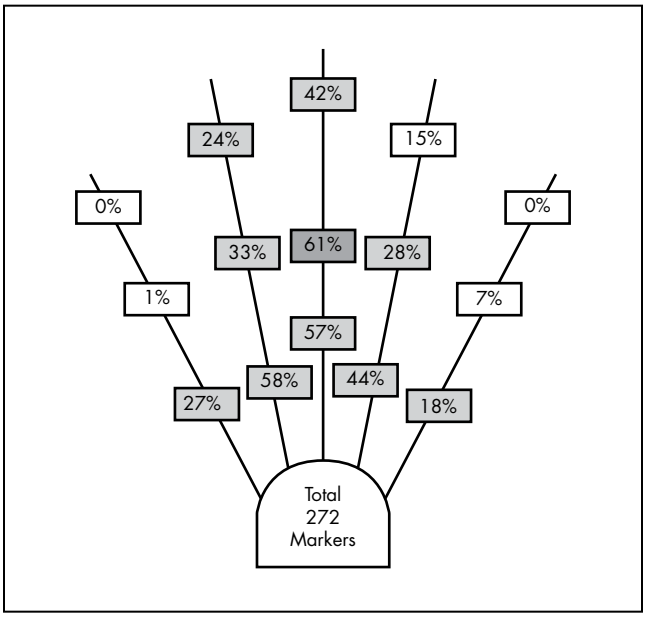
Research using these physical models resulted in the promulgation of influential theories and relatively precise mathematical formulas to describe concepts such as particle velocity profiles, the ellipsoid of loosening and of draw, and the relationship between these bodies (e.g., Figure 13.9-4). It was later determined from full-scale marker trials that the shapes of the flow and movement envelopes were not exactly elliptical (Janelid 1975); however, they are close enough for the ellipse to be used as a basic design concept in sublevel caves (Power 2004b).



In practice, these theoretical explanations of flow in bins and hoppers serve mainly to give a broad understanding of flow in a highly controlled environment. Taken in isolation, they comprise a highly idealized, single-level description of granular flow with only a general relationship to granular flow in real sublevel caving environments. However, results from these models were useful in guiding design of early sublevel caves and provided important insights into the mechanisms controlling flow. They also led to the development of some of the fundamental concepts underpinning the method, which are well established today (e.g., drawing drawpoints interactively and loading from side to side in drawpoints).

Although model studies provided a basic understanding of gravity flow mechanisms, full-scale field trials were needed to obtain flow data in operational sublevel caves. Marker trials involve the placement of markers (usually short lengths of steel piping or cable) into internal marker rings before the experimental production ring is blasted. These markers are collected as the ring is mucked, and the resulting data is analyzed to assess the flow patterns and ultimate recovery of the ring.

The earliest comprehensive trials were those carried out by Janelid at Grängesberg mine in Sweden (Janelid 1972). Janelid's marker trials showed gravity flow in the full-scale environment but only with reference to recovery from the level on which the rings were blasted. They were carried out on relatively small sublevel caving layouts (approximately 3-m-wide crosscuts on 7-m crosscut centers and 13-m sublevel heights). For the relatively small ring tonnages drawn, the trials showed high angles of draw and irregular draw patterns not quite elliptical in shape (Figure 13.9-5).



In recent times, marker trials have become more popular in response to significant changes in sublevel caving geometry, which are partly due to improvements in drilling and blasting technology. Figure 13.9-6 shows a comparison of changes in sublevel caving geometry at the Kiruna mine in Sweden between 1983 and 2008.

The Kiruna 2000 program of marker trials was also single-level trials, although they did not have the same density of markers as the Grängesberg trials and relied on visual identification of markers at the drawpoint for recovery of experiment information. This resulted in only about a third of the installed markers being recovered (Gustafsson 1998). A

diagram summarizing the results of these trials (Figure 13.9-7) indicates a total of 272 markers recovered and shows the percentage of markers recovered from various locations in the marker rings. This analysis indicates that most markers recovered were almost directly above the drawpoint. One important advantage of the Kiruna trials was that they gave an indication of recovery from greatly upsized sublevel caving rings, with crosscut widths, spacings, and sublevel heights all approximately double those used at Grängesberg.

The Kiruna marker trials showed that, although mining scale had dramatically increased because of improvements in equipment technology and a focus on cost reduction, granular flow properties had not changed, leaving large parts of the fired production rings unrecovered (if viewed only from a single-level perspective).

Marker trials carried out at the Ridgeway mine in New South Wales, Australia, were the first comprehensive multilevel marker trials concentrating on granular flow through an entire sublevel caving system (Power 2004a, 2004b). Carried out between 2002 and 2006, they involved more than 20,000 markers in more than 70 trial rings, with data on marker recovery collected up to six levels below the level on which the marker rings were fired. These trials involved the placement of markers in three planes of markers, evenly spaced within the burden of the production rings (nominally 0.65 m, 1.3 m, and 1.95 m from the next production ring to be fired) (Figure 13.9-8).

An important component of these trials was the confidence level gained from the systematic magnet-based marker recovery procedure, which removed some of the uncertainty associated with the need to visually identify markers at the drawpoint and allowed analysts to more confidently assess areas of recovery and nonrecovery in individual rings.

Analysis of data from these trials first introduced the concepts of primary, secondary, and tertiary recovery for the

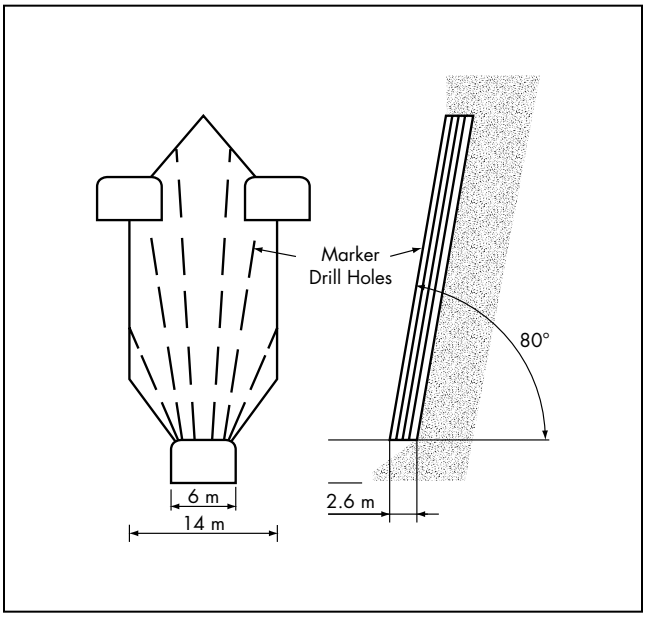

Figure 13.9-8 Layout of marker rings for Ridgeway marker trials. Drill holes in succeeding marker ring planes were offset to increase spatial coverage of markers. Markers were placed at 1-m intervals within marker drill holes.

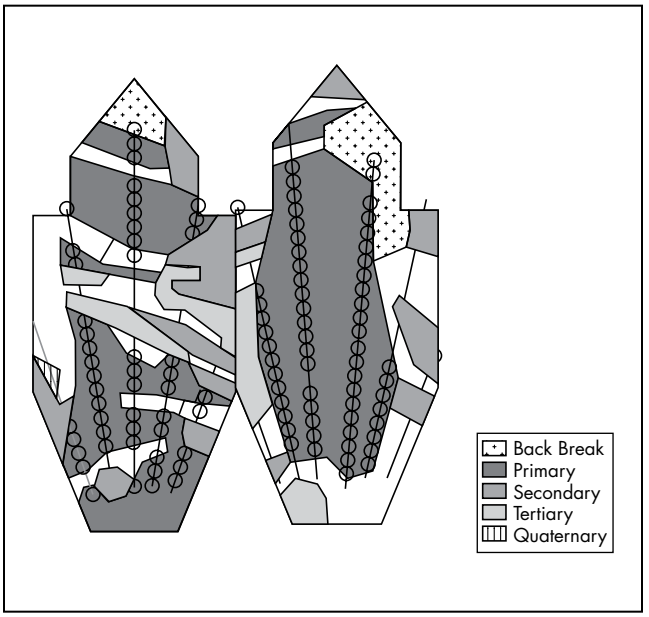

Figure 13.9-9 Marker trial results from Ridgeway showing typical width of draw for flow in adjacent crosscuts (indicating noninteraction between primary drawzones)

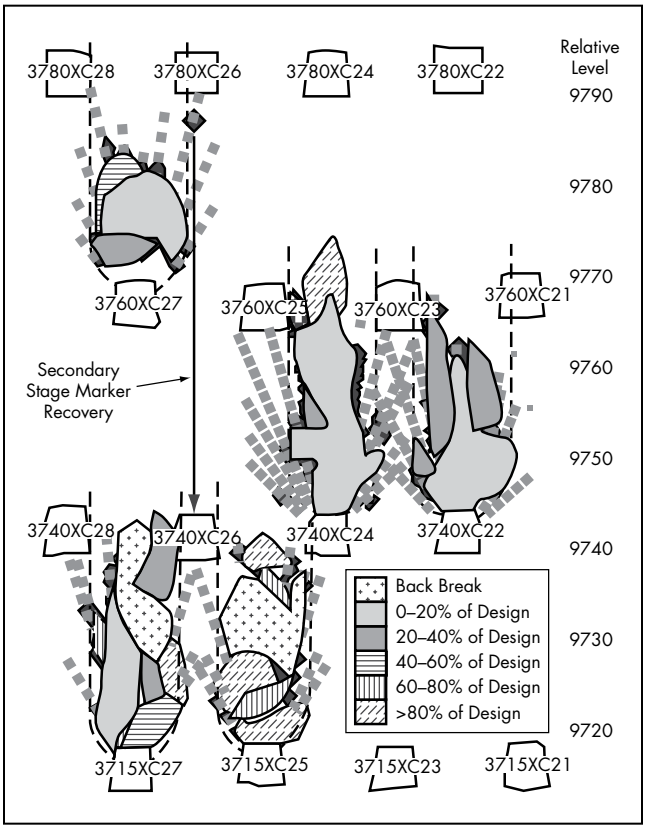
three main levels on which sublevel caving ore is recovered. *Primary recovery* is defined as ore reporting to the drawpoint on the level from which its sublevel caving ring was fired, whereas *secondary* and *tertiary* refer to ore that reports on successive levels below this. These trials also allowed testing of a number of theories that had gained traction in the absence of solid data and allowed other advances in understanding of granular flow in real sublevel caving environments.

Similar trials were later carried out at Perseverance mine in Western Australia (Hollins and Tucker 2004; Szwedzicki and Cooper 2007). These trials aimed to determine the precise time of marker arrival at drawpoints and therefore required manual collection of markers in order to determine exactly when, in the draw cycle, each marker appeared at the drawpoint. Although this made multilevel analysis and completion of a large, statistically significant trial program more difficult, important data largely comparable to previous field trial programs was collected.

More recently, research has led to the development of *smart* markers, which can transmit a radio frequency signal to receivers that record their extraction location and time (University of Queensland 2007).

The following sections discuss some of the new understanding that has been gained from full-scale marker trial programs carried out since 2000.



Width of Draw

Width of draw has consistently shown to be, on average, less than the width of the fired ring. The Ridgeway layout comprised 5–6-m-wide crosscuts on 14-m crosscut centers, as this mine was designed using a recovery rather than cost-reduction focus (Power and Just 2008). Here, a 6-m-wide drawpoint generally produced a primary recovery zone with a maximum width of between 8 m and 12 m. Therefore, despite the relatively close crosscut spacing, interaction between primary drawzones rarely occurred. Figure 13.9-9 illustrates this situation for sections taken through two adjacent crosscuts. All the different stages of recovery were recorded and are represented, and it is clear that the primary recovery zones do not interact.

Prior to the completion of these trials, a theory known as interactive draw (as proposed for sublevel caving) had been put forward (Bull and Page 2000) and influenced the design of some sublevel caving mines. This theory suggests that by drawing from adjacent sublevel caving crosscuts interactively or in close sequence, zones of low pressure can be created between the drawpoints, allowing the rock to flow at lower angles than in drawpoints that are drawn in isolation. Prior to this, physical modeling results had also been used to suggest that drawing from an interactive front, rather than in isolation, would decrease dilution ingress from the sides of the rings and reduce hang-ups (Janelid 1974).

In reality, interactive draw did not result in primary drawzones flowing to the full width of the ring and interaction with adjacent crosscuts (Power 2004a). Similar trials completed at Perseverance mine also indicated no evidence of interactive draw in any of the trial areas (Hollins and Tucker 2004). Summary results from these trials clearly show the episodic nature of flow from individual rings; those at relative narrow draw widths were similar to ones seen at Ridgeway (Figure 13.9-10).

Figure 13.9-5 also shows (albeit for reduced production tonnages) that recovery zones for rings spaced on 7–8-m centers at Grängesberg are not interacting, even though strict interactive draw controls were used in these experiments. Flow here was only allowed to develop to half the height seen at later mines (given the smaller sublevel spacing). Figure 13.9-7 also suggests no interaction between adjacent crosscuts at Kiruna, even though these results summarize the marker recovery results of all the trials completed in its program, rather than

Source: Hollins and Tucker 2004.

Figure 13.9-10 Summary of the Perseverance marker trial results

of an individual marker trial. This is not surprising given the relatively large crosscut spacing at Kiruna mine.

In practice, every mine will have a range of differing input conditions that will affect marker trial outcomes, added to which are the significant differences seen between trials at individual sites. Even so, the results on width of draw at different sites are relatively similar.

Depth of Draw

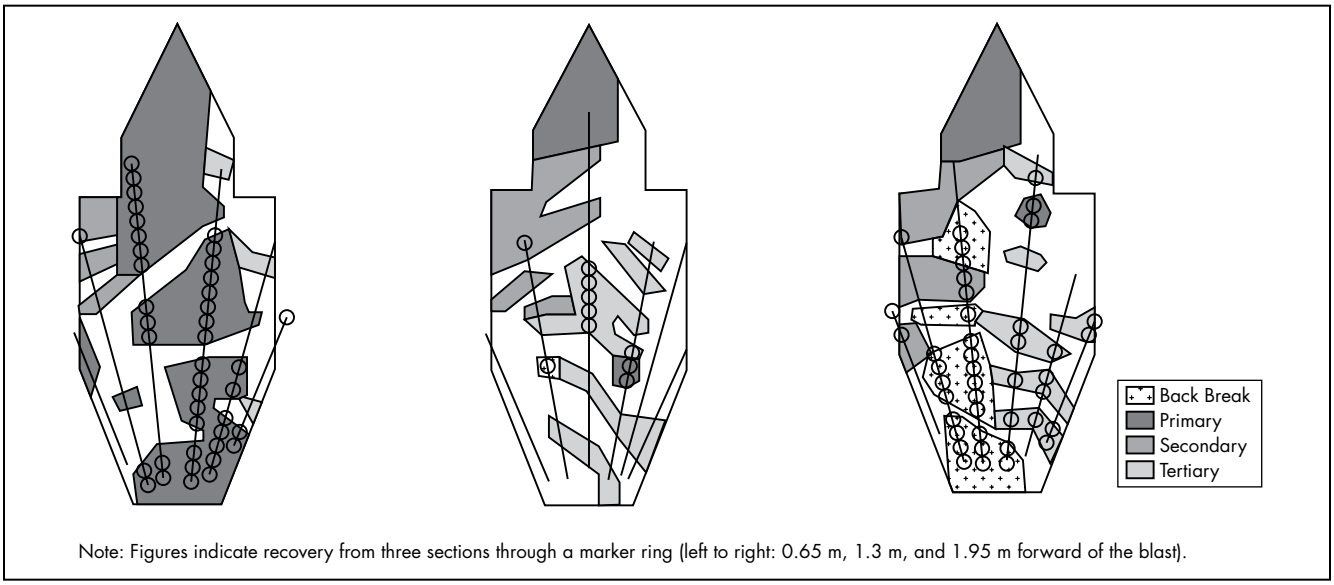
In approximately 20% of cases, draw at Ridgeway never extended to the full 2.6-m depth of the ring. In more than 50% of cases, the primary flow zone only reached full ring depth late in the draw cycle for a small percentage of the ring height. Figure 13.9-11 shows an example of the primary draw, which is both narrow and shallow.

There is some conjecture about the cause for shallow draw as seen at Ridgeway. Visual observations indicated that unrecovered rock at the back of the ring sometimes retained the original rock-mass texture (Figure 13.9-12). However, if a drawpoint opened up, the less mobile ore at the back of the ring often collapsed into the drawpoint. This indicates that the rock was being fractured but the fragments were not being effectively separated from one another. However when hang-ups occurred and the LHD was used to dig farther into the base of the ring, greater depth of draw was sometimes achieved, with corresponding higher recoveries.

The shallow draw at Ridgeway shows a variation from the argument that early dilution entry originates behind the ring (from the waste side of the ring). Like other mines (Gustafsson 1998; Hollins and Tucker 2004), Ridgeway commonly measures early entry of rock from outside the ring (at approximately 20% draw). However, this rock has been shown to originate from the level above the ring, due to flow piping preferentially up the solid face of the ring.

One of the assumptions underlying the sublevel caving method is that the entire ring is fractured effectively, compacting the waste ahead of it and allowing the ore to be drawn relatively undiluted from the drawpoint. Some, however, have shown that the space available to allow adequate swell (and particle disassociation) for all portions of modern sublevel caving rings is insufficient (Hustrulid 2000). The Ridgeway results may support this hypothesis, indicating that the rock at the back of the ring is not being mobilized because of the combination of lack of opportunity to swell and cushioning of the ore at the free face of the ring. It is also possible that differing modes of dilution entry are occurring at different mines, where different blasting and draw control practices are used. Marker trials allow the opportunity to learn more about the sources of dilution entry and for mine operators to refine drill-and-blast and draw control practice to postpone and reduce dilution entry.

Ore Recovery over Multiple Levels



Before completion of the Ridgeway marker trials, assumptions about levels of primary recovery were significantly higher than those actually measured. However, although a lower than expected primary recovery is achieved on average (approximately 50% for 120% ring tonnage extracted), much of the remaining ore is recovered by draw from levels below. Even with this low primary recovery percentage, Ridgeway's closely spaced drawpoints, favorable ore-body geometry, and tightly managed draw control enable it to recover a high proportion of the ore fired, with relatively low levels of dilution (Power and Just 2008).

This indicates the importance of viewing the sublevel caving system as a multiple-level system, rather than making design decisions based purely on recovery from the primary level alone. Figure 13.9-13 illustrates how ring recovery is spread over many levels at Ridgeway. Figure 13.9-14 indicates that an equation can be fitted to this data with a good fit.

It is this general sense of order within an apparently chaotic system that has enabled the development of a number of forecasting tools that can be used with reasonable accuracy in operational mines for estimation of recovery, development of draw control strategies, and optimization of recovery through the targeting of residual grade.

Back Break

Back break is a phenomenon that is difficult to simulate effectively in physical models but can be seen in many marker trials and generally in sublevel caving production drifts. It occurs when a ring blast breaks rock away from the next ring to be fired in the crosscut. This back break often occurs at the brow but can also be present along the full height of the production ring, depending on ground conditions. This was noted in marker trials carried out by Janelid at the Grängesberg mine (Janelid 1972) and has also been seen at Ridgeway (Power 2004a) and Perseverance (Hollins and Tucker 2004). Back break is still ore recovered on the primary level and thus can be included, from a grade forecasting perspective, with primary recovery. Its effect on blasting and flow, however, can be significant. If a blast

Note: Figures indicate recovery from three sections through a marker ring (left to right: 0.65 m, 1.3 m, and 1.95 m forward of the blast).

Figure 13.9-11 Example of shallow primary draw

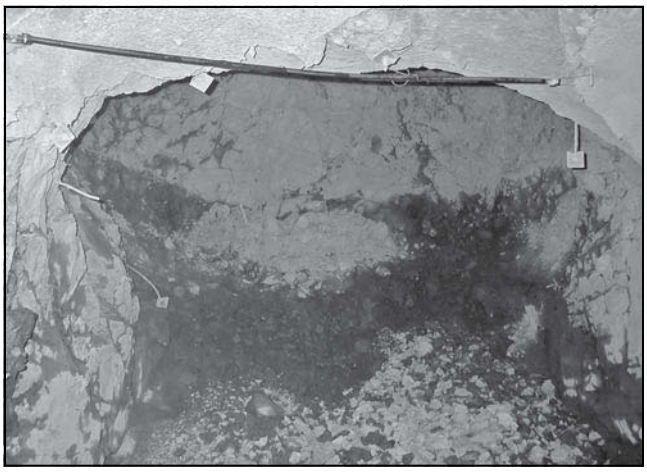


Figure 13.9-12 Intact rock-mass structure visible at the back of a ring in which shallow draw has occurred

produces high amounts of back break, rock flows through this broken area, effectively changing the brow position of the blasted ring and reducing the likelihood of drawing to the full ring depth (Figure 13.9-15).

Figure 13.9-16 shows an example of a ring that has suffered significant back break, indicating that back break from the previous ring has broken almost to the full burden of the next ring to be fired. It is probable that this back break influenced the performance of the blast ring and possibly recovery. In this example, back break extends to the base of the ring; however, primary flow still does not reach the central marker plane for the lower half of the ring. This indicates that, even when ore is likely to have been well fragmented due to a high relative powder factor, shallow flow can still occur.

Parts of a ring that have been damaged by the previous blast can be significantly thinner than the rest of the ring. They will be blasted with a greater effective power factor, causing the blast to behave differently than intended. Generally, the zone of greatest explosive concentration produces most back break. Because this is also the area of greatest explosive concentration in the next ring, this accentuates changes in the actual blasting powder factor distribution for this ring.

Chaotic and Variable Flow

Figure 13.9-16 shows how back break in one ring can affect blasting and flow performance of the next ring to be blasted. Because the blasting and flow behavior of the vast majority of sublevel caving rings cannot be practically measured, it is not known what effects are being generated to other rings. If it is accepted that performance in one ring will affect performance of rings around it, and that these events cannot be predicted, it follows that sublevel caving flow should be treated as a chaotic system. Some of the parameters producing significant variability in sublevel caving systems include

- Rock mass properties,
- Blast design,
- Ability of charging crew to implement blast design (blocked holes, etc.),
- Hole deviation,
- Blasting performance of rings around the current ring,
- Hang-up occurrence impacting draw, and
- Grade variations impacting draw.

Although it is impossible to predict the flow outcome from a particular ring, the research program carried out at Ridgeway identified five common primary flow behaviors by which most of the trial results could be classified. These are shown in Figures 13.9-17 and 13.9-18. Although general primary recovery zones are shaded in these figures, it should be assumed that the rippling flow effects (discussed later) would result in portions of these drawzones being left for recovery on subsequent levels or not being recovered at all.

Figure 13.9-19 shows the relative frequency of these draw behaviors and that the standard and standard/shallow draw classes produce the highest ring recoveries (calculated after the secondary level). As depth of draw is reduced, width of draw increases. If apex mobility is low, width of draw is also likely to be low, and recovery is also likely to decrease.

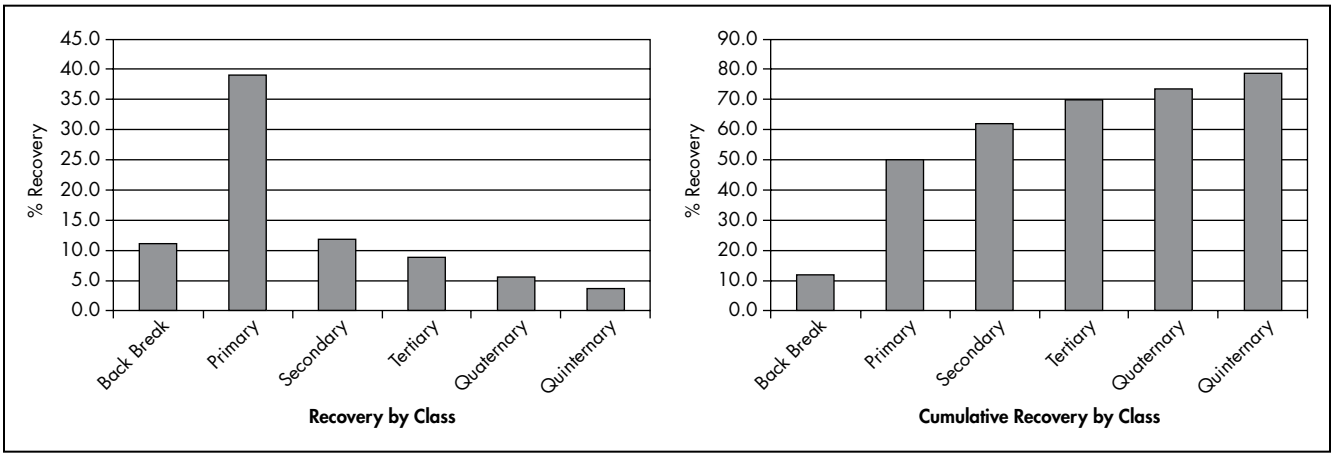

Figure 13.9-13 Recovery by class at Ridgeway

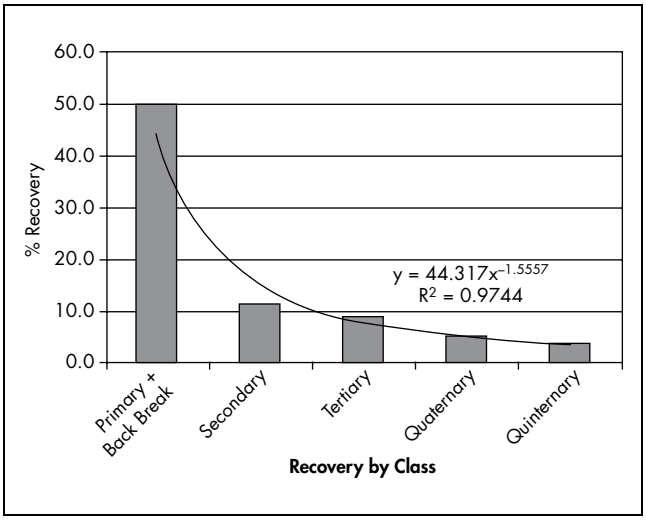

Figure 13.9-14 Recovery formula

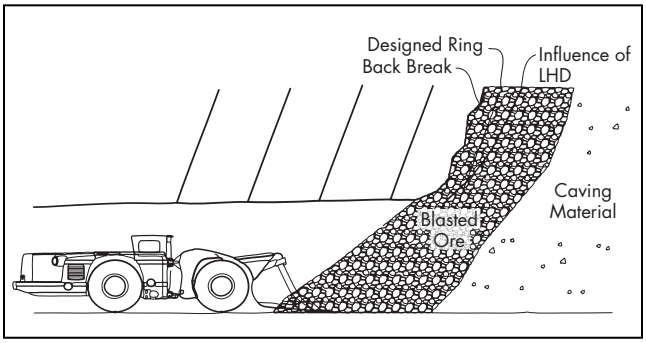

Figure 13.9-15 Impact of back break on ore mucking

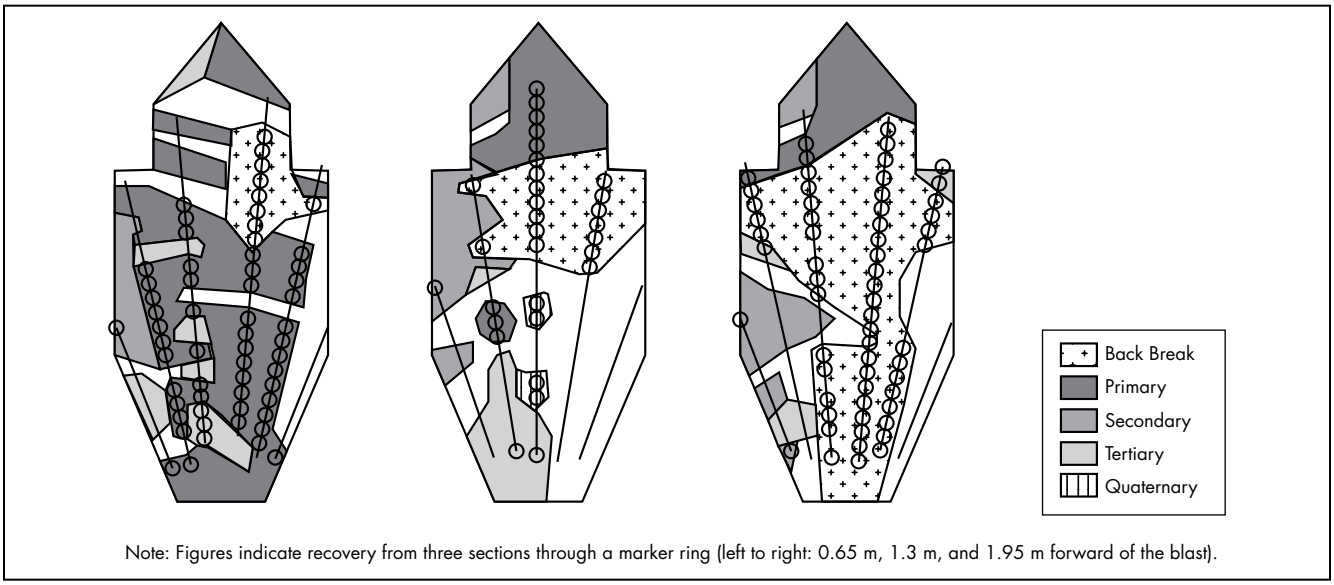

Although not discussed in detail here, coupling full-scale flow assessment with analysis of the drill and blast factors producing these flow types is also important. Marker trials and other drill-and-blast research programs can be used to develop a greater understanding of drill-and-blast, and its effect on flow can be used to optimize operational drill-and-blast design. This research is also used as the basis for layout, blasting, and draw control design for new sublevel caving mines.

Many of the figures included here show examples of ripple patterns in ore recovery. These patterns produce regions of recovery interspersed with sections of nonrecovery, resembling ripple patterns produced in sand due to water flowing normal to the ripples. Researchers suggest a process whereby rock flowing toward the drawpoint encounters zones of lower mobility and continues around these on its original course. These ripple patterns indicate that, although a flow zone may progress through a certain region in the ring, parts of this region are often left unrecovered. Ripple patterns are often at slightly different orientations for different draw classes, suggesting that flow has progressed at different orientations for different recovery classes. The relatively narrow draw pipes progress subvertically from individual drawpoints to heights of at least 55 m, as illustrated in Figure 13.9-20, which shows the results of a secondary draw trial.

In this trial, no primary draw was taken in the rings on the upper level, allowing secondary draw attributable to the rings below to be studied. The primary recovery zone in the lower ring is produced by the same flow event as the secondary recovery zone on the level above. Flow from the ring below appears to have progressed into the center of the ring above (left). The secondary flow zone in the upper ring seems to have been preferentially broken in the blast, possibly due to more concentrated explosive density in the center of the ring. It is likely that low mobility in the apex of the ring below has caused this flow outcome (also resulting in very little secondary recovery from the upper ring on the right).

Episodic flow patterns from individual rings were also identified in the Perseverance marker trials (Hollins and Tucker 2004). Similarly, field experiments conducted at the Kiruna mine showed pulsations of waste entering the drawpoint, with increasing levels of waste appearing with tonnage drawn (Figure 13.9-21). These pulsations were believed to be related to differential mobility in the blasted ore from different parts of the ring and waste rock.

The results of the early model-based research into granular flow in sublevel caving led to advances in design and draw control practice and to a general understanding of granular flow. In many cases, the data recovered from marker trials now supplements or has replaced information previously gained from physical models. Such trials allow testing in theoretical thinking on sublevel caving granular flow in full-scale operational environments but must be designed and analyzed as part

Note: Figures indicate recovery from three sections through a marker ring (left to right: 0.65 m, 1.3 m, and 1.95 m forward of the blast).

Figure 13.9-16 Example of significant back break

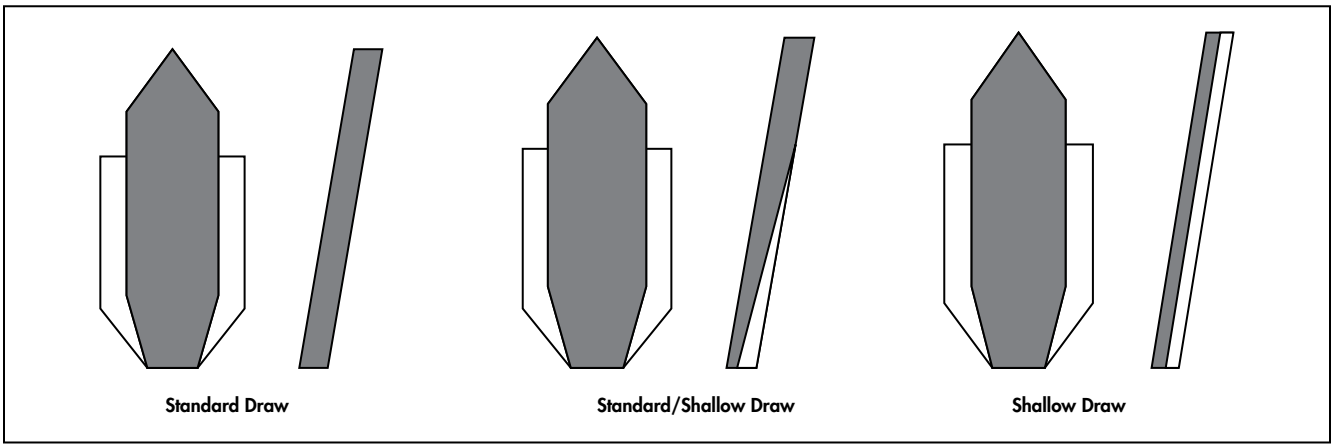

Figure 13.9-17 Primary flow behaviors at Ridgeway

of a systematic scientific program to be completely effective. They often produce results that lead researchers in totally new directions of thought.

Other results through full-scale research of the more recent understanding of flow (particularly in its multilevel nature) are improvements in computer-based forecasting and optimization capabilities. Several different methods of numerical flow modeling specifically designed for sublevel caving environments are now available. Some of these methods not only accurately forecast monthly production grade but also the targeting of high-grade zones and regions of the ore body where extraction has been low. In some cases, they allow shutoff simulation to produce detailed drawpoint-by-drawpoint production targets in situations where visual or weight-based draw control systems are ineffective.

With the continued development of new technology targeted at sublevel caving (e.g., smart markers and improved computing capacity for research into drill-and-blast effects and numerical modeling of granular flow), it is likely that sublevel caving will continue to be a productive and economically viable mass mining method.

MINE DESIGN

Layout selection is a critical success factor in all aspects of a sublevel caving operation. The layout directly relates to the ore recovery, drill-and-blast effectiveness, excavation stability, and the cost of mine development. Because it is a fundamental success factor, considerable attention needs to be given to selecting the layout prior to commencing mine establishment and determining the critical success factors for the mine. A mine focused on low-cost production will implement a different layout than a mine focused on maximizing recovery. Mine layouts will probably change over the operating life of the mine, so the original layout is often modified as a result of lessons learned under operational conditions.

Layout Orientation

Layout orientations are generally classed as either transverse or longitudinal. The transverse layout is generally applied in wider ore bodies, greater than approximately 50 m, where the parallel production drifts are driven across the ore body, according to Figure 13.9-22A. For widths below this, the production drifts are generally driven along the strike of the ore

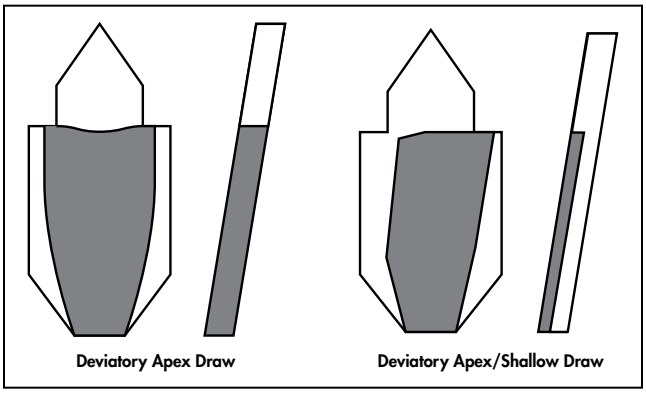

Figure 13.9-18 Primary flow behaviors at Ridgeway

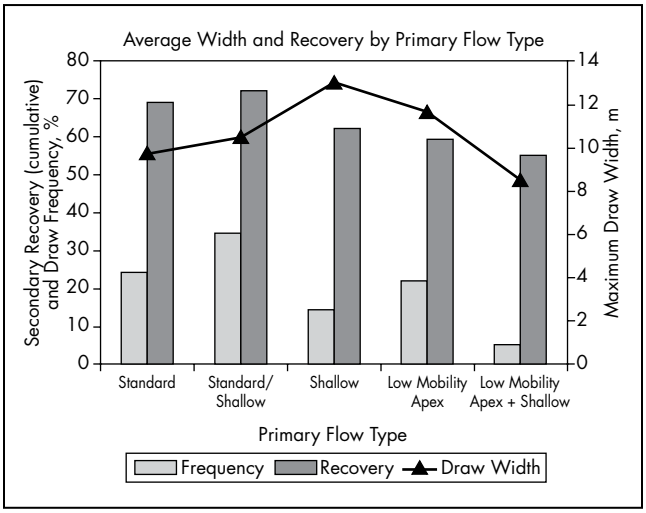

Figure 13.9-19 Frequency of primary draw behaviors and their effect on width of draw and recovery

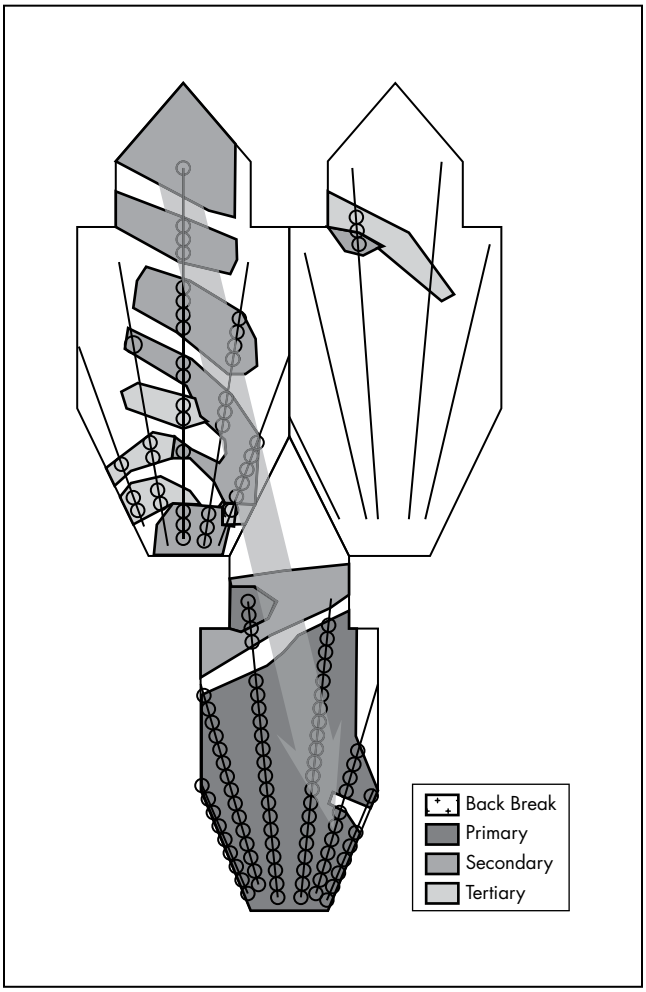

Figure 13.9-20 Example of height of draw and deviation due to low mobility in the apex, from secondary recovery trial

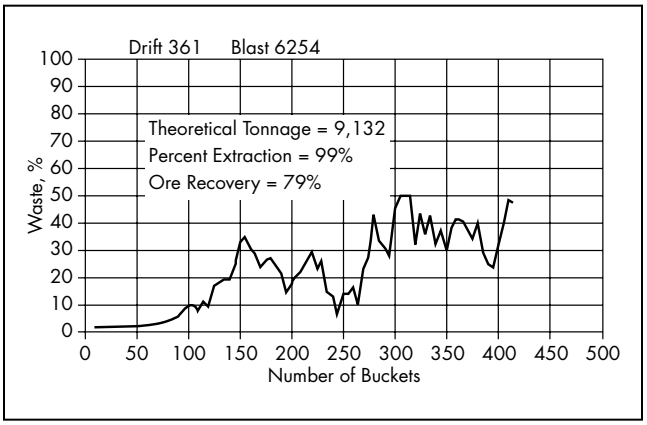
body in a longitudinal fashion, according to Figure 13.9-22B. The longitudinal layout may contain as few as one drift on a level depending on ore-body width. The choice of orientation is predominantly determined by the width of the ore body but can also be influenced by geotechnical and economic factors.

The transverse layout is generally more productive than the longitudinal because of the number of active production faces that can be made available. Some mines will operate with a mixture of layouts due to a variable ore-body geometry, although transition between the two styles is difficult in a vertical sense because of the criss-cross nature of the layouts. However, if transition is required between the layouts, it may be prudent to skip a level and recommence sublevel caving operations with the new layout and allow the skipped level to cave in rather than trying to perform complex production ring drilling and blasting. This technique was successfully employed at the Perseverance mine (Wood et al. 2000).



For either layout type, the supporting development is similar with a perimeter drift containing either orepass tipping points or truck-loading stockpiles. The perimeter drifts are also used to provide access to the primary ventilation circuit and enable the installation of secondary fans to allow airflow to be delivered to the production working areas on the level.

Layout Dimensions

Sublevel Height

The sublevel height is generally measured as the vertical floor-to-floor distance between the levels. It is determined by the dip of the ore body and the physical limitations of the production drill-and-blast equipment. If the ore body is vertical, then dip is not a constraint on sublevel spacing. However, as the ore body flattens, the sublevel height needs to be reduced to avoid incurring excessive amounts of hanging-wall dilution, as well as minimizing the amount of unrecoverable ore on the footwall.

Over the years, advances in drill-and-blast equipment have seen the sublevel height increase from less than 12 m to more than 30 m in some cases. The key criterion for drill-and-blast is to ensure that satisfactory fragmentation is achieved through the entire ring. To achieve this, the drill holes must be evenly spaced, straight, and adequately charged with the appropriate type and strength of explosive. The proposed drill pattern is an integral part of selecting the overall sublevel layout and impacts not only the sublevel height but also the drift dimensions and the drift and pillar spacing.

Source: Hustrulid 2000.

Figure 13.9-21 Pulsations of waste entering a ring at the Kiruna mine

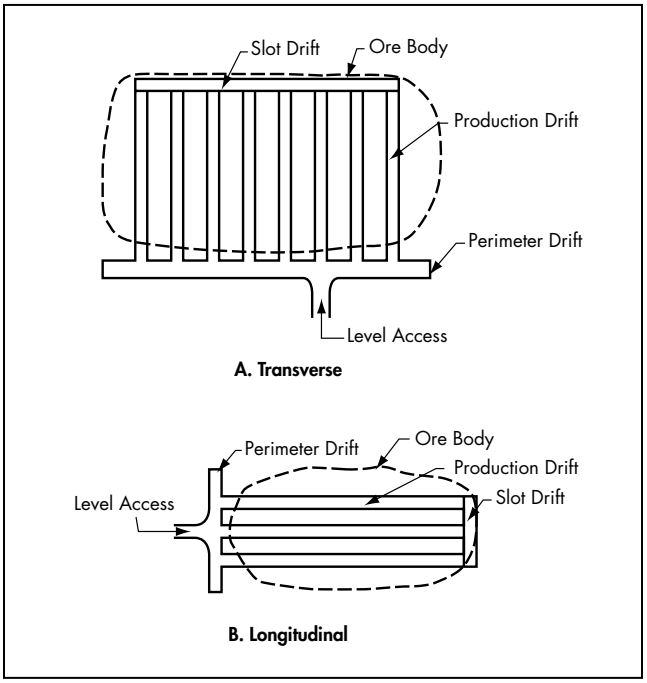


Figure 13.9-22 Transverse and longitudinal layouts

Production Drift Spacing

Important factors in selection of production drift spacing include

- Potential ring shape produced by the combination of sublevel height and production drift spacing (will it produce a ring shape that can be efficiently blasted?);
- Granular flow properties inherent to the mine (based on drill-and-blast procedures and rock-mass characteristics) and the likely recoveries to be achieved;
- Value of the mineral being mined and whether a cost-reduction or recovery-emphasis strategy will be followed;
- Geotechnical factors; and
- Production drilling and charging factors.

For maximum ore recovery, the entire level would theoretically be excavated, similar to a coal longwall operation, but this is impractical. Therefore, a trade-off is required between the amount of ore potentially recovered on its original level and the amount left in the cave for recovery, hopefully, on lower levels (with more associated risk to its ultimate recovery).

Thus, the spacing of the production drifts is strongly influenced by the operating philosophy of the mine. The more cost-focused a mine is, the wider the spacing between the production drifts, because this reduces the amount of expensive development required (Power and Just 2008). Figure 13.9-23 illustrates this for two different layouts, showing theoretical primary recovery zones only. Recovery-focused mines will try to place the production drifts as close together as practical in an attempt to maximize the amount of ore recovered on the primary level to minimize the effects of dilution, as shown on the left side of Figure 13.9-23.

An indicative estimate for the ellipsoid of draw width can be generated by either using a ratio of 1.4:1.7 of the drift width or the drift width plus 1.5 m on each side, according to the following formula:

$$W_{DE} = W_D + (1.5 \times 2)$$

where

W_{DE} = ellipsoid of draw width, m
W_D = drift width, m

Previous estimates for this W_{DE}/W_D ratio for the much smaller sublevel caving layouts also predicted this same ratio range of 1.4:1.7 (Hustrulid and Kvapil 2008).

Because sublevel caving relies on the extraction of ore from not only the level on which it is fired but subsequent lower levels, it is important to overlay the extraction envelopes over all levels to gain an understanding of likely system recovery rather than just recovery on a single production level. In extreme cases, significant overlapping of theoretical draw ellipses may result in excessive extraction of these areas, which can lead to early dilution entry. Conversely, too much of a gap between the extraction envelopes could lead to consolidation of material on the sides of the rings, which may cause poor firing conditions, due to the limited void available. Stress concentration areas may also result, which could lead to damage of the production drifts.

Production Drift Shape

The shape of the production drift impacts the mine's ore recovery and productivity. Ideally, the production drifts are as wide as possible to allow the maximum flow of ore. To further assist with flow, the drift roof should be as flat as practical while still providing adequate support to the roof and brow. A wide and flat roof also assists in improved spacing of the production drill holes, which limits the impacts of blasting on the brow, as well as reducing the amount of back break. If the drift roof is overly arched, the flow can be preferentially funneled to the center of the drift, leading to early dilution. In some cases, a trade-off will be necessary (i.e., an arch may be required to produce a wider stable drawpoint).

Greater drift widths also improve the productivity of the LHD machines. An LHD can tram faster in a drift where it has plenty of clearance. At the muck pile, the width is also an advantage for the LHD, because it is able to load from side to side, ensuring a more even flow of material into the production drift, as illustrated in Figure 13.9-24. In addition, the loader is able to extract material from deeper into the drawpoint,

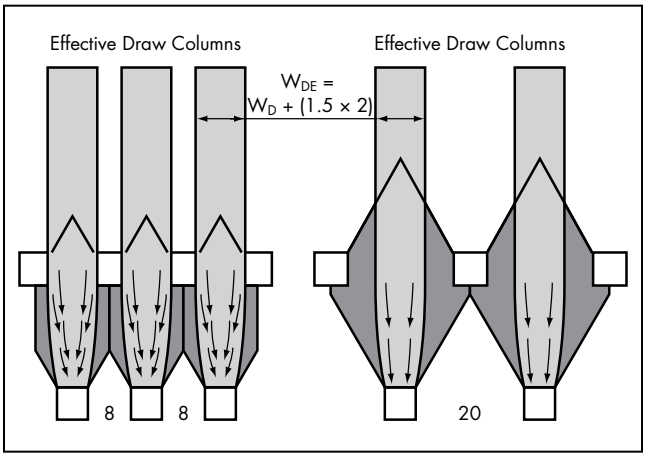

Figure 13.9-23 Effect of drift spacing on primary ore recovery

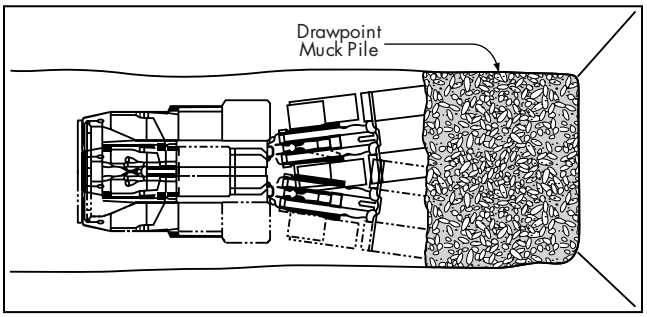

Figure 13.9-24. LHD side-to-side loading in a drawpoint

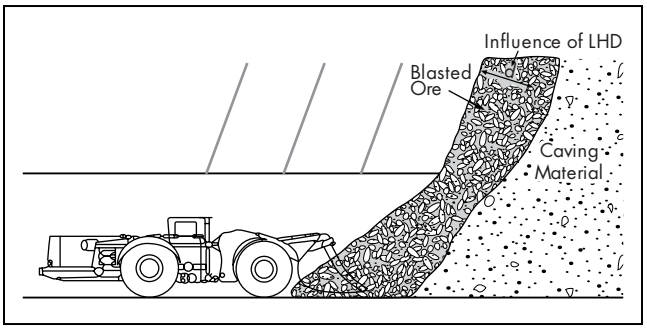

Figure 13.9-25. Influence of LHD on cave material

because it is not extracting the material from the center of the drift, which has rilled the farthest out from the brow, as illustrated in Figure 13.9-25. This further improves ore recovery and influences the burden of the production rings, because the cave material loosens in front of the next ring to be fired.

Minimizing the height of the drift roof restricts the rock's ability to rill too far from the brow. As previously stated, if the depth of material excavation by the LHD can be increased, then the overall ore recovery will be increased. The drift height, however, is usually a trade-off between length of rill and size of machinery required to achieve the desired production rate. Although it is possible to obtain custom-made machinery to fit the optimal drive height, this strategy can have drawbacks if the machinery fails to meet production targets, as machinery replacements are generally not immediately available. In the

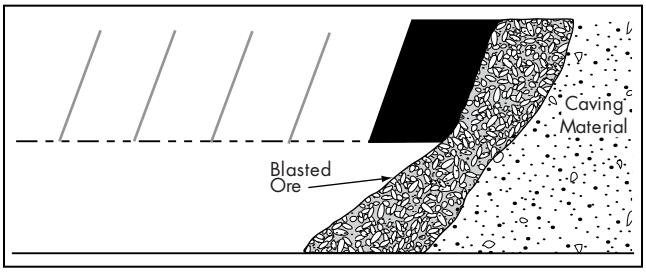

Figure 13.9-26 Unique sublevel cave-blasting conditions

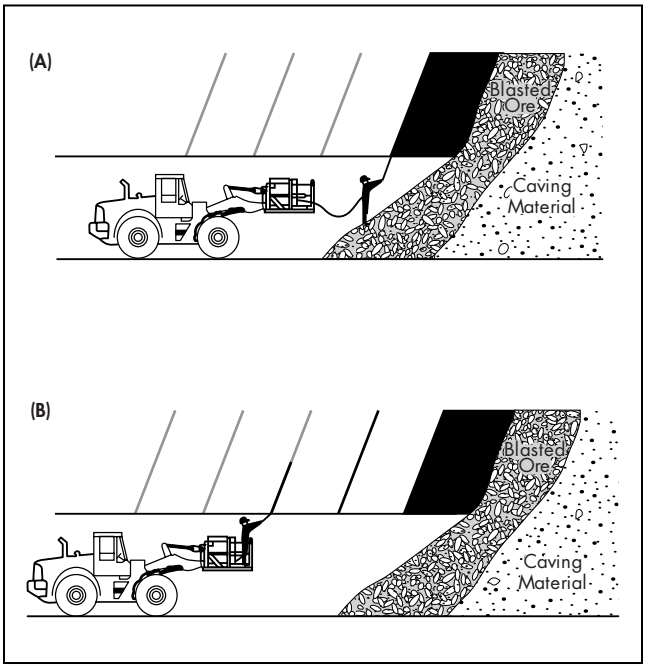

Figure 13.9-27 Charging option set-ups

authors' experience, it is generally the production drill that limits the drift height, and, as the large-scale operations push for longer and longer production holes, this is likely to remain the case. Low-profile LHDs are generally available to achieve the desired production rates, but the desire to drill with longer and longer drill rods for greater hole accuracy is forcing average drift heights higher.

Production Drill-and-Blast

The drill-and-blast requirements of a sublevel caving mine are unique because the blasting environment is always choked. This means that every production ring is blasted against the combination of previously blasted ore and waste sitting in and around the production drift (Figure 13.9-26).

Because of the environment in which the blasting occurs (i.e., the only free face is the roof of the production drift), the blast's function is different from nearly every other production drilling situation. With sublevel caving blasting, the intent is to initially compact the caved material in front of the blast to create a void area for the fired ring to access. After the fired ring is in the void area, the intent is to fragment the ore slice as much as possible so that it will preferentially flow when mucking commences. Although this is the intent, the reality is somewhat different. The nature of the fanned ring pattern used

in sublevel caving and the reducing ratio of development-to-production work against the intended blasting criteria. With the reduction in this ratio, the only true swell available to the blasted rock is reduced and in some cases is <10%, while the blasted rock itself still wants to swell to >30% of its in-situ volume. This lack of initial swell results in the holes fired first, and those sections of the hole close to the drift have the opportunity to swell and move into the drift as desired, while the ends of the holes have limited opportunities to swell and move. In addition, the fan nature of the drill pattern ensures that explosives are concentrated in the center of the ring relative to the outer holes. This creates smaller, more uniform fragmentation in the center, which is thus more mobile than the material at the edges. These fragmentation and flow characteristics affect the gravity flow and ore recovery performance for the mine (Trout 2002).

With the diamond layout style of sublevel caving production drifts, a wide variety of production drilling patterns can be used. With the wider-spaced production drifts, a pattern involving larger and longer holes will generally be used, although, as the production drifts are brought closer together, the drill holes will interact. When this occurs, the production rings often need to be offset by approximately 1 m to reduce the chances of sympathetic detonation between the holes or damage to the neighboring ring when the rings are fired. Steeper side holes will lead to better funneling of ore to the drawpoint and smaller *dead zones* at the sides of the ring but also to higher apexes at the top of the ring (which can be more difficult to blast effectively).

The production drill rings are generally inclined forward by 10° to 20°. This inclination assists in feeding the ore preferentially into the drift by providing a small overhang to the diluting material directly above. The inclination also ensures that the holes are all drilled on a similar plane for improved blasting results and additional protection of the ring brow. Because prevailing structures in the rock mass can sometimes adversely affect rings inclined forward at similar angles, the amount of forward inclination may need to be adjusted in different parts of the mine in order to achieve optimal results.

The sublevel caving production rings can be charged with either ammonium nitrate fuel oil (ANFO) or emulsion products. Prior to any charging activities, the production holes should be *dipped* by the charging crew to ensure that the holes are clear of obstructions and are drilled to the correct depths. Often, charging personnel must stand on the muck pile to charge the ring, as the charging unit frequently cannot get the operators to the production ring because of the rill of broken rock in the drawpoint and the height of the drive (Figure 13.9-27A). This can lead to significant risk of injury and inferior drill-and-blast results. Safety hazards include the muck pile rilling unexpectedly or trip hazards resulting from the uneven nature of the muck pile on which the operators work.

To provide a safer charging environment, the preloading or precharging of multiple rings can be implemented (Figure 13.9-27B), although this is subject to the local regulators and may take time to get approval. *Precharging* relates to fully loading and priming the production rings, whereas *preloading* refers to the practice of only placing the explosive in the hole but not the detonator, which is added immediately prior to blasting. When utilizing precharging, the tails of the detonators are tucked back up the hole so they do not impede the LHD when it is mucking the rings in front; the tails are only pulled out when the ring is ready to be hooked up for blasting.

The implementation of precharging/loading in recent years at a number of large-scale operations has had significant benefits for those operations, including improved safety of personnel around the drawpoint brows, a decoupling of the charging and mucking activities, the removal of production disruptions caused by hole blockage and dislocation, the elimination or significant reduction in the number of production ring redrills, and improvements in draw control (as less mucking is needed to prepare the ring for firing).

Drawbacks to precharging/loading include the need to have a number of production rings predrilled in order to allow the charging and drilling processes to be independent. From a safety perspective, when a precharged/loaded ring is behind a misfire, the scope is limited to get a drill rig back to assist with the misfire unless the drill rig has a remote operation function or the explosives are washed from the precharged/loaded ring. For this reason, precharging is often easier to implement in mines with better geotechnical conditions, where charged holes are less likely to be dislocated or brows lost. If the ore body contains aquifers or seeping water, precharging/loading may be also unsuitable when using ANFO, because the explosive column can be desensitized or washed out by the time the ring is ready to fire (emulsion should overcome this issue).

Because of the choked blasting conditions of sublevel caving rings, a single production ring per drift is generally only fired at any one time. Firing of multiple rings may be undertaken in areas of very poor ground conditions, but this introduces the risk of misfires and leaves pillars within the cave, which can cause problems on the level below. It also leads to lower overall recovery, because most of the ore in the ring farther from the brow cannot flow to the drawpoint and can be occluded by waste flowing from above. Depending on infrastructure constraints and required production rate, some mines fire rings in multiple production drifts at the same time to ensure broken stocks are sufficient for the LHD fleets.

Hang-ups are a normal feature of the sublevel caving mining method, with up to 50% of rings hanging up at some stage of the mucking cycle. In mines with more closely spaced drawpoints, the hang-up can sometimes be cleared by removing additional material from the production drifts on either side of the hung-up drift. This material removal appears to disturb rock in the affected drawpoint by acting to release pressure on either side of the hung-up ring. Other hang-up retrieval methods include water cannons and (as a last resort) explosives, because they often damage the drawpoint brow. If a hang-up cannot be cleared within a specified period, the next ring in the production drift must be fired and the mining process continued.

Although production drill-and-blast design is an input into the overall layout of the sublevel caving mine, it can be readily changed as the characteristics of the ore body become more fully understood. The shape of the production ring may not vary significantly, but the drill-and-blast parameters may. Design parameters, including hole diameter, number of holes in the ring, drill-hole toe spacing, production ring burden and dump angle, and explosive column densities and lengths, can all be modified with relative ease. When adjusting the production drilling parameters, it is important to take a holistic view of the sublevel caving operation in order to ensure that the changes made will not dramatically and negatively affect other parts of the process.

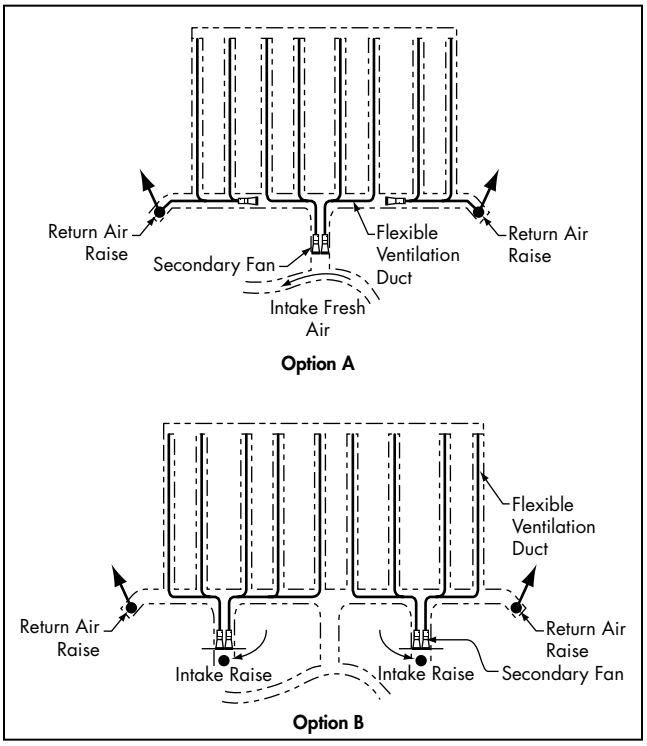

Figure 13.9-28 Variable ventilation layouts for sublevel caving operations

Services

The active ore production areas are all dead-end headings. A single fan may be used to supply up to four production drifts, as the ducting can be tied off in the headings that are not in use. If multiple secondary fans are required on the level, they may need to be set up in a cascading style (Option A, Figure 13.9-28). This means that a fan will be placed downflow of another fan and, in essence, will receive the used air from the upflow fan. This cascade style of secondary ventilation can lead to lost production time if there is a significant amount of dust in one of the drawpoints upflow of the secondary fan, because all the dust will be blown into the headings serviced by the downflow fan. Each level is set up as its own primary circuit so the levels do not interact with each other. Primary intake and return raises with fixed ventilation infrastructure are used to direct the appropriate amount of air throughout the mine. Figure 13.9-28 shows two styles of level ventilation: Option A is for mines using the main access decline as their fresh air source, whereas Option B is for mines that heat or refrigerate their intake air.

The cave itself may provide a path for airflow after it has broken through to the surface, though this will be determined by the porosity of the cave column and the pressure differences between the surface and the cave workings. Generally, movement of air through the caved rock will be in the form of leakage rather than a volume that can support mining activities. Individual mining circumstances will ultimately determine how much air passes through the cave zone area.

Water and compressed air are reticulated to each level to support the mining activities. After development of the level is completed, the compressed air line may be recovered unless required by the production drill. The water line is used for production drilling and to feed the drawpoint sprays mounted on the drift roof to keep the dust levels down during mucking. Drainage on the sublevels is important in ensuring that maximum production rates are achieved. The production drifts are usually driven on a slight incline of between 1 in 50 (2%) and 1 in 40 (2.5%) to remove the pooling of water along the drift or at the face. In addition to the introduced water for the mining process, water is also associated with aquifers that have been breached during mining. Sumps are generally located in the perimeter drift with a drain hole drilled to the level below. The production water can then be collected at a mine dam located lower in the mine and pumped out via the mine dewatering pump system.

Communications systems are run onto the production levels for radio communications, as well as to control any automated or semiautomated mining equipment, including production drill rigs and LHDs in some of the larger-scale sublevel caving operations. Such systems may also be utilized to transmit real-time production data to a central production management area. The larger-scale sublevel operations using automation or the tele-remote operation of equipment are doing so in an attempt to remove workers from hazards associated with drawpoint brows and in the general underground environment. The LKAB mines in Sweden are leading the way in this field. They use the automation of machinery to provide production increases by allowing the machines to work extra hours while the operators are located on the surface or an area of the mine not impacted by the mining process, especially the blasting and clearance cycle.

Geomechanical Factors

With sublevel caving, a number of geomechanical factors must be considered when either laying out the mine or making large-scale operational decisions. These include

- Quality of the ore body and hosting rock mass,
- Orientation and magnitude of the major and minor stress parameters, and
- Presence of large-scale and microstructures.

Prior to establishing a sublevel caving mine, an assessment of the likelihood of natural caving is required. The assessment is a specialized geotechnical task and is beyond the scope of this chapter. However, inputs for these techniques rely on a number of key geotechnical parameters, so it is imperative when diamond drilling into a deposit that may be applicable for caving that all of the relevant information is recorded. If stability assessments indicate that the ore body will not cave naturally, then sublevel caving may not be suitable, unless reliable techniques for cave preconditioning and/or caving assistance are available.

The orientation of the stress field will often determine the retreat direction of the sublevel caving production front. If there are no other influencing factors, it is preferable to retreat perpendicular to the major principal stress direction. By retreating in this manner, the effects of the stress field can be "shadowed out" after production has been initiated on a sublevel. This creates a distressed environment for the majority of production headings in the mine, because the stresses will be forced to wrap around, under, and over the production areas.

Stress that builds up around the periphery of the working areas is called abutment stresses, which can result in rock movement and bursting, depending on the rock strength-to-stress ratio. The ground support requirements are therefore greater in the perimeter drives than in the production drifts.

The bullnose section of the pillars at the turnout points of the production drifts from the perimeter drive are especially susceptible to stress damage, as shown in Figure 13.9-29, because they are reduced in size with the retreating of the cave front.

Production drive stability can also be impacted by the abutment stresses as production on the level above passes over the lower-level production drifts. The preferred ground support system in a sublevel caving operation is one that can yield slightly without failing when the abutment loads come on but is still sufficient for working at the brow in the distressed conditions. Some ground support combination examples include grouted rebar with 50 to 75 mm of fiber-reinforced concrete or split sets with wire mesh.

Identifying mine scale and minor structures is important when laying out the mine, because they can be used to assist in the propagation of the cave or in controlling the effects of the abutment stresses. Should the major structures not be favorable to the cave's progression, then considerable care needs to be taken to monitor caving progress, because it may be necessary to reduce or stop production in certain cave areas to reduce the impacts of these structures. The orientation of the minor structures is also important, because it can influence the inclination of the production rings. Such inclination on a plane parallel to the minor structures can reduce the number of production hole dislocations and therefore improve productivity.

Water-bearing aquifers or surface water courses—that is, streams and dams in the caving area—also need to be identified prior to the commencement of caving activities to ensure that there are no unexpected water or mud inrushes during the operation of the mine. Where an aquifer or water course cannot be dewatered prior to caving, extreme care should be taken and evacuation procedures implemented as the cave encroaches on the water-bearing area. Generally, as the cave propagates, it will ensure that a large number of fractures are created in the cap rock, which will breach the aquifer and potentially drain it before the main cave back moves through the water-bearing zone. However, in extreme cases, uncontrolled mud flows can be generated by excessive and poorly controlled draw in combination with high inflows of water (either from aquifers or channeling of precipitation through subsidence zones) and suitable clay mineralogy. When this is a risk, use of a robust inrush hazard management plan with appropriate triggers and controls is beneficial. Prior to commencing a recent sublevel caving operation at the Kiruna mine, engineers were forced to drain a small lake, while engineers at the Ridgeway mine identified an aquifer system below the surface and monitored it as the cave progressed, noting only minimal water reporting to the production drawpoints, as the majority of the water was absorbed in saturating the cave column.

PRODUCTION DRAW CONTROL

Draw strategy and production management are extremely important in sublevel caving operations to enable the accurate prediction of ore and waste flow from the cave after production commences. The draw strategies and production management plans used at each mine need to be variable and flexible in order to cope with unforeseen circumstances such as the early inflow of waste, hang-ups, geotechnical instability, and arrival of large oversize material at drawpoints.

Draw Strategy

The objective of a draw strategy is to maximize the overall ore recovery while minimizing the impacts of dilution. To achieve this, an effective sublevel caving mine relies heavily on a draw control system that is variable and adaptable to the constantly changing operational situations, including unscheduled equipment breakdowns and production incidents. Effective draw control practices also rely on an understanding of the cave's flow characteristics and the grade distribution in and above the ore body being mined.

Any adopted draw control system needs to include guidelines to allow the frontline management to make tactical decisions. Such guidelines will be grouped according to authority levels—ranging from the LHD operator to the general manager of the mine. In mines with a distinct visual or physically distinguishable difference between the ore and waste rock, guidelines will dictate the percentage of ore-to-waste in the drawpoint when production must stop for a particular drawpoint. To allow decisions to be made, mines without this distinction must rely solely on the tonnage drawn from the drawpoint followed up with a sampling system.

Regular monitoring of the drawpoint status is imperative to achieve overall efficient draw strategy and to ensure that underperforming or troublesome drawpoints are identified early so their potential impact can be minimized. Draw strategies can be classed as either *independent* or *interactive* and are determined by the mine layout and overall mine objective. These terms refer to drawpoints where tactical extraction targets are linked to those of surrounding drawpoints (interactive) and those where tactical production targets can be generated without reference to surrounding drawpoints (independent). Theories discussed previously concerning the widening of draw columns due to interaction through interactive draw do not have bearing on these draw strategies.

Independent draw is often used by operations with a limited number of production drifts available for mucking. Under these circumstances, each individual drawpoint is often depleted before moving onto the next one. The penalty for this type of draw strategy is a greater risk of dilution piping in from above and impacting adjacent production drifts. Interactive draw style operations rotate the LHD between a number of neighboring drawpoints in a fixed sequence, which is repeated until all of the drawpoints have been completed and the next set of rings fired. The interactive approach enables the blasted and caved material to be extracted over a larger lateral area, thus reducing the opportunity for dilution piping. Depending on the ore flow characteristics of the mine and the mine layout selected, either approach may maximize the overall mine performance.

As previously identified, drawpoints can be operated individually or in groups. In mines with substantial numbers of drifts on each level, the practice of grouping a number of drifts together and treating them as a single entity can substantially reduce the complexities of managing the operation on a short-term basis. The orientation and shape of the production front will be influenced by the stress field and major structures. No standard exists for the shape of the cave front, because all mines will have varying conditions and operating requirements. The three most widely used cave-front layouts are the flat, en echelon, and stepped, as shown in Figure 13.9-30.

When selecting a cave front, thorough consideration needs to be given to the lead–lag rules that will be used to operate the sublevel caving. The term *lead–lag* refers to the maximum and minimum spacing between either individual or groups of drawpoints being retreated across the levels. These rules are 3-D, because they also include the level above and the level below

Figure 13.9-29 Example of perimeter drive damage in sublevel caving operation

the specific level. When defining the lead–lag rules, the main influencing factors are stress field constraints, which relate to the minimum distance required between production fronts on adjoining levels to preclude stress damage. Damage can also occur when drawpoints retreat past their neighbors on the same level. The impacts of stress can be mitigated by increasing the amount of ground support in the sections of the drift, though additional support will be limited by the ability to cost-effectively change the lead–lag distances. Another operational limit to lead–lag distances is the interaction of drilling and charging activities within adjoining drifts. Most operations will have an exclusion limit around a charged hole, which must be considered when establishing lead–lag rules.

Compaction of the cave column is also another potential factor. If a level retreats too close to the one above, stability of the cave in front of the upper level may be compromised, and the ore blasted on that level may be more difficult to recover. Conversely, if the distance between the vertical levels is too great, it may take too much time for the lower level to pass under the upper level, and the cave may recompact or reconsolidate, depending on its characteristics, causing considerable production and ore losses.

Production Management

A number of factors impact the theoretical production rate of a sublevel caving operation, including

- Ore-body geometry;
- Cave fragmentation of both ore and waste;
- Mine layout and excavation size;
- Equipment employed, fleet size, and number; and
- Materials-handling capacity

As the sublevel caving method is now often used in more competent ore bodies, opportunities for larger, stable excavations exist. This is transforming production rates for sublevel caving operations as larger equipment is used. In most sublevel caving mines, the majority of activity occurs within the confines of the level with little activity in the access declines. This makes the method efficient, with some operations achieving >35,000 t/operator per annum, as relatively few operators are required underground once the mine is operational.

Overall, the aim of sublevel caving mining is to become as factory-like as possible. This approach is achieved by taking a holistic view of the mining method from the face through to the surface in the understanding that overall mine productivity is governed by the lowest-producing component. With the increase in equipment size and technology, larger fragmentation can be accommodated at the drawpoint, but this may cause downstream issues for the shaft/conveyor or truck fleet used to haul the material out of the mine. As such, it is imperative that the mine production system is integrated with the materials-handling system, as well as with the mill, to ensure overall optimum mine performance.

Recovery and Extraction

Recovery factors relate to the percentage of mineral recovered from the ore body relative to the amount blasted. Mineral recovery from sublevel caving operations can be above 85% of the quantity of in-situ mineral blasted. However, this recovery can be inflated by inflow of low-grade mineral contained in diluting rock from outside the mining boundary.

Extraction or tonnage factors relate to the percentage of tons drawn relative to the tons fired. This percentage varies from site to site but is generally between 80% and 125%. When the extraction rate is more than 100%, this is termed *overdraw*. Depending on the draw control strategies and grade distributions within the ore body and host rock, individual drawpoints may be drawn in excess of 1,000% and still be returning material above the shutoff grade (the grade at which drawpoints should theoretically be shut down). This generally occurs when previous levels of the mine have been significantly underdrawn because of geotechnical or mine design factors.

Some ore bodies will have physical differences between the ore and waste, which are readily identifiable—for example, color or weight. This allows mine personnel to assess in real time whether or not a drawpoint is still running at the required grade. In these situations the mines are able to more selectively recover ore left behind on previous levels. However, they must be careful to ensure that their grade control methods are accurately calibrated in order for their shutoff targets to be met.

Other operations with no readily identifiable physical difference between the ore and waste will often run to a tonnage limit and stop draw at a point independent of the drawpoint grade. This tonnage strategy can lead to a considerable amount of mineral being left in the cave, which these operations will then try to recover over subsequent levels by increasing their planned draw rates using a broader, less selective strategy. Under these systems, total tonnage factors for the mine can be slightly higher than situations where selective grade control can be applied.

Fines migration can also influence extraction strategies, especially when sublevel caving is applied beneath open pits with significant exposures of weak, weathered materials or in ore bodies with weak hanging walls. The cave column applies a significant amount of comminution to the rock as it flows, so weak material is often reduced to a small fragmentation size referred to as fines. Fines can also be created through the overcharging of the blastholes. Due to the properties of gravity flow, fines material will descend through the cave column faster than the coarser rock fragments, sometimes prematurely closing drawpoints, affecting ore-handling system efficiency or creating the potential for mud rush when combined with the introduction of large amounts of water to the cave column.

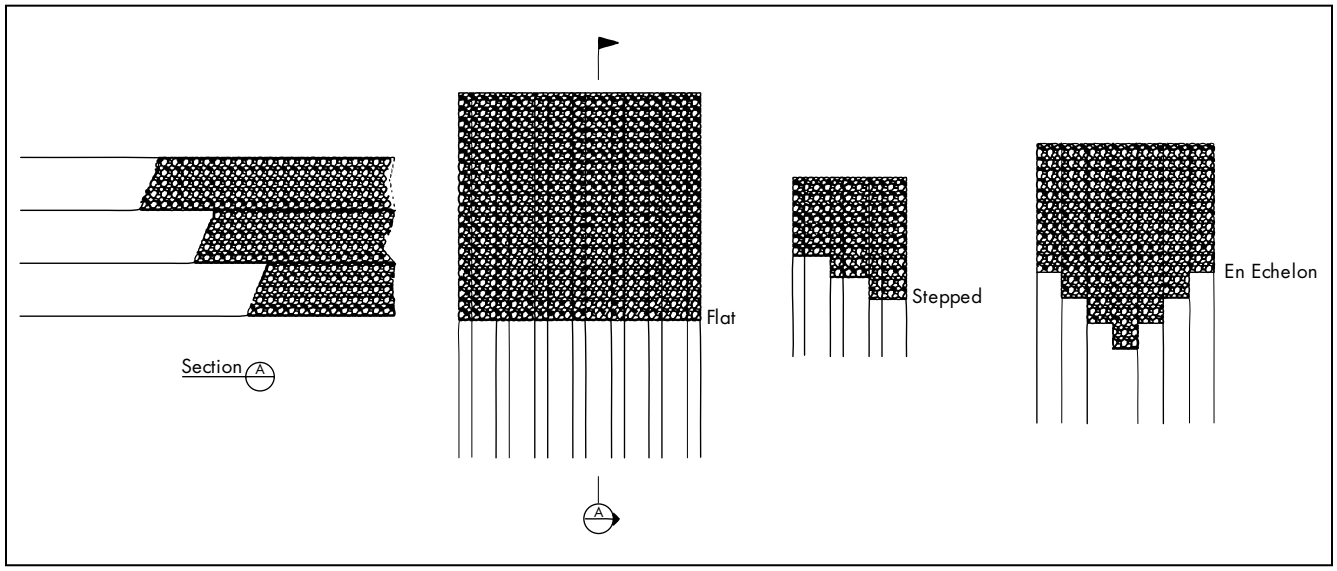

Figure 13.9-30 Examples of cave-front geometries

TECHNICAL COMPONENTS

Cavability

The caving of the host (or *cap*) rock above the sublevel caving operation is crucial to the success of the mine. Mine-scale structures and the general geotechnical conditions of the host rock influence the rate of cave propagation and the size of the footprint required to ensure caving.

There are two distinct phases to the caving of the cap rock: (1) initiation of caving and (2) the continuation of caving as the mine continues deeper (Figure 13.9-31). Should either of these stages not occur and the cave stalls or forms a stable arch, there are considerable safety risks relating to the creation of voids and the potential for air blasts. Cap rock failure may occur as either a time- or production-dependent failure. Time-dependent failure occurs when the cap rock yields and fails only at intermittent periods—a mode that can lead to significant cap rock failures depending on how much swell room is available. Production-dependent failure occurs when the cap rock unravels almost immediately after an air gap becomes available, largely controlled by extraction of the blasted material. Time-dependent failures are often accompanied by a small number of significant seismic events, whereas production-dependent failures tend to have a significant number of seismic events of a small magnitude. The mode of cap rock failure will determine the production ramp-up rate of the sublevel caving mine, because a number of safety hazards can be created if the initial production rates are not matched to the cave propagation rate.

The most significant safety risk is the creation of an excessive air gap, which can lead to a dangerous air inrush/air blast when the cave back yields. In order for rock to cave, some form of air gap has to be present. The geomechanical properties of the rock mass, the footprint of the production level, and the draw control strategy of the mine determine the size of the air gap that can form. Sublevel caving operators must manage their operations to ensure that the size of any air gap that forms is limited and does not constitute a hazard to mining personnel.

Void monitoring is a critical process when establishing a cave under any conditions. The results from the cave-monitoring system need to be cross-checked with the production figures to determine the type of cap rock failure mode that is in place and to ensure that there is a suitable coverage of blasted and caved material above the active production drawpoints to prevent a dangerous inrush of air into operational areas. It may be prudent to reduce or even stop production for a period of time in the sublevel caving to allow the cap rock failure a chance to catch up and return to the safety operating guidelines. Continuing to produce while creating a significant air void can have catastrophic results when the cap rock ultimately fails.

To maintain an understanding of how the cave is progressing, cave monitoring throughout the life of the operations is important. A cave-monitoring system should consist of a number of complementary measurement techniques to allow for the cross-referencing of results. Microseismic systems placed outside the expected cave column give an indication of the seismogenic zone, which exists just above the cave back (Duplancic and Brady 1999) and can be used not only until the cave breaks through to the surface but also as it relaxes over the life of the mine. Open holes into the cave back area can be used until the cave reaches a predefined distance from the surface where it is no longer safe for people to travel above the cave back. The open holes can be plumbed for depth using weighted wire rope and in some cases also provide access for borehole cameras. As the cave approaches the surface, the open holes can be used to place extensometers and time-domain reflectometers, which allow for remote monitoring of the failure of the cap rock.

Subsidence

As a caving method, sublevel caving will create a surface expression and a crater that deepens with time. This surface movement zone is referred to as the subsidence area. Understanding the likely size of this area is imperative when locating major infrastructure both on the surface and underground. Motion

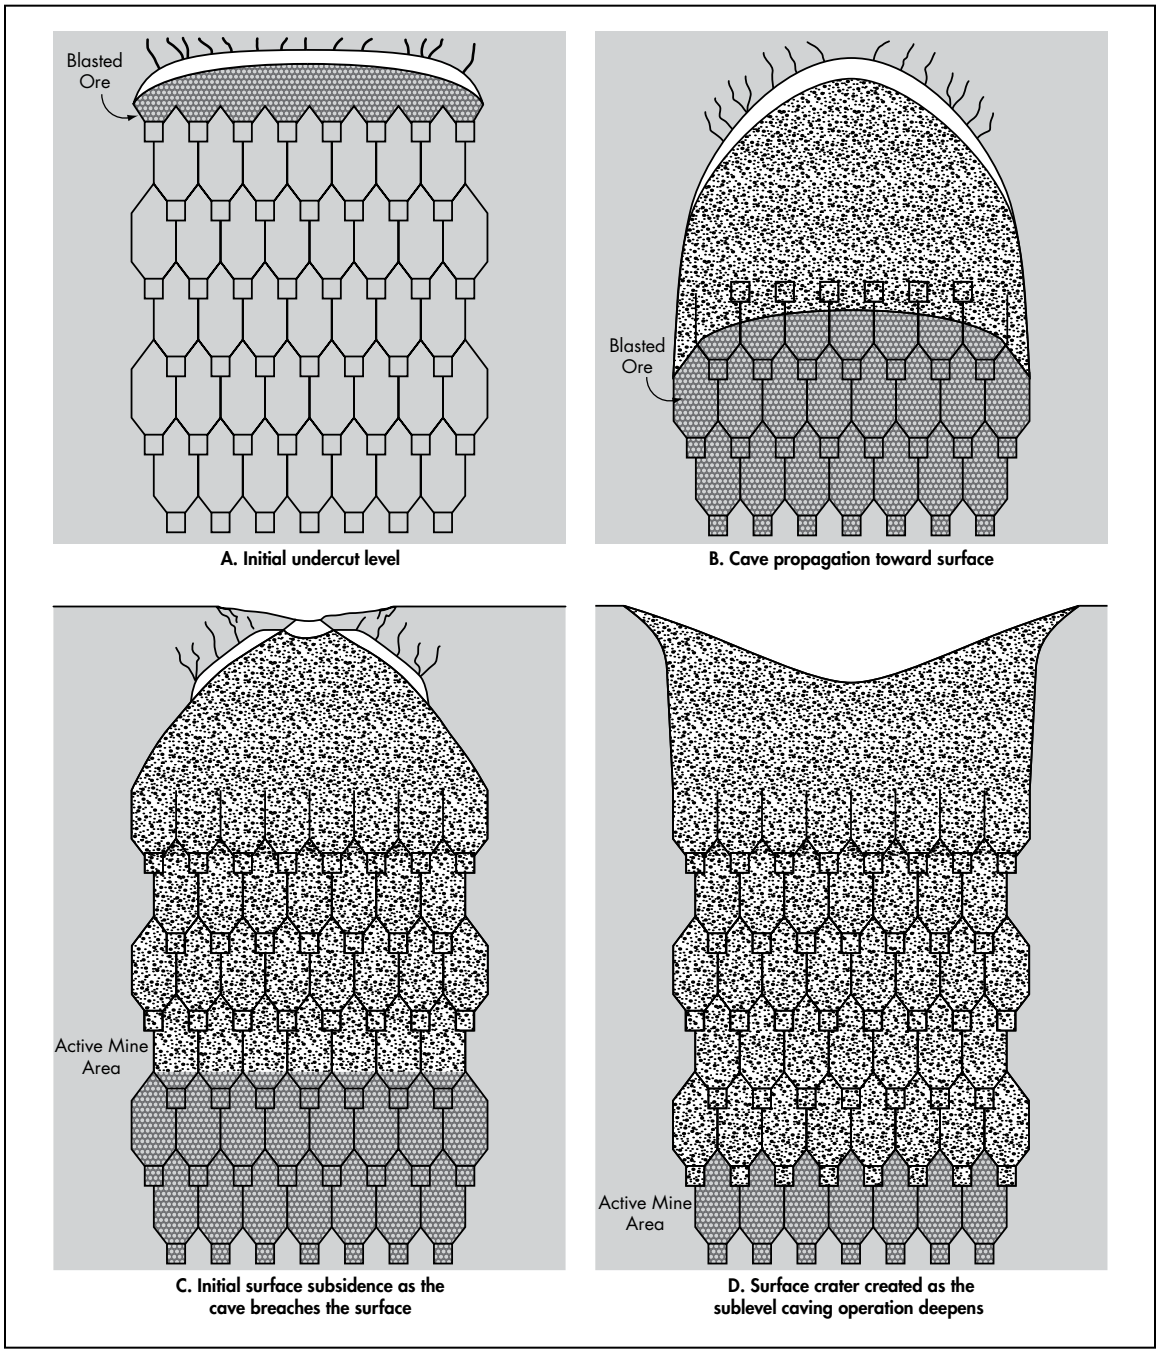

Figure 13.9-31 Stages of cave propagation

sensors and aerial surveys (Figure 13.9-32) can be used to monitor the growth of the subsidence area to determine if it correlates closely with the production being drawn from the mine. Should a discrepancy occur between the surface growth and mine production, a review of the potential void creation should be undertaken to ensure there is no risk to the work force.

As the subsidence zone creates a direct link from the surface to the underground workings, it is imperative that water inflow restrictions are placed around the subsidence zone where practical. For sublevel caving mines below an open pit or at the bottom of a valley, this can be a significant issue as these areas are catchments for rainfall. In these situations, monitoring of the rainfall and the saturation of the cave column may be utilized to determine the appropriate operational response. The flow of water into the subsidence area may not only result in additional pumping from the workings but can create a mud-rush issue when combined with the fines located within the cave column.

In the simplest case of a uniform vertical ore body, the initial cave crater will generally have vertical walls until the crater reaches a sufficient depth for slumping failure to occur. The surface expression will gradually expand as the crater deepens and an exclusion limit needs to be implemented. The

size of the subsidence and fractured zone around a cave will vary due to the host rock conditions, major structures, and so forth, but a rule of thumb estimate is 65° from the lowest level, as shown in Figure 13.9-33.

A variety of methods can be used to estimate subsidence effects, wherein the reader is referred to other sections in the handbook.

ACKNOWLEDGMENTS

The authors acknowledge the efforts of all involved in advancing the understanding of sublevel caving mining, because this chapter is a synopsis of many presentations, research programs, and personal discussions.

CHAPTER 13.10

Block Caving

Charles A. Brannon, Gordon K. Carlson, and Timothy P. Casten

Block caving is a mass mining system that uses the action of gravity to fracture a block of unsupported ore, allowing it to be extracted through preconstructed drawpoints. By removing a relatively thin horizontal layer at the base of the ore columns using standard mining methods, the vertical support of the ore column above is removed and the ore then caves by gravity. As broken ore is removed from the ore column, the overlying ore continues to break and cave by gravity.

Although some relatively smaller block cave ore bodies are caved and mined as a single production block, most existing and planned block cave mines use either of the following:

- An extended block caving system that divides the deposit into discrete production blocks; or
- A single cave front (or series of fronts, or "panels") advancing forward through the ore body, continually opening up new production areas as the earlier caved areas become exhausted.

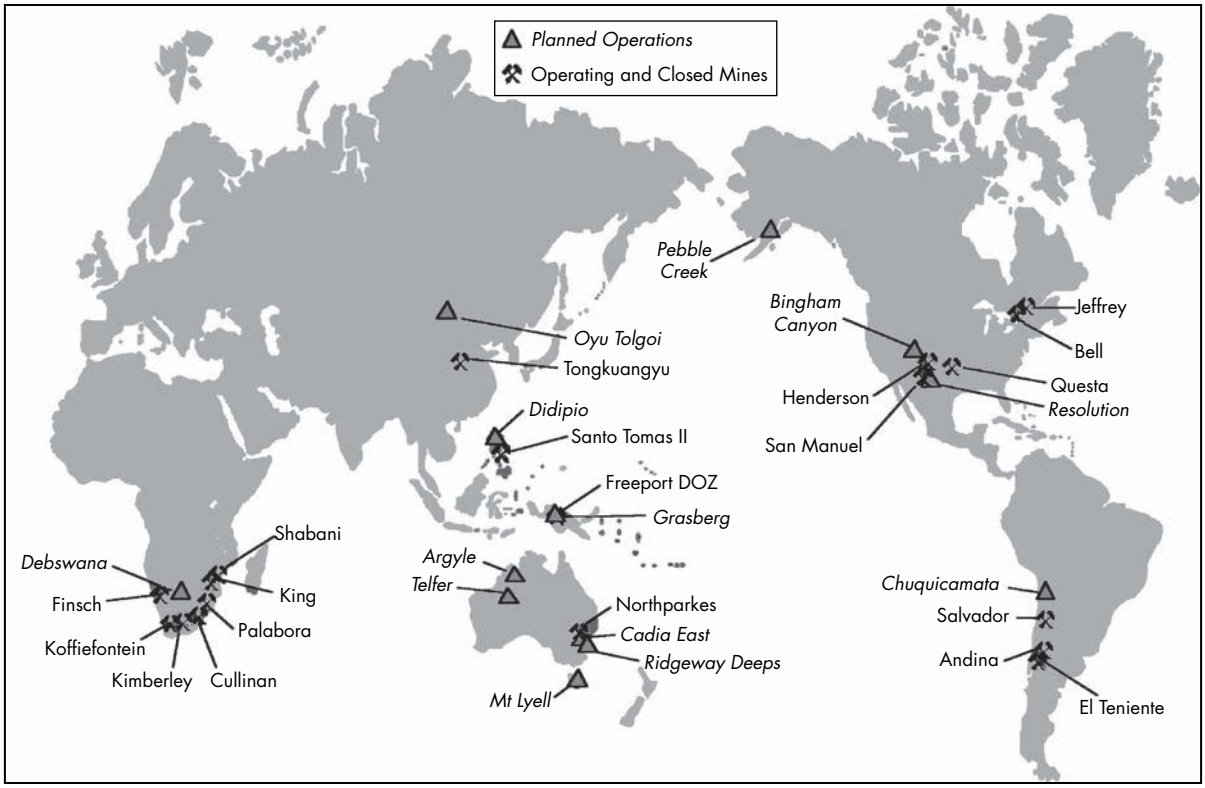
The block caving method typically allows for relatively large volumes of production after the mine has been developed and production ramp-up has been achieved. The preproduction development period can be significant (typically 5–10 years, depending on the length of time to achieve the initial access). The up-front capital required prior to any return on investment is very high because much of the production levels and infrastructure must be in place before caving can begin. After the mine has reached its sustained maximum production rate, the operating cost tends to be very low with minimal additional infrastructure required to maintain the high production volumes. Block caving is generally the least expensive of all underground mining methods, and can in some cases compete with open-pit mining in cost.

The proceedings from the MassMin conferences, held every 4 years, are outstanding sources of case histories as well as theoretical discussions of block caving. Many of the discussion points in this chapter are drawn at least in part from the many excellent papers in those proceedings. The two latest proceedings are from 2004 (Karzulovic and Alfaro) and 2008 (Schunnesson and Nordlund). An excellent reference book on the geotechnical design aspects of block caving is *Block Caving Geomechanics* (Brown 2003).

CURRENT AND PLANNED CAVING MINES

Figure 13.10-1 shows the worldwide distribution of active and planned block and panel caving mines. A number of the planned mines will be developed under very large open pits that will be exhausted in the next 10–15 years. Thus, many of the planned caving mines will be very large deposits, mined at greater depths.

As technology improves, the trend is for higher production rates in these deposits. The largest caving mines in the world in 2009 were producing in the range of 75,000 t/d (metric tons per day) from a single footprint. At the same time, mining complexes such as El Teniente in Chile were producing 130,000 t/d from a number of production blocks. Planned production rates from future mines are as high as 160,000 t/d, indicative of the evolution of caving mines into "rock factories" capable of these high production rates.



Another trend in the future is for increasing mining depths, as the new "super caves" are developed beneath the open-pit mines and other undeveloped deep deposits begin to come on-line. As technology improves our ability to manage issues in deep mines such as in-situ stress, temperature gradient, and more competent ore bodies, this trend is expected to continue. Currently, caving mines are being contemplated in excess of 2,000 m deep.

ORE-BODY CHARACTERISTICS

As for any mining method, determining the applicability of the caving method must consider many different aspects, including the location, type, size, geotechnical characteristics, and value of the ore body. No single formula can be readily applied to determine the suitability of an ore body to a particular caving method.

The caving method is typically applied to large, fairly flat-dipping ore bodies, or porphyry-type ore bodies, with rock

mass characteristics that are amenable to sustainable, large-scale, rock mass failure (caving). The lateral extents of the ore body must be sufficient to both establish and sustain the cave. The required dimensions to achieve this will vary and depend on key characteristics such as rock strengths, fracture frequency and orientation (fragmentation), and in-situ stress conditions. The height of the ore columns must be sufficient to pay for the costs of developing and maintaining the production levels from which the ore is extracted. At the same time, the ground conditions must allow for development of the mine openings required to exploit the ore body, as well as for proximal location of required infrastructure.

GEOTECHNICAL CHARACTERISTICS

The geotechnical character of the rock mass to be caved is a key factor in the ability to effectively initiate and propagate the cave and successfully and efficiently produce ore for life of mine. An understanding of cavability, fragmentation, and stress are primary elements in designing and operating a caving mine.

Rock Mass Characterization

During the process of mine method selection, a thorough understanding of the rock mass behavior is required in order to assess cavability, fragmentation, mine production level design, mine infrastructure design, and surface impacts. For this purpose, topics that require a thorough understanding include

- Geology, including geometry, lithology, and structural features of the ore body as well as the surrounding country rock;
- Hydrology, including surface features and groundwater flow models;
- Geotechnical studies;
- Rock mass classifications;
- In-situ stresses; and
- Discontinuities of the rock mass (faults, joints, bedding, etc.).

Cavability

The cavability of the deposit is a fundamental feature of mine design. Initiating the cave, and then sustaining the cave throughout the mine life, is critical for achieving the desired productivity and thus directly impacts the economics of the project. The cavability may be established through empirical comparisons of the rock mass to other known caving operations, numerical modeling, or both.

A key aspect of the cave design is the hydraulic radius (HR), which is a calculation of the area of the caved zone divided by the length of the perimeter. Geotechnical studies will determine the required HR to initiate the cave, and also the HR required to sustain the cave. This ties directly into the mine design, as the production blocks must honor the required HR for that deposit. In general, caves tend to grow laterally in a circular fashion trying to reach equilibrium. In contrast, long laterals with narrow leads (extended rectangles) may satisfy the HR requirement but may not cave until more area has been opened.

Fragmentation

The fragmentation characteristics of the deposit are perhaps the single most important geotechnical feature. Fragmentation

impacts most aspects of mine design and operation, including drawpoint size and spacing, equipment selection, production rates, draw control requirements, dilution, hang-ups, and mill throughput. Thus an accurate prediction of fragmentation is a key to a successful mine design, and yet this prediction is one of the more difficult to produce with confidence.

The fragmentation of a deposit changes over time, and all of the stages below must be considered in the mine design:

- *In-situ fragmentation* refers to the natural, unaltered blocks before any caving takes place.
- *Primary fragmentation* is the distribution of block sizes during initiation of the cave.
- *Secondary fragmentation* is the fragmentation that occurs as the blocks move through the draw column during mining.

Monitoring

Monitoring of the progress of the cave development is important for many purposes, including

- Safety by maintaining a reasonable air gap between the cave back and the cave muck pile;
- Initiation and development of caving in order to validate the conceptual models, but also to allow modifications to the design as required by that information;
- Stability of the production and infrastructure areas in order to react to issues such as areas of excessive convergence; and
- Surface subsidence monitoring.

BLOCK CAVE MINE DESCRIPTION

Following is a discussion of block cave mine planning that offers additional details about the layout of a block caving mine.

Mine Layout

A block caving mine consists of several horizontal operating levels—the undercut level, extraction level, service/ventilation level, and haulage level. An additional level for drainage may be required, depending on water conditions in the mine.

Undercut Level

Undercut level designs depend on the method of undercutting chosen. Undercut methods are described in more detail later in this chapter. In the cases of pre- or advance undercutting, the undercut level is much closer to the extraction level and the major apex pillar is formed during the undercutting process. Post-undercutting usually places the undercut level drifts directly over the extraction level drifts and at the top of the major apex. Long-hole drilling and blasting is required for the formation of the drawbell in all cases but is sequenced differently according to method. Pre- and advance undercutting start with the extraction of the rings across the drawbell and create the angles of the major and minor apexes. This is followed by a final blast from the drawpoint to create the drawbell connection between the undercut and extraction levels. Post-undercutting has the opposite sequence, with the initial blast from the drawpoint, followed by a series of bell formation shots from the undercut level to create the drawbell. The final sequence of shot or shots will be the undercut rings, which will remove the remaining pillar material at the undercut inducing caving.

Extraction Level

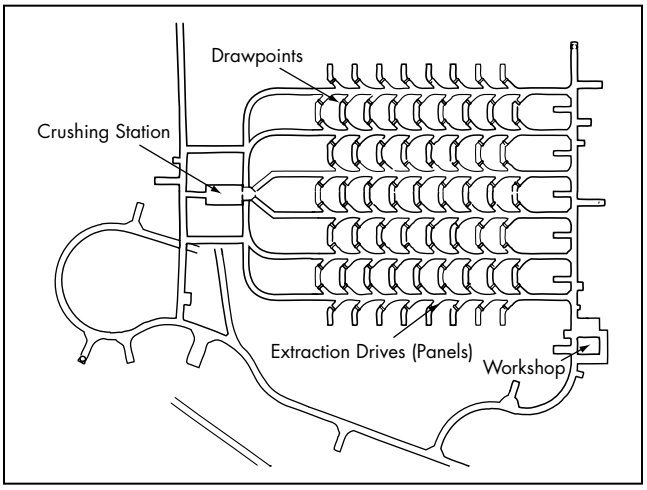
Although there are a variety of possible extraction level layouts, there are two main drawpoint layouts employed in the majority of current and planned caving mines: the offset herringbone and the El Teniente (or "straight-through"). Both methods have advantages and disadvantages that must be considered when selecting the layout.

Herringbone layout. Figure 13.10-2 shows an example of an offset herringbone extraction level layout. Herringbone designs are best suited when electric load-haul-dumps (LHDs) are to be employed because the mining direction is the same on both sides of a production drift. Electric LHDs also help minimize the ventilation requirements. This option tends to be used in smaller-footprint operations such as Northparkes (Australia) and Palabora (South Africa) that do not require the ore body to be split into multiple production blocks. The drawbell of the herringbone layout is rectangular and lends itself well to single-shot drawbell blasting.

El Teniente (or "straight-through") layout. In the El Teniente layout, the drawpoint drifts are developed in straight lines oriented at about 56°–60° to the production drifts and the major apexes. Figure 13.10-3 is an example of the straight-through layout at the Henderson (Colorado, United States) mine. The minor apexes are short and inclined to the major apexes. The El Teniente layout is generally considered to be more robust than comparable herringbone layouts because it has a better pillar shape.

From the development perspective, the El Teniente layout has advantages over the herringbone layout, especially in a panel caving operation. The El Teniente straight-through design allows for the drawpoints to act as temporary crosscuts and accesses or "pseudo fringes," well before final boundary drifts must be completed. The straight line drifts in the El Teniente layout make development more efficient and cost-effective, and potentially create less overbreak, especially around the nose pillar.

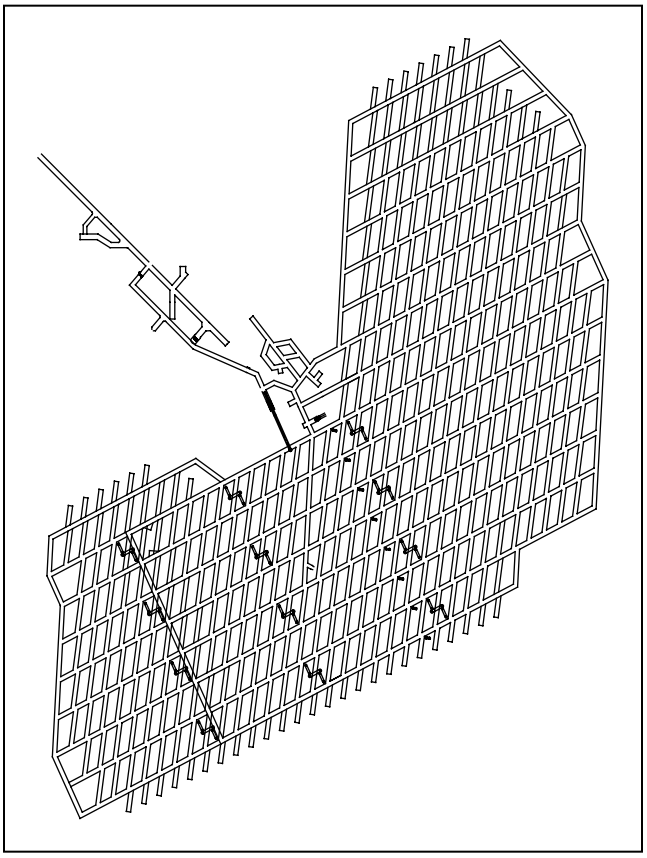
Temporary fringes can be achieved with the herringbone layout, but this is more difficult as the drawpoints are staggered and therefore the temporary fringe drifts are not straight. In addition, the boundaries of the panels in a large deposit become problematic. Such problems occur because if a fringe drift is established between panels, the width of the pillar between the herringbone layouts on either side of the fringe drift is excessive, and merging the caves across that pillar is very difficult and likely to cause excessive weight problems.



From a scheduling perspective, the El Teniente layout also has advantages over the herringbone layout. This is because a line of drawpoints outside of the planned production block can be used as a "temporary or pseudo fringe," and in this way development meters can be deferred. This also postpones construction of drawpoints, grizzlies, and chutes. Overall this would delay capital spending as well as reduce the risk of slipping on the planned schedule.

A significant disadvantage of the El Teniente layout is that it is impractical for electric LHDs using trailing cables. With a herringbone layout, the LHD can produce from all drawpoints in a production drift while facing the same direction. But with an El Teniente layout, the LHD will have to change direction for either side of the production drift. This will require additional lost productive time to disconnect and reconnect the trailing cable at the other end of the production

drift. The flexibility of having diesel equipment that can easily move to other areas or function in the mine is an advantage for El Teniente layouts. Of course, diesel equipment requires a higher ventilation airflow rate.



A safety concern in the El Teniente layout is with tramming the loaded LHD bucket-first. This restricts the operator's visibility 50% of the time because he or she has to operate the LHD in both bucket-first and engine-first positions in order to pull from all drawpoints. Secondary breaking units and pedestrians who access operating panels are examples of an increased risk that has to be managed in this case. Procedures are typically in place to protect pedestrians in a working panel and include lights, reflective personal protective equipment, and worker/machine proximity detection systems. A positive aspect of the El Teniente design is that the LHD operator always enters the drawpoints from his side of the LHD, giving him better visibility for safety and operational efficiency.

Another safety issue is the concern over the impact of a wet muck spill in an El Teniente layout. During a significant wet muck spill the straight-through configuration of the El Teniente layout can result in the LHD being pushed back into the adjacent drawpoint by the wet muck and being completely covered. This results in greater damage to remote-controlled LHDs and an extended time required for recovery of the gear from the muck spill. With the herringbone layout, the LHD is typically pushed down the drift and remains exposed. In either case, areas of wet muck would need to be worked by remote-controlled or automated LHDs, thereby eliminating any risk to the operators.

Service/Ventilation Level

The service/ventilation level is typical of a larger-footprint mine and is primarily a way to provide intake and exhaust ventilation across the production footprint for the undercut, extraction, and haulage levels. It also provides an access to these levels that is independent of production accesses and activities. Smaller-footprint mines will typically not require a separate ventilation level and will simply use the existing levels (extraction and haulage) to provide the required ventilation.

A large caving footprint is a very porous system from a ventilation point of view, with many accesses and cross connections in the preproduction and production areas. In order to provide reliable fresh air splits and exhaust connections, a series of ventilation plenums are required. This is usually via two ventilation levels (intake and exhaust) located between the extraction level horizon and the haulage level. This series of plenums are connected to vent raises that intersect the production levels in key points. The ventilation levels cover the extent of the footprint and are usually quite large-diameter drifts, which makes them good candidates for a service level. The service level can be used to access the haulage level in key areas as required for development as well as for construction and repair of haulage level infrastructure. This is especially important in a rail haulage system where independent rubber-tired access to the track is required for cleanup, construction, or maintenance work. The service level can also be used to assist with level drainage and waste haulage, and act as a conduit for services such as water, compressed air, and power.

Haulage Level

The haulage level design will be determined by the type of transportation method required—rail haulage, trucks, conveyors, or a combination of these. Each method has its advantages and disadvantages, which need to be carefully weighed in the context of that particular deposit before development begins because conversion after the fact is almost impossible.

The greatest advantage of rail haulage is its ability to move large tonnages in a single movement. This is especially

important if the material requires long-distance travel to either crusher systems or to a surface milling facility. Some of the drawbacks to this system include large capacity bins to accommodate train sizes, grade and curve radii restrictions, increased power consumption (for electric locomotives), track maintenance, electrical capital and maintenance, and potential production shortfalls as a result of disabled trains in the loading drifts or main haulage lines.

The greatest advantage of truck haulage is its flexibility. Trucks have the ability to maneuver in smaller areas and can be reversed in traffic flow if the need arises. Road maintenance is continual but not labor intensive, and generally a single disabled truck can be removed from the traffic flow fairly easily, thereby reducing production shortfalls. Another advantage of a truck haulage level is the ability to modify designs easily over the course of time if new reserves or discoveries come into play. The main disadvantages of truck haulage include significantly smaller payloads, which require larger fleet sizing, larger ventilation requirements, increased maintenance costs, more labor, and the inability to efficiently move large daily tonnages long distances. In the case of the Henderson mine, for example, a fairly confined truck haulage route to a centralized crusher feeds a 24-km conveyor system to the mill and has proven to be very reliable and productive.

Several small-footprint caving operations (e.g., Northparkes and Palabora) use a system of conveyors to gather the production material from multiple crushing stations onto a central conveyor that feeds production shaft hoisting.

MINING METHODS

The selection of the methods used to undercut and extract the ore from a caving operation are fundamental to the success and efficiency of the operation. Selecting the appropriate methods at the design phase is key, as making major changes in methodology after the mine is in production can be difficult and costly.

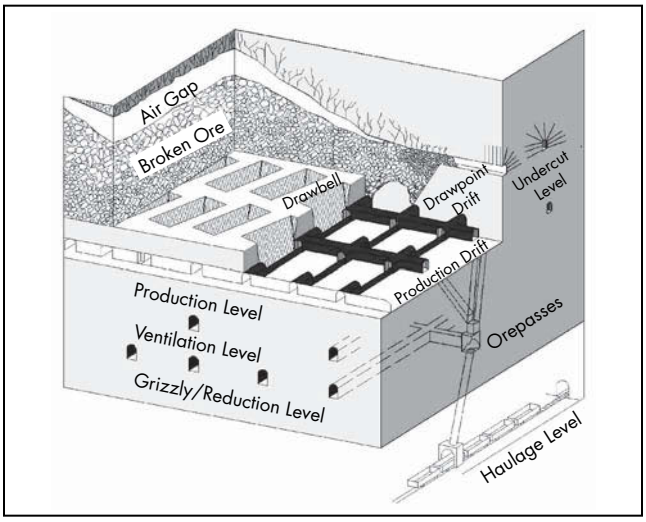
General Mining Systems

The key to designing a suitable mining system is to have a good understanding of the geotechnical characteristics of the deposit. In particular, the fragmentation of the deposit will control the width of the "draw cone" or area of influence of the drawpoint as the material is mined. The area of influence then determines the required spacing of the drawpoints.

The three principal methods of block caving are the gravity, slusher, and LHD systems. Historically, the gravity system was commonly selected for ore bodies consisting of finer material essentially free-flowing to the drawpoint. For somewhat coarser material, the slusher system was employed, while the LHD system was employed for relatively coarsely fragmented deposits. Today mines are moving toward higher production rates with greater reliance on mechanization and automation, and moving away from the labor-intensive gravity and slusher mucking systems. The majority of existing and planned block caving operations now use some variant of the LHD (rubber-tired) system of mucking. Of course, this assumes that the ground conditions allow for development of stable production levels that can handle the size of the equipment. The majority of this section is therefore devoted to the LHD mining system.

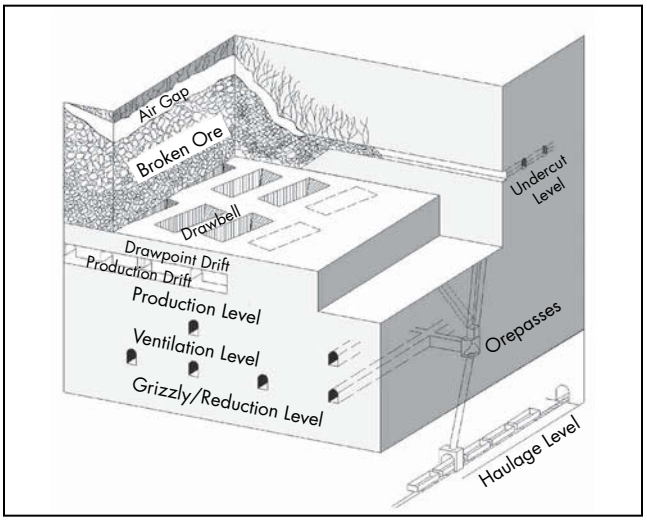
Full-Gravity (Grizzly) System

The grizzly system consists of the haulage level, transfer raises, grizzly level, finger raises, and undercut level. The haulage and grizzly levels are driven across the ore block to be mined. This work can be done simultaneously because they are on different levels. Finger raises are driven from the grizzly level to the undercut elevation, and then short horizontal connections are driven between the tops of the finger raises forming pillars that will later be long-holed and blasted to initiate the caving action. Transfer raises are driven between the haulage and the grizzly level with a loading chute at the haulage level and grizzly rails for sizing at the grizzly level. After the undercut has been blasted, broken ore flows down the finger raises and is sized by the grizzly rail spacing, passes into the transfer chutes, and is loaded into rail cars. Sledgehammers or semi-mobile rock breakers are used to break up oversized pieces at the grizzly. Some large pieces may hang up in the finger raises, and these are usually broken up by secondary blasting with packaged explosives placed strategically against the oversized rocks. The Andina copper mine in Chile is an excellent example of the grizzly system.



LHD (Rubber-Tired) System

The use of LHD equipment usually requires that the drawpoints be spaced at greater intervals to allow room for the equipment to operate. The larger equipment requires larger drift/drawpoint excavations, so larger spacing is also needed for pillar strength. The wider spacing is suitable for coarser rock; finer fragmented deposits may require tighter drawpoint spacing and therefore smaller equipment. This system consists of the haulage level, ore-transfer raises, the production level, drawpoint entries, draw cones to the undercut level, and undercut drifts. Long-holing and blasting is used to form the undercut that promotes caving. The large draw cone will allow larger pieces of ore to move down near the drawpoint where small drills and explosives can be used to break up the larger pieces; high hang-ups practically never occur with this system. The haulage, production, and undercut levels can be developed simultaneously using separate accesses. The haulage and production levels should be separated by a substantial distance to provide adequate storage in the transfer raises, so that the loading of the trains is not delayed waiting for the LHDs. When the haulage and production drifts are complete, the transfer raises and drawpoint entries can be driven. Drilling of the draw cones can be done from the drawpoint entries or from the undercut level. Freeport-McMoRan's Henderson molybdenum mine in Colorado, the DOZ copper-gold mine in Indonesia, and CODELCO's El Teniente copper mine in Chile are examples of mines that use the LHD system.



Undercutting Methods and Issues

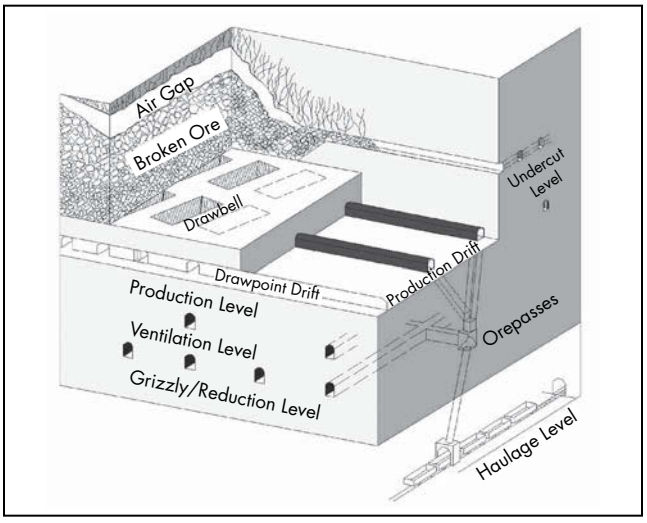
The undercutting strategy, design, and management are critical elements to a successful block cave mine. Some of the aspects of undercutting to consider include the following:

- Undercutting strategy (post-, pre-, or advance undercutting methods)
- Undercut design (initiation, direction, and shape of the undercut face, rate of undercut advance, and undercut heights)
- Shape of the undercut and extraction method (flat versus "crinkle" undercutting)
- Impact of the undercut design on stresses in the undercut and extraction levels
- Drill-and-blast designs for the undercut and drawbell

Courtesy of G. Flores.
Figure 13.10-4 Post- or conventional undercutting

Courtesy of G. Flores.
Figure 13.10-5 Pre-undercutting

Post-Undercutting



Post- or conventional undercutting refers to undercut drilling-and-blasting after development of the underlying extraction level has been completed (Figure 13.10-4). Drawbells are also prepared ahead of the undercut blasting. Production blocks can be brought into production more quickly than with other undercutting methods, and this method has been most successfully used on smaller mining footprints. Other advantages are that this system requires about half of the development on the undercutting level as the other undercutting systems. In addition, no separate ore-handling facility is required on the undercut level, because the ore is transferred through the already-developed drawbells.

The primary disadvantage is that the mine openings are all subjected to the abutment stresses when the cave front passes through during undercutting. The resulting damage to the major and minor apex can be substantial and reduces the effective life of the drawpoints and production drifts (or at least often requires repair work to maintain drawpoint integrity). Selection of this method requires careful consideration of ground conditions and stress issues. Drawbell blasting can be easier to recover from because the undercut is not yet blasted, but conversely, undercut remnant pillars (stumps) can be difficult to deal with. The drawbell can be mucked clean and inspected prior to undercutting.

Pre-Undercutting

In pre-undercutting, the undercut is mined ahead of the extraction level development (Figure 13.10-5). This allows the development of the extraction level in a destressed environment. This method is typically seen in small-footprint mines and in mines where ground compaction is not deemed an issue.

The pre-undercut can occur quite some distance ahead of the last drawbell, with a considerable amount of development and construction work carried out in the cave shadow area. The footprint has to be small enough that the pre-undercut does not sit idle too long, allowing the abutment stress to refocus on the undercut level or the extraction level through compaction. In addition, facilities must be developed to handle the swell muck from the undercut level.

Courtesy of G. Flores.
Figure 13.10-6 Advance undercutting

Advance Undercutting

Advance undercutting is increasingly popular and many future caving mines are planning to use this technique. In this method, the undercutting is completed above a partially developed extraction level (Figure 13.10-6). The extraction drifts, and in some cases all or part of the drawbell drifts, are completed before the undercut passes. When the undercut has passed, the drawbelling is completed. The crucial drawbell blast is thus completed in a destressed condition. Because significantly less of the extraction level excavation is completed in this method, damage to the pillars can be greatly reduced. The cave is brought into production more quickly than for the pre-undercut method, and the probability of damage from compacted undercut material is reduced.

Typically an advance undercut only extends ahead by the length of one drawbell, thereby keeping the active cave close to the leading edge of the cave front. If the caved undercut is left to sit for too long before taking the drawbell beneath, it

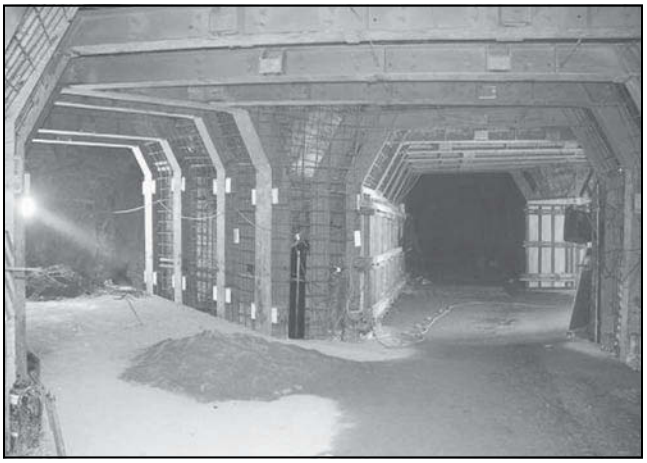


Figure 13.10-7 Extraction level under construction using an advanced undercut, DOZ mine, Indonesia

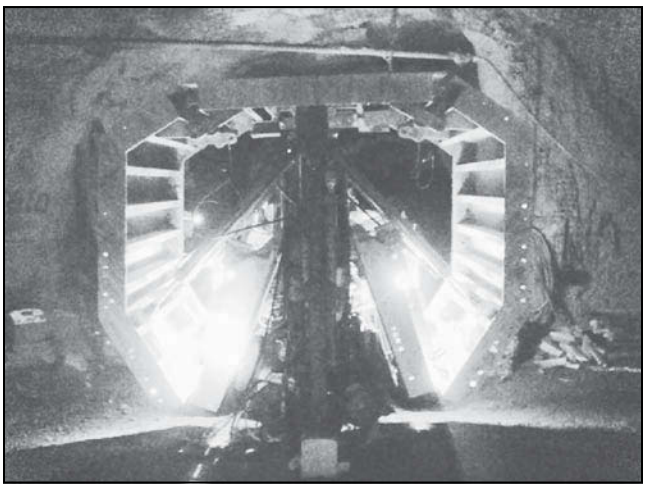

Figure 13.10-8 Drawpoint construction-forming jumbo, Henderson mine

can begin to compact and "accept" the weight of the ground above. The abutment stress is redirected to the undercut level and far less damage is seen on the extraction level.

A separate level for undercutting is required and typically has twice the development as the other undercutting methods. Because development and construction occur ahead of the undercutting and drawbelling, this method requires relatively greater up-front capital and use of development resources. It can be difficult to recover a drawbell if it is not blasted properly. If this becomes necessary, a hung drawbell needs to be drilled from the adjacent drawbell to the unblasted drawbell through the minor apex.

PREPRODUCTION DEVELOPMENT AND CONSTRUCTION

When initial mine development is complete, and depending on the geotechnical requirements for the area, a significant amount of preproduction ground support may be required in the extraction level to maintain panel and drawpoint integrity for the duration of the caving and production periods. The production period can last from 3 to 5 or more years depending on the drawdown rate and column heights. The ground support may, for example, consist of grouted threadbar (or cable) bolts, wire mesh, and shotcrete throughout the extraction area and will vary depending on ground conditions.

Preproduction work is followed by drawpoint construction, which typically consists of two lintel steel sets placed at the mucking point of the drawpoint to protect the brow and pillar from erosion by the caving material. The goal is to maintain the opening for the life of the ore column with a minimum of repair. Figures 13.10-7 and 13.10-8 show typical drawpoint construction. The lintel sets are often concreted and bolted in place, with the posts being set into concrete in the floor. The drawpoint and panel floors are typically concreted. Some operations choose to add surface hardening products and steel wear bars (often this is simply used rail) to prevent early floor wear from both mucking and tire wear by the LHDs. If the area has particularly poor ground, a full series of steel sets and concrete may be applied to the drawpoint and panel section in addition to the two lintel sets.

A typical drawpoint and corresponding section of panel may cost in the range of US$250,000 to US$500,000, depending on the level of support required. Designing for adequate drainage in the panels is key as water can play a major role in early floor cracking and wear. A good general rule is to keep panel roadways at a minimum 3% gradient to ensure adequate drainage.

Some mines are small enough that a separate ore handling level is not required (e.g., Palabora and Northparkes). Where the footprint is larger and the haul distance to the crusher is prohibitively high, a separate haulage level is employed. As the panel and drawpoints are being constructed, the relevant orepasses, ore handling systems, and ventilation infrastructure must keep pace. Orepasses can be drop raised, raise climbed (mechanically or manually), or raise bored down to a handling level. The top of the orepass is usually fitted with a grizzly and often a rock breaker for oversize material. Grizzly dimensions vary depending on the orepass size and handling method, and can range from 400 $\times$ 400 mm up to 1,000 $\times$ 1,000 mm openings for mines with the larger equipment that can handle material of that size. Grizzlies should be sized to the estimated fragmentation parameters; otherwise, excessive choking can occur and clearing the obstructing material will decrease the LHD efficiencies. Ideally, as much of the rock reduction or breaking as possible should be done at the primary crusher to reduce secondary breaking requirements on the extraction level. This requires the largest-sized grizzly openings that can be delivered to by the LHD without causing hang-ups in the orepass or other downstream systems. With a 1,000 $\times$ 1,000 mm grizzly the orepasses would need to be at least 4,000 mm in diameter, with chutes and transport systems sized accordingly. The DOZ mine in Indonesia initially used 1,000 $\times$ 1,000 mm grizzlies on a 4,100-mm-diameter orepass. These fed into large chutes and 55-t-capacity haul trucks that dumped at a 1,370 $\times$ 1,955 mm gyratory crusher.

Figure 13.10-9 shows a typical grizzly installation from the DOZ mine. The grizzly openings are 800 mm, feeding into a 4.1-m-diameter bored orepass. The bumper is 300 mm high.

The orepasses can vary in length and angle depending on the haulage level elevation. Orepass diameter is a function of grizzly size and expected material types. A good general rule is to keep the orepass diameter greater than three to four times the size of a grizzly opening to minimize the potential for hang-ups. The base of the orepass is fitted with a typical lip and gate chute arrangement that is used to load either trucks

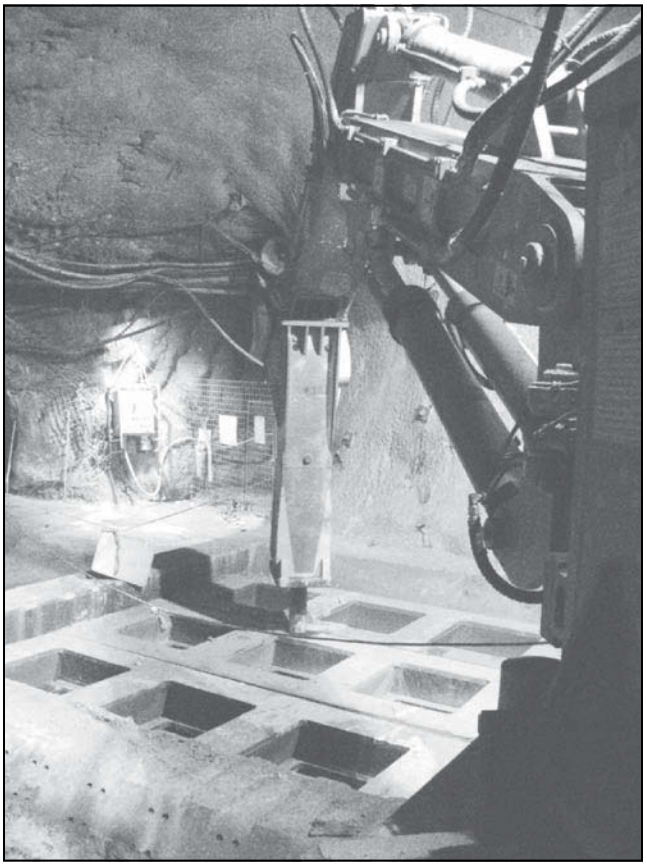

Figure 13.10-9 Grizzly installation example at the DOZ mine

or rail cars with ore. Where the broken ore is fine enough, a feeder may be used to load onto coarse ore belts. The haulage level delivers the ore to a primary crusher from which it is transferred to the surface by means of conveyor, hoists, or rail (as surface topography permits).

PRODUCTION

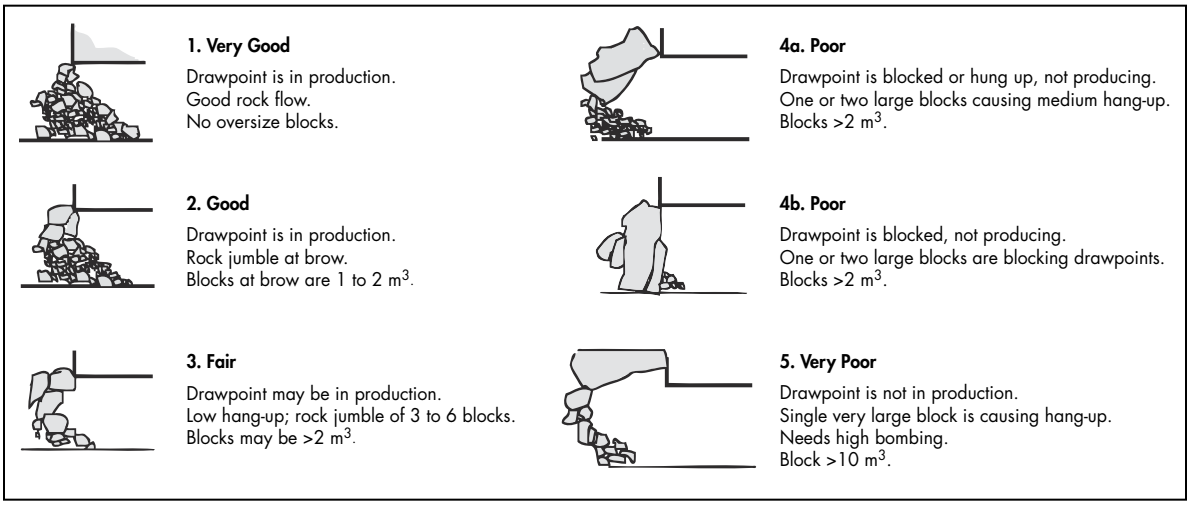
The production rate of a caving mine plays a major role in the required infrastructure, the time to ramp up to full production, and the drawpoint opening requirements. Selecting the production rate is one of the primary mine design variables required early in the process.

Capacity

A primary benefit of block cave mining is the high production capacity relative to other underground mining methods. Some of the larger caving mines in the world are producing up to 75,000 t/d from single mining blocks (the DOZ mine in Indonesia), and mines operating in multiple mining blocks are producing greater than 130,000 t/d (El Teniente, Chile).

Those upper limits will continue to grow as more and more of the large open-pit mines in the world transition to underground mining and the technology for large-scale underground production improves. Mines are being planned today that will exceed 150,000 t/d when at full production.

Setting the sustained maximum production rate for a caving operation is a key variable in the mine design process. The production rate is driven by several criteria: the rate of drawpoint opening, the rate of draw (t/d per drawpoint), the height of draw (HOD), the life of each drawpoint (calculated from the previous two variables), and ventilation and ore-handling constraints. The latter two variables typically act as a step function in production capacity, as the addition of either ventilation capacity or ore-handling infrastructure results in a significant step-up in production capacity for a mine. The goal is to ramp up production to achieve a production rate that is sustainable over a period of time, in the order of 7 to 10 years. That may be less than a potential maximum production rate, because it would not make economic sense to ramp up to some maximum rate only to have production immediately fall back as the mining block begins to become depleted. Commonly, the construction of drawpoints proves to be a primary limiting factor in the production ramp-up.



The maximum possible production may not be the economically best option, and an analysis of the economics of the mine plan needs to be considered. For example, should an inordinate amount of incremental capital be required to achieve a modestly higher production rate, cash-flow analyses would indicate that the optimal plan would be for the lower production rate.

Daily draw rates commonly range from about 150 to 600 mm. The allowable safe rate of draw depends on the rate at which the ore will cave. Drawing faster than the cave rate can result in an "air gap" that can produce conditions for a dangerous air blast should the cave fail suddenly. Coarsely fragmented material typically caves more slowly than weak, more finely fragmented material. In addition, coarsely fragmented ore will require extra effort in secondary blasting of oversize material and hang-ups, affecting the average rate of draw for those drawpoints.

Drawpoints at the leading edge of the cave are commonly mined at significantly lower rates to allow for new cave growth and to minimize opening of an air gap at the leading edge. In addition, draw rates can change over time for a given drawpoint; as the draw column is pulled, the material commonly becomes finer-fragmented through comminution in the column. Typically, early in the life of the drawpoint, very slow average draw is achieved due to coarse fragmentation and the resulting oversize and hang-ups that need to be dealt with. Most block cave planning tools use some sort of production rate curve that takes the change over time of the draw rate into account, so that the production capacity of the mine is not overestimated.

Another major consideration in determining the optimal production rate for a caving operation is the manner in which the cave is advanced in the ore body. Large deposits cannot be caved in a single pass because the advance of the cave front is slowed by the limits of the drawpoint opening rate, and the cave fronts themselves get excessively long. Long, slow-moving cave fronts generate a range of geotechnical issues that can be very damaging to the mine (Araneda and Sougarret 2007). Thus, the larger footprints must be divided into smaller mining blocks that can be caved and managed effectively, which limits the risk of excessive geotechnical issues. Larger deposits will require multiple caves that at times will be adjacent to or merged with other blocks. The issue then becomes one of production block design and drawpoint opening sequences that allow for an overall sustained production rate and at the same time are geotechnically achievable.

The maximum HOD varies from deposit to deposit and commonly ranges from 200 to 400 m, although column heights of >500 m have been achieved. The limit depends largely on

Source: Srikant et al. 2004.

Figure 13.10-10 Drawpoint rating system at DOZ mine

the ability to maintain the drawpoint and production drifts in good and safe operating condition. If a drawpoint is well constructed, excessive stress conditions avoided, and an even draw maintained, the life of the drawpoint can be maximized. It may be necessary to repair or rebuild a drawpoint for higher draw columns more than once, which is a common occurrence in mines with high column heights.

With a good estimate of the maximum sustained production rate and the life-of-mine production profile, the size and quantity of the major ore-handling and ventilation infrastructure can be designed.

Drawpoint Opening Rates

The rate at which an operation can open new drawpoints controls the production ramp-up as well as the full production rate that can be sustained. If the number of new drawpoints does not equal or exceed the number of drawpoints closed for depletion or due to damage, then production cannot be sustained. Commonly the development and construction of the drawpoint is the critical path to drawpoint opening rates. Undercutting and drawbelling can generally keep up with the pace of drawpoint construction.

For example, a typical maximum sustained rate of drawpoint opening for the DOZ mine is 10 drawpoints per month (usually referred to as five drawbells). The Henderson mine typically opens four to six drawbells a month, although the mine has peaked at higher rates.

Drawpoint Opening Sequences

Few aspects of the design of the block cave mine are more critical than developing a workable drawpoint opening sequence. The drawpoint opening sequence determines the order in which the ore is extracted. Where possible, preference is commonly given to the higher-value zones of the deposit. However, equally importantly, the sequence determines the shape and direction of the advancing cave and, for larger mines, determines how the production blocks interact with each other as the mine life progresses. It is critical to devise an opening sequence that is geotechnically sound; otherwise, the production goals, and perhaps even the mine itself, can be put at risk.

The mining sequence on a large-footprint cave will also drive the development and construction schedule. With a smaller footprint (e.g., Northparkes), the whole mine can be developed and constructed prior to caving. On larger footprints (e.g., DOZ, El Teniente, or Henderson) the development and construction of the levels takes place on an as-needed basis ahead of the caving front. This reduces early capital expenditures and smoothes development and construction activities. Overextending development in a large, active cave can often cause ground control problems in the open areas, especially if they sit for extended periods of time in stressed ground ahead of the cave front.

Production Issues

Cave fragmentation is a key issue, as the amount of ore that requires secondary breaking is a major factor in the ability of the mine to reach and sustain its maximum production level. Coarse fragmentation can give rise to high, medium, and low hang-ups in the drawpoints as well as excessive secondary breaking at the grizzly. Figure 13.10-10 shows the types of hang-ups that may occur.

Low hang-ups are dealt with using smaller drills and can be easily reached by the operators. Often nonexplosive breaking techniques are used to prevent damage to the drawpoint and lintel set area. The same mechanism can be used to break oversize material in the drawpoint or material too large to go through the grizzly. Mobile rock breakers and fixed rock breakers at the grizzly areas are also employed for secondary breaking.

When a drawpoint has been caved, accessing the drawpoint past the lintel set is too dangerous as it exposes personnel to falling rock. Longer-reach equipment is required to deal with intermediate and high hang-ups past the lintel set. An intermediate step is the use of a water cannon to “sound’ the hang-up and often bring it down by dislodging key sections. These units consist of mobile water tanks with a high-pressure water nozzle fitted to a robotic boom.

Medium-height hang-ups are dealt with using single-boom jumbos and harness remotes to drill holes in the key rocks. In some cases high bombing will be used without drilling. A bundle of explosives is tied to the end of a series of

blasting sticks and placed at key intersections of the hang-up to dislodge and bring the arch down. This process is high risk, however, as personnel spend considerable time around the front of the drawpoint and are exposed to potential falling and bouncing rocks.

In a high hang-up, the coarser fragmentation "jumbles" together inside the drawbell at a height above about 8 m. These are very rare occurrences and are handled using remote long-boomed drilling and charging rigs or by drilling through the major apex and blasting the larger rocks.

Ventilation

There are several components to ventilating a caving operation that bear particular attention. Planning these components into a general scheme early on will reduce operational trouble at a later stage. Because multiple LHDs will be operating in parallel galleries, sufficient air must be provided to support this. Regulation and control of the airflows becomes critical (especially with diesel equipment) in order to maintain appropriate levels for emissions and heat. Additional volume is also required in panel caving operations to support the development, drawpoint construction, and shotcrete/concrete operations that will be in the same panels, albeit upstream from the production.

Depending on the form of undercutting, more parallel paths on the undercut level will need to be planned for. This needs to be done years ahead of the actual caving. Henderson mine designs, for example, take several paths across the panel at set intervals to allow for the changing of the main intake as the caving advances. The intake level uses loop connections so that the airflow is equalized across the width of the panel and will not starve the last intakes to the production level at the end of a drive. Likewise, as the cave progresses over a long length, proper design can allow for the conversion of the intake paths to an exhaust path at the back end, thereby reducing the overall requirements to a boundary drift.

Another aspect that deserves attention is the orepass connections to the exhaust for dust mitigation. Every time a bucket of muck is dumped, dust will congregate at the orepass and potentially move downstream in the main drift. This not only causes visibility issues but also compromises the filtering and air conditioning systems on the LHDs. By connecting to the exhaust level, either at intercepts or through other channels, regulation of air can be accommodated to cause a slight drawdown, pulling the dust out of the production drift without compromising the overall airflow downstream of the orepass. In small-footprint caves, orepasses can be designed in the middle of the production drifts and, if connected to the main exhaust, will allow two LHDs to operate in the same panel from opposite ends without interference.

A final prudent design consideration is to have direct exhaust connections around any and all underground crusher stations. Often multiple accesses for high production rates are designed at these stations without proper assessment of the ventilation requirements to support them.

Automation

Caving mines lend themselves to automation due to the regular drawpoint layouts and fairly consistent nature of the production operations. Several caving mines employ automated LHDs on the extraction level (e.g., the DOZ and El Teniente mines) and in some cases automated trucks (e.g., the Finsch mine in South Africa) and rail (e.g., El Teniente) on the haulage level. Many aspects of rail haulage systems are automated and can typically be managed from a remote control center. The automated equipment operates in isolated areas to prevent worker/machine interface issues. Automation is employed to improve productivities and reduce exposure of operators to injury. In certain mines the risk of rock bursting or wet muck rushes is great enough to warrant the removal of the operator from the panel area. These areas have been typically operated using remote control stations, but automated technology provides better guidance for tramming than manual remote control. The automation uses scanning lasers mounted fore and aft on the LHD to scan and remember the tunnel profile on a single horizontal section. This allows for greater LHD speeds and less damage from side wall collisions. The buckets still require manual remote loading using cameras, as the muck type and size have been shown to be too variable to allow automation of the bucket-loading process. The isolation of areas due to remote and automated loading can cause productivity issues as all automated equipment is shut down when personnel are present for drawpoint sampling, inspection, secondary breaking, and so on.

Typical Equipment

Production in rubber-tired operations today is fairly standardized around the LHD equipment. These may be electric- or diesel-driven, both having their advantages and disadvantages. Small footprints and herringbone drawpoint designs favor the electric LHD, which also requires significantly less ventilation support. Diesel-driven LHDs have more versatility to move anywhere and can be used for more than production mucking. However, they do require significantly more ventilation. Newer regulations for dust, noise, and diesel exposure are also driving operators to use enclosed, air-conditioned cabs, which reduce some visibility but definitely give the operator a much-improved working environment. Capacities will vary, depending on ore characteristics and drift sizing, but generally range from 8 to 14 t in load capacity for most caving operations. Some of the super caves plan to use 17-t LHDs.

Production haulage is typically by truck or by train. In the case of trucks, most are end-dump designs in the 40–60 t range. These smaller trucks are designed more for development haulage but are being used in a production mode in many mines. PT Freeport Indonesia's DOZ operation employs 55-t-capacity trucks. The Henderson and Andina mines operate 80-t side-dump trucks, which have good haulage characteristics, but only on level ground. They are designed for production haulage only and cannot easily negotiate ramps when loaded.

Trains will be sized according to production requirements. The larger block cave mines using rail will typically use full-size rail equipment with a rail gauge of 1.4 m. For example, the El Teniente operation produced more than 130,000 t/d in 2008 using electric locomotives ranging from 72 to 130 t for ore haulage. Each of the five coarse ore trains hauls 18 bottom-dump railcars at 100 t per car. Another large caving operation plans for trains with two 40-t locomotives and 24 cars at 30 t per car. Rail systems lend themselves very well to automation and, in the right environment, can have much lower operating costs than haul trucks.

Several varieties of long-hole drills exist, and newer computerized versions are available. As with most other equipment, new regulations for operator exposures are pushing operators to use enclosed-cab drills. Undercut drilling requires

these drills to have the capability of 360° rotation. Some drills have the enhanced ability to drill at forward angles from the perpendicular, so that the same machine is able to drill the V-cuts as well as undercut rings. Depending on the method of undercutting (explained in previous sections), other drilling equipment such as blind-bore machines or raise machines will be required for the bell relief slot raise.

In addition to the primary production equipment, a wide range of support equipment is used to develop and support production needs. In direct support are the secondary drills and rock breakers used to deal with hang-ups and oversize. Although these types of equipment may seem of lesser importance at first glance, they are probably among the most valuable tools for maintaining high production. The ability to efficiently clear choked or hung drawpoints has a huge impact on the ability of LHDs to meet draw-control parameters and production requirements. Storage of boulders for secondary blasting not only detracts from a LHD's primary function of production but requires removal of the LHD from mucking operations to load and blast this oversize. A variety of smaller drills and breakers are on the market, but no standardized methodology has arisen as yet to combat these issues. Some particular examples of this style of equipment were described in a previous section.

Also to be considered is the variety of equipment that supports the development and general operation of the mine. In particular, the concrete/shotcrete delivery systems are an integral part of maintaining appropriate development leads and ground support. Shotcrete placers, concrete pumps, drawpoint-forming equipment, and concrete transporters are critical components of the mobile fleet. Concrete/shotcrete batching systems, whether surface or underground, and the support needed for material storage are major considerations in infrastructure design to ensure a smooth operation.

Miscellaneous support equipment for moving workers, materials, and utilities throughout the mine should also be given careful thought. Forklifts, lube/fuel trucks, high-lift trucks for hanging utilities and ventilation fans/ventlines, water trucks for dust suppression, cable trucks for power runs, and service trucks for localized construction should all be understood and planned for. These types of units are as critical as production equipment for keeping the operation working efficiently and minimizing disruption to production.

Support equipment for rail haulage operations typically includes smaller (12-t) locomotives, often diesel-powered so as to be independent from issues with the electrical power supply. Functions handled include shift change, track repair, cleanup under ore chutes, switching and marshalling, electrical and control maintenance, and development support. In addition to the locomotives, a variety of flat cars, man-haul cars, and muck cars are used.

CAVE MANAGEMENT

The ultimate goal of the cave management functions is to safely maximize the recovery of the ore reserves. An effective cave management system is critical to the block cave mine operation and has an active role in virtually all phases of the mine. From the calculation of mining reserves and development of the production forecast, the drawpoint opening schedule is developed. The development drifting, construction, and undercutting plan are then based on that schedule. As caving proceeds, draw orders are developed that will pull the cave evenly to avoid early dilution, while managing issues such as drift convergence, rock bursts, areas of high stress, excessive dilution, water inflows, and the like. The cave must be monitored and plans altered to account for any issues that arise.

Reserves, Reporting, and Forecasts

The initial ore reserves are established during the feasibility and detailed design period, which sets the target production rate and guides the mine layout, design, and development and production schedules. Typically, mine planning and scheduling software is used.

Production forecasting is a critical process in cave management. The metal to be produced from the mine is the ultimate goal for the caving operation, and so as accurate a prediction as possible is required. Forecasting is an ever-evolving process. As mining proceeds and more is learned about how the cave is progressing, it is necessary to modify forecasting assumptions to match predicted to actual metal recovery as closely as possible.

As the ore body is mined, production data is tabulated and reported. This information must be reconciled back to the predicted tons and grade, as well as to the actual tons and grade received by the concentrator facility. These reconciliations provide key data on the modeling of the draw behavior of the cave, which in turn feeds into both the forecasting and reserve models.

Tracking the Progress of the Cave

How the cave progresses has a major impact on what can be expected from the drawpoints and so provides a constantly changing input into the forecasting process. Geotechnical monitoring provides input on the overall geometry of the cave. Geological observations at the drawpoints are reconciled back to the in-situ geological models that determine key parameters for modeling the draw such as the dilution rates and draw cone interaction.

Managing the Cave

When issues such as excessive weight problems or wet muck develop, modification of the draw in the problem areas can often alleviate or eliminate those issues. It is therefore important for cave management to understand and react to those issues. Special draw orders for specific drawpoints might be issued to address those issues. For example, a hung-up drawpoint might be causing excessive weight in a production drift, so orders are implemented to prioritize blasting of that hang-up. Extra tons might be pulled from that drawpoint and surrounding drawpoints for a period of time until the condition is stabilized. For a drawpoint with wet muck, a priority will be placed on pulling ore from that drawpoint, which helps to pull the water from the cave and prevents the water from spreading to additional drawpoints.

Draw Control

Draw control is an essential component in the caving process. Controlling the shape of the cave back and keeping the drawdown of the cave even and controlled will minimize cave issues such as early dilution, accelerated breakthrough to older workings, and excessive air gaps. Proper cave draw will improve the prediction of ore grades for the diluted block model. Draw control is managed by setting daily draw orders for each drawpoint in the mine. A record of draw is held in a database and regularly compared to the plan. Corrections in the short-term draw order are made to keep the draw control

in line with the long-term plan. Systems to monitor draw from each drawpoint can range from a manual form filled out by the operator on an honor system or an electronic tagging system where every drawpoint has an individual tag that registers with a reader on the LHD every time a bucket is taken.

Drawpoint sampling is performed based on tonnage drawn and the HOD. Frequency of sampling is typically increased as a drawpoint nears the end of its life so the drawpoint can be closed as required to prevent overdilution. Sampling involves personnel manually sampling each drawpoint using some form of a sampling grid. Although this statistically tends to be quite a poor sample, it is a good indicator of drawpoint grades and can be compared back to the model to ensure a reasonable correlation.

CAPITAL COST CONSIDERATIONS

Caving operations typically require a significant commitment in up-front capital expenditures, and capital development for a caving mine requires a long lead time. The mine accesses and infrastructure, as well as sufficient portions of the operating levels, have to be in place before caving begins. This is particularly true for the current and planned super caves exceeding 100,000 t/d, Some of the deep deposits may take several years just to establish access and ventilation to the deposit, followed by multiple additional years developing the mine infrastructure. Once production is initiated, the time required to ramp up to full production is significant. As an example, a mine with a planned full production of 100,000 t/d may require 5 years after caving is initiated to reach that objective. Thus for a large caving operation, the lead time from initial access development to full production can be 10–15 years.

Capital estimates are typically divided into the following:

- *Capital development*, which includes all preproduction and production buildup development and infrastructure required to bring the mine to its sustainable full production rate; and
- *Sustaining capital*, work required on long-term development, facilities, or systems to sustain full production operations, but not direct production costs.

A typical breakdown of capital development and sustaining capital components follows. A number of the categories are the same as for the operating cost breakdown; these costs are classified as capital or operating, based on whether or not full production has been achieved.

- Drifting and excavating:
  - Rail haulage, conveyor drift, material handling excavation
  - Ramps and accesses, fixed facilities (shops, lunchroom, etc.)
  - Extraction and undercut fringe drift; production drift, drawpoint drift, drawbell drift development
  - Production and drilling drift on extraction and undercut levels
  - Ventilation drift and accesses, mass excavation, dewatering drifts
  - Shafts, raises, ventilation raises, orepasses, and waste passes
- Preproduction:
  - Ground support
  - Drawbelling and caving
- Ground repair (drawpoint rebuild and repair, and production drift repair)
- Indirects (costs not directly allocated to production, such as ventilation, electrical, engineering, water control, and maintenance)
- Equipment and infrastructure:
  - Rail or truck haulage, or other ore-flow infrastructure
  - Drawpoint construction
  - Mobile equipment
  - Power generation
  - Fixed facilities (ventilation, pumping, batch plant, shops, offices, warehouses, compressors, etc.)

Table 13.10-1 Development capital requirements for an 80-kt/d block cave mine (in 2009 U.S. dollars)

Capital Outflows	$, in millions
Drifting and excavating	260
Preproduction	10
Ground repair	10
Indirects	
Technical services and management	50
Electrical (including power cost)	130
Safety and miscellaneous	30
Mechanical shop (including fuel cost and rebuild)	170
Equipment and infrastructure	
Haulage and ore-flow infrastructure	190
Mobile equipment	250
Power generation and distribution	100
Fixed facilities infrastructure	100
Total development capital cash outflows	1,300

Table 13.10-1 presents a generic example of development capital costs for an 80,000-t/d block caving operation to illustrate the distribution of costs by major category. These expenditures occur over about a 10-year period from initial access development through to full production.

OPERATING COST CONSIDERATIONS

Block caving is typically the lowest-cost underground mining method. This is principally because the amount of drilling and blasting per metric ton of ore is much less than with any other system. Once the cave is progressing, blasting is limited to secondary breakage of oversize material within a drawpoint. In addition, because permanent production levels are established from which all ore tonnage is mined, total development drifting per metric ton of ore is substantially less than for other methods. Block caving lends itself to a high degree of mechanization, both in the production areas and in the ore-flow infrastructure. The overall result is lower costs due to reduced requirements for labor, mobile equipment, and consumables.

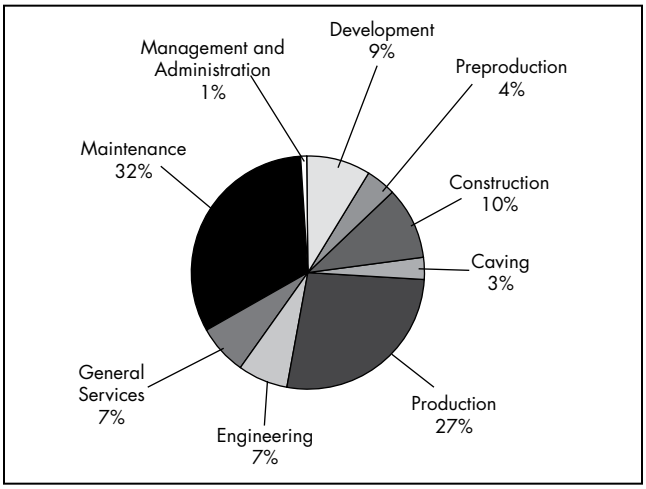


Table 13.10-2 is an example from an 80,000-t/d block cave mine operating in 2009, to illustrate the general distribution of costs by category. Of course, costs can vary widely from mine to mine because of many factors such as country of operation, ground conditions, infrastructure requirements, maturity of the mine, depth, and so on.

LABOR

Block caving mines can be highly mechanized and efficient operations, commonly achieving more tonnage per worker-shift than any other underground method, and potentially producing many times more tonnage per worker-shift. The initial labor required to develop a caving mine can be relatively high

Table 13.10-2 Annual operating costs breakdown for an 80-kt/d mine (in 2009 U.S. dollars)

Category	Direct Cost, $	
	in millions	per metric ton
Production	10	0.36
Development	16	0.59
Raises	5	0.17
Preproduction	12	0.43

Figure 13.10-11 Distribution of labor by category at the DOZ mine producing 50 kt/d

and is a factor in the early, high-capital expenditures typically required to bring a block cave into production. As major infrastructure items such as crushers, fixed facilities, ventilation, and ore handling systems are completed, labor levels will reduce down to a set of relatively specialized crews that focus on the repetitive activities required to achieve and maintain full production. These crews typically consist of (a) level development, (b) preproduction support, (c) construction, (d) caving, and (e) production. In addition, required support groups include management, engineering, geology, geotechnical, mine services, logistics, maintenance, and electrical crews. Most of these skill sets are common to most underground mining methods.

In a caving operation, the control and interaction of these different crews in a fairly constrained area can be a challenging task requiring clear management, good engineering, and seasoned supervision. Each of those key activities listed above requires careful scheduling to prevent the various crews from obstructing each other. In addition, the crews must work around interruptions such as scheduled and unscheduled blasting and shifting priorities to ensure that the cave is propagating well and being drawn correctly.

As the mine life progresses, activities such as development, construction, and undercutting will be completed before the mine is closed. Thus the number of different crews begins to decrease until finally the mine will be left with only production activities. In the case of small-footprint caves, all of the preproduction activities are managed by contractors, and production crews are quickly the only set of crews that remain. Northparkes Lift 1 was a good example of this with only 63 employees involved in production at 22,000 t/d as the mine had been fully constructed. In the case of the much larger-footprint DOZ mine, where development and preproduction activities continue on an actively producing and expanding cave front, labor levels remain higher for longer periods with approximately 1,800 personnel planned to produce at 80,000 t/d with only about one-half of the ore body developed. Figure 13.10-11 shows the labor distribution by category for the DOZ mine in 2005, when the mine was ramping up to a production rate of 50,000 t/d.

RISK CONSIDERATIONS

This section presents a review of typical risks in the block caving process. The first part discusses risks that present major operational hazards, and the second part discusses risks to consider when designing or operating a caving mine. A detailed discussion of the risk assessment process is beyond the scope of this chapter, but an informative section on operational hazards and risk assessment for block caving can be found in Chapters 10 and 11 of *Block Caving Geomechanics* (Brown 2003).

As with any mining project, a detailed risk assessment is required. Typically a *qualitative* risk analysis is initially completed to identify potential risks to the project, assess the likelihood and consequences of those risks, and develop an action plan to mitigate or eliminate the identified risks. A *quantitative* risk assessment, where a cost is calculated for each risk should its consequences be realized, could then be completed.

Major Operational Hazards

Major operational hazards that could result in loss of life or premature mine closure and are associated with caving methods include (1) issues with "inrushes" such as air blasts, mud rushes, or water; and (2) issues with stability of the underground workings, such as rock bursts or major excavation collapses.

Inrushes

An *air blast* may occur when the draw rates exceed the cave propagation rate, so that an air gap develops in the cave (prior to propagation of the cave to surface). Should the cave back then experience a large enough failure into the air gap, the compression of the air in that confined space can produce a rapid flow of air through exposed underground openings and can produce a violent and damaging air shock wave.

A *mud rush* is a sudden inflow of saturated fines from the drawpoint or other underground openings. A mud rush can occur when water builds up within caved material that contains sufficient potentially mud-producing materials. The inrush is then triggered by a mechanism such as production from the drawpoint, blasting, or seismicity. The sudden inflow puts at risk the personnel in the path of the mud rush. Mud rushes are a fact of life in caves with the appropriate conditions and must

be managed to mitigate the risk to the people and to the operation. For example, automated or remote-controlled loaders can be used to produce from the wet areas. A key is to attempt to keep the material moving in the wet areas to minimize the buildup of the wet material and prevent the event from spreading further into the cave.

An external mud rush might occur when the cave breaks up into a saturated zone of material such as a tailings or slimes retention area, or perhaps a backfilled zone from an upper lift of the mine. Tailings or slimes ponds should never be sited over caving areas as catastrophic failures and inrushes can and have occurred that can claim hundreds of lives (e.g., West Driefontein in South Africa and Mufulira in Zambia).

Underground Stability Issues

A *rock burst* is an underground seismic event that, depending on its scale, can cause violent and significant damage to excavations in the mine. Rock bursts are the result of stored strain energy that is released suddenly into the rock mass. The induced stresses are high enough to overcome the strength of the rock mass and the released energy cannot be absorbed in slips or fractures. Rock bursts will usually occur only in strong, brittle rocks such as quartzite or granite. Effects include violent fracture and expulsion of rock from and near the boundaries of excavations, and the full or partial closure of mining excavations. Damage can range from localized spalling in a drift to complete destruction and closure of a part of the mine.

Current and planned caving mines are tending toward deeper, higher stress conditions, and in stronger and more brittle rock. Thus it is expected that the risk of rock bursts in future caving mines is an issue that will have to be addressed.

An additional type of collapse is stress-induced, but unlike a traditional collapse, it is generally progressive rather than sudden and violent. Collapses of this type are typically caused by the stress abutment produced ahead of the undercut; this is sometimes referred to as "weight" problems. This type of collapse involves failure of the pillars left on and above the extraction level. It may take weeks or months to develop and once initiated is difficult to arrest, although some mines have had success by overpulling from drawpoints within the stressed areas. Such collapses are exacerbated by the presence of faults or other discontinuities in the rock mass, by a change in rock type, or by incomplete blasting in the undercut level that leaves a "stump" or remnant that puts excessive stress (point loading) on the major or minor apex.

Major Risk Categories

The following subsections address major risk categories that must be considered during the planning and operation phases of a caving mine.

Geotechnical Issues

Most block caving operations, which tend to be large in size and occur at considerable depths below the surface, are difficult to explore completely in advance of having to make a development decision. Virtually all aspects of the mine design—from level designs, ground support criteria, ore-flow systems, equipment fleets, and so on—depend on a design that correctly incorporates the geological and geotechnical aspects of that deposit. Therefore, a considerable number of risks are present in the category of geotechnical information. A few of the potential risks include

- Cavability—An assumption that the ore will cave completely and in a predictable manner.
- Fragmentation—Underestimation of the fineness of the fragmentation that causes the drawpoint spacing to be too large, leading to isolated draw and loss of reserves. Underestimating the coarseness of the fragmentation can cause excessive hang-ups in the drawpoint, leading to excessive secondary blasting, and creating a bottleneck in an ore-flow system that was designed for fine fragmentation.
- Caving performance
  - **In-situ stress:** Underestimation of the stress levels encountered leads to inadequacies in ground support, mass excavation designs, and undercut sequencing.
  - **Undercut sequence design:** The geometry of the panels and the sequence of the undercutting are key components to the caving performance. Should the chosen design prove to be unstable, large portions of the production area could be lost and ground repair would be extensive, leading to lost or delayed production.
  - **Caving rate:** If lower than expected, ramp-up will be delayed.
  - **Cave shape:** If the developing cave fails to propagate as expected, excessive dilution could be introduced earlier than anticipated.
- Excavation stability
  - Panel excavations may be designed too large in areas of unanticipated poor ground conditions, resulting in too large a drawcone spacing and loss of reserves. The poor ground also leads to weaker pillars and excessive ground repair costs.
  - Location of the major underground fixed facilities relies on identifying adequate areas of good ground conditions in which to locate those facilities.
  - Orepasses are at risk as the cave front passes and must be designed to handle the abutment stresses.

Other Issues

The following are additional risk categories to be considered during planning and operation of a caving mine:

- **Fixed facilities design.** Infrastructure required to deliver workers and materials to the mine must be adequate for the production rates required. The ore-flow system must be capable of adequate ore delivery to the mill.
- **Environmental impacts and permitting.** If surface impacts exceed those anticipated, it could have an impact on the mine life or production capacity. For example, larger-than-expected subsidence areas that affect the surrounding area, or development of acid rock drainage exceeding that permitted, and so on.
- **Procurement.** Lead times for procurement of major components can be lengthy, leading to delays in mine development and production if not managed properly.
- **Labor.** Many future major block cave mines are scheduled to be developed and operated in similar time frames in the next few decades. Experienced labor, both in engineering and operations, may be limited when needed.
- **Safety.** For new mines, various aspects of the operation will comprise new types of facilities unfamiliar to the personnel, and will require training, familiarization, and supervision to minimize hazard exposure.

PART 14

Mineral Processing

CHAPTER 14.1

Introduction to Mineral Processing

Maurice C. Fuerstenau and Kenneth N. Han

The term *mineral processing* is used in a broad sense throughout this chapter to analyze and describe the unit operations involved in upgrading and recovering minerals or metals from ores. The field of mineral processing is based on many fields of science and engineering. In addition, environmental science and engineering have become inseparable components; the steps involved in mineral processing have to be founded not only on sound scientific and technological bases, but on environmentally acceptable grounds as well.

GOALS AND BASICS OF MINERAL PROCESSING

In the traditional sense, mineral processing is regarded as the processing of ores or other materials to yield concentrated products. Most of the processes involve physical concentration procedures during which the chemical nature of the mineral(s) in question does not change. In hydrometallurgical processing, however, chemical reactions invariably occur; these systems are operated at ambient or elevated temperatures depending on the kinetics of the processes.

The ultimate goal in the production of metals is to yield metals in their purest form. Mineral processing plays an integral part in achieving this objective. Figure 14.1-1 shows a generalized flow diagram for metals extraction from mining (step 1) through chemical processing. Steps 2 and 3 involve physical processing, and steps 5 and 7 involve low-temperature chemical processing (hydrometallurgy). All four steps are considered part of mineral processing. High-temperature smelting and refining (pyrometallurgy), steps 4 and 6, are not included under the heading of mineral processing.

Table 14.1-1 specifies processing routes from ore to pure metal for a number of metals. Processing routes can be quite different, and more than one route may be possible for many of these metals. For example, in the extraction of copper or gold from low-grade ores, dump or heap leaching is commonly practiced. The choice of this leaching practice is frequently driven by the overall economics of the operation. Because crushing and grinding of ores are quite expensive, leaching of ores in large sizes is attractive compared to the leaching of finely ground ores, even though the overall recovery of metals from the leaching of fine particles is, in general, much greater than that obtained with large particles. The introduction of this innovative leaching process has made feasible the mining of many mineral deposits that could not be processed economically through conventional technologies.

METALLURGICAL EFFICIENCY

One of the most important and basic concepts in mineral processing is metallurgical efficiency. Two terms are commonly used to describe the efficiency of metallurgical processes: *recovery* and *grade*. These phenomena are illustrated in the generalized process presented in Figure 14.1-2. In this example, 100 t/h (metric tons per hour) of ore are being fed into a concentration operation that produces 4.5 t/h of concentrate and 95.5 t/h of tailings. In upgrading this process, then, 1.0 t/h of the desired material, A, is introduced into the unit operation and 0.9 t/h (4.5×0.2) of this material reports to the concentrate, resulting in 90% recovery ($0.9/1.0 \times 100$). The grade of the mineral, A, has been improved from 1% to 20%. The term *percent recovery* refers to the percentage of the valuable material reporting to the concentrate with reference to the amount of this material in the feed. Sometimes obtaining the highest possible recovery is not necessarily the best approach in a concentration process. High recovery without acceptable grade will lead to an unsalable product and is therefore unsatisfactory.

Mineral processing engineers are responsible for optimizing processes to yield the highest possible recovery with acceptable purity (grade) for the buyers or engineers who will treat this concentrate further to extract the metal values. To achieve this goal, economic assessments of all possible technological alternatives must be conducted.

ECONOMIC CONCERNS

Table 14.1-2 summarizes the total U.S. supply and recycled supply of selected metals in 1996. Although the data shown here are historic (reprinted from an earlier publication), the trends are still current. The total supply of iron and steel includes supply from primary and secondary sources as well as imports; these two metals represent by far the largest of commodities produced and consumed, followed by aluminum,

*Only crushing is practiced; grinding is usually omitted.

copper, and lead. The recycled supply of these metals from processing scrap is strikingly high. In addition, the tonnage of precious metals consumed is rather small. However, because of the high prices of precious metals, their monetary value is substantial. For example, the monetary value of 516 t (metric tons) of gold was $12.8 billion in 1996, compared to $10.7 billion for 5.3 million t of copper and lead.

Table 14.1-3 lists the relative abundance of various metals in the earth's crust. Most metals are present in extremely small concentrations in nature, and none of these metals can

be recovered economically at these concentrations. Rock that contains metals at these concentrations is not ore; ore is rock that can be processed at a profit. An average copper ore, for example, may contain 0.3% to 0.5% copper. Even this material cannot be treated economically at high temperature without prior concentration. There is no way that rock containing 4.5 kg (10 lb) of copper and 903 kg (1,990 lb) of valueless material can be heated to 1,300°C (2,372°F) and treated to recover this quantity of metal economically. Concentrating the ore by froth flotation to approximately 25% or more copper results in a product that can be smelted and refined profitably.

UNIT OPERATIONS

Numerous steps, called unit operations, are involved in achieving the goal of extracting minerals and metals from ores in their purest possible form. These steps include size reduction, size separation, concentration (froth flotation, gravity concentration, and magnetic and electrostatic concentration), dewatering, and aqueous dissolution.

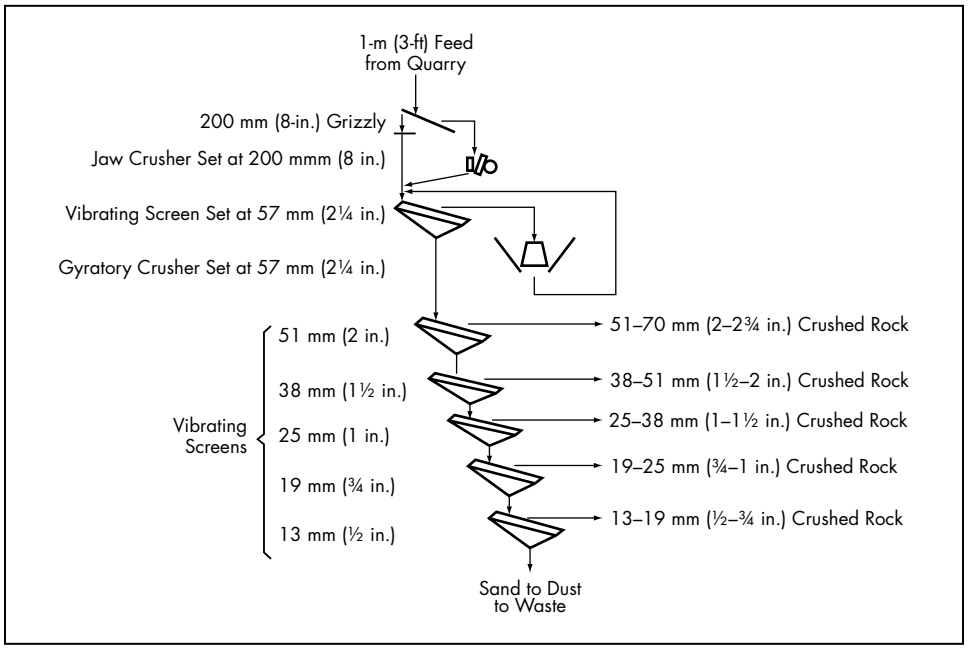

Figure 14.1-3 Flow sheet for crushing and grading rock

1. **Size Reduction.** The process of crushing and grinding ores is known as *comminution*. The purpose of the comminution process is threefold: to liberate valuable minerals from the ore matrix, to increase surface area for high reactivity, and to facilitate the transport of ore particles between unit operations.
2. **Size separation.** Crushed and ground products generally require classification by particle size. Sizing can be accomplished by using classifiers, screens, or water elutriators. Screens are used for coarse particulate sizing; cyclones are used with fine particulates.
3. **Concentration.** Physicochemical properties of minerals and other solids are used in concentration operations. Froth flotation, gravity concentration, and magnetic and electrostatic concentration are used extensively in the industry.
   - **Froth flotation.** The surface properties of minerals (composition and electrical charge) are used in combination with collectors, which are heterogeneous compounds containing a polar component and a nonpolar component for selective separations of minerals. The nonpolar hydrocarbon chain provides hydrophobicity to the mineral after adsorption of the polar portion of the collector on the surface.
   - **Gravity concentration.** Differences in the density of minerals are used to effect separations of one mineral from another. Equipment available includes jigs, shaking tables, and spirals. Heavy medium is also used to facilitate separation of heavy minerals from light minerals.
   - **Magnetic and electrostatic concentration.** Differences in magnetic susceptibility and electrical conductivity of minerals are utilized in processing operations when applicable.
4. **Dewatering.** Most mineral processing operations are conducted in the presence of water. Solids must be separated from water for metal production. This is accomplished with thickeners and filters.
5. **Aqueous dissolution.** Many metals are recovered from ores by dissolving the desired metal(s)—in a process termed *leaching*—with various lixiviants in the presence of oxygen. Following leaching, the dissolved metals can be concentrated by carbon adsorption, ion exchange, or solvent extraction. Purified and concentrated metals may be recovered from solution with a number of reduction techniques, including cementation and electrowinning.

EXAMPLES OF MINERAL PROCESSING OPERATIONS

Figure 14.1-3 shows a typical flow sheet for crushing and sizing rock in a quarrying operation. Run-of-mine ore can be present as lumps as large as 1.5 m (5 ft) in diameter. In this figure's example, 1-m (3-ft) lumps of rock are fed to a crusher that reduces the material to 200 mm (8 in.) or less in diameter. After screening to remove rock that is less than 57 mm (2¼ in.) in size, rock between the sizes of 57 mm (2¼ in.) and 200 mm (8 in.) is further reduced in size by a gyratory crusher. The product from this step is then classified by screening to the desired product for sale.

Figure 14.1-4 shows an integrated circuit demonstrating crushing, grinding, size separation, and gravity concentration of a tin ore. Initial size separation is effected with a grizzly set at 38 mm (1½-in.). Oversize material is fed to a jaw crusher set at 38 mm (1½-in.), and the crushed product is then further reduced in size to 20 mesh by ball milling. The minus-20-mesh material is classified by hydrocyclones set at 150 mesh, and the minus-150-mesh material is sent to shaking tables to concentrate the heavy tin mineral, cassiterite. The middlings in this process receive additional treatment. The concentrate from this operation is reground and sized at 200 mesh. Two-stage vanning is used to produce a fine tin concentrate.

The flow sheet describing the flotation processing of a copper ore containing chalcopyrite and molybdenite is shown

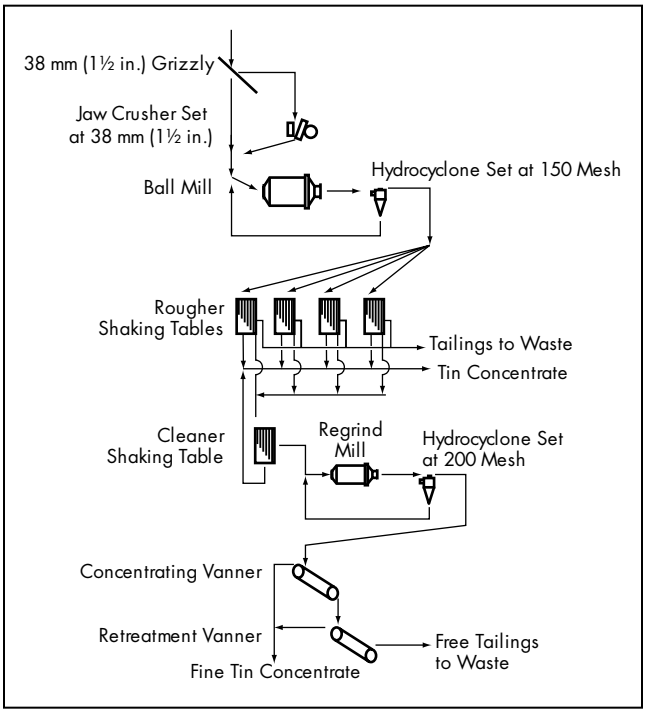

Figure 14.1-4 Flow sheet for the gravity concentration of a tin ore

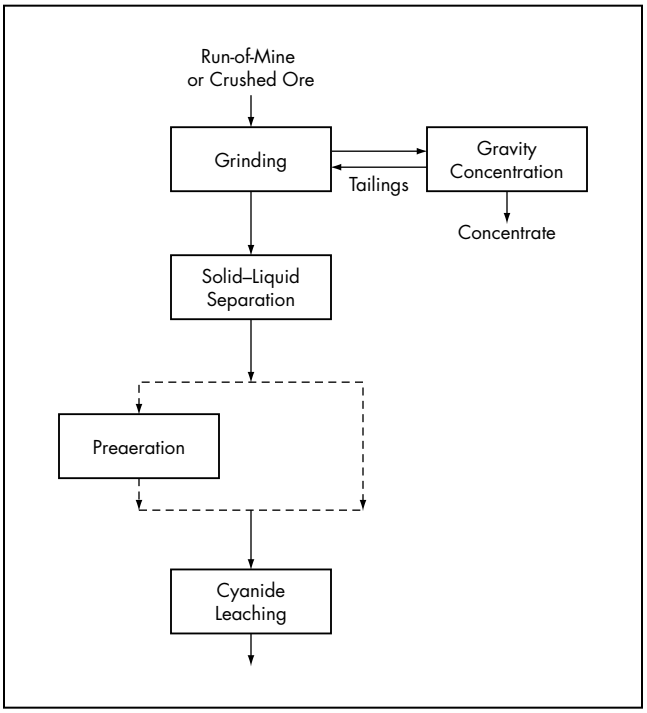

Figure 14.1-6 Flow sheet options for grinding and agitated leaching of free-milling oxidized gold ores

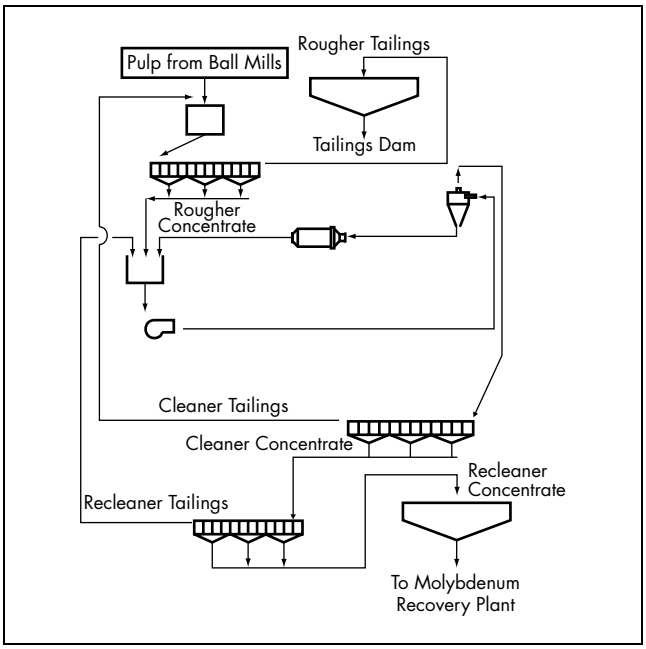

Figure 14.1-5 Flow sheet for the flotation of copper sulfide ore

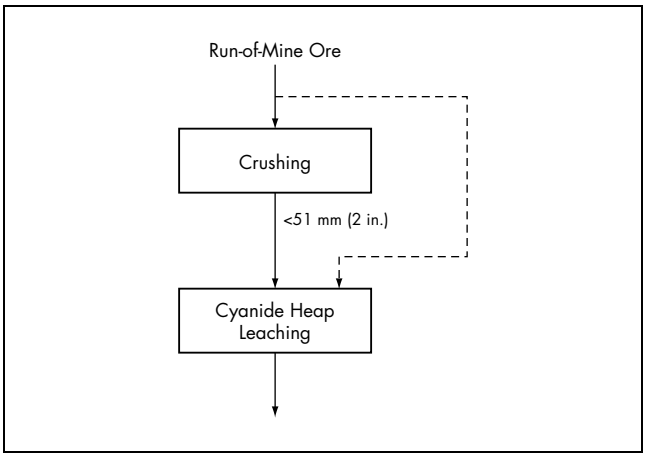

Figure 14.1-7 Flow sheet for heap leaching of oxidized gold ores

in Figure 14.1-5. After grinding and classification, pulp is fed to rougher flotation. The rougher tailings are thickened and sent to a tailings dam. The rougher concentrate is classified, and the oversize is reground. Cyclone overflow is fed to cleaner flotation, and the cleaner concentrate is recleaned. Cleaner tailings are recycled back to rougher flotation, and the recleaner concentrate is thickened and sent to the molybdenum recovery plant for further processing. In this operation, the feed contains 0.32% Cu and 0.03% Mo. Rougher concentrate, cleaner concentrate, and recleaner concentrate contain 7% to 9% Cu, 18% Cu, and 25% Cu, respectively. Recleaner concentrate also contains 2% to 3% Mo.

Figure 14.1-6 depicts a flow sheet for processing free-milling oxidized gold ore. The kinetics of gold leaching is slow, and gold ores are frequently ground to less than about 76 mm (3 in.) before leaching. Even then, one day is usually required in the leaching step. In this process, run-of-mine ore is crushed and ground. The ball mill discharge is subjected to gravity concentration to recover the larger particles of free gold. The tailings from this operation are thickened, and the underflow from the thickeners is then subjected to cyanide

leaching. In some instances, ores may contain oxygen-consuming minerals, such as pyrrhotite and marcasite, and a preaeration step may be conducted ahead of cyanide leaching.

Heap leaching has revolutionized the gold mining industry. Low-grade oxidized ores containing approximately 0.933 g gold per metric ton (0.03 oz gold per short ton) of ore can be processed with this technology, whereas they could not be processed by the higher cost of the grinding/agitation leaching (milling) process. Figure 14.1-7 presents a simplified flow sheet of heap leaching. As the figure shows, run-of-mine ore may or may not be crushed. If crushing is done, the ore is generally crushed to <51 mm (<2 in.) in diameter.

ACKNOWLEDGMENTS

CHAPTER 14.2

Crushing, Milling, and Grinding

John Mosher

Comminution is the collective term used to describe the progressive reduction in size of run-of-mine (ROM) ore. Size reduction is required either to prepare the ore for market (for iron ore and coal, for example) or, as in the case of base and precious metals, to allow liberation and separation of the valuable constituents. For ore requiring beneficiation, liberation and separation are the essential steps in mineral processing. The degree of liberation attained by comminution defines the grade–recovery curve for a given beneficiation process, as well as typically representing the largest category of mineral processing capital and operating expenses. As such, the comminution process has a large impact on an operation's bottom line. Proper circuit design and operation are critical to overall project success.

Crushing and grinding have been regarded as separate processes, with each step performed on a certain size range of material. This concept is rooted in the historical conventional circuit that entailed staged crushing, followed by open-circuit rod milling and closed-circuit ball milling. Modern equipment has blurred this concept, with autogenous grinding/semiautogenous grinding (AG/SAG) mills and high-pressure grinding rolls (HPGRs), in particular, spanning a broad range of comminution applications and particle size ranges.

This chapter addresses in general terms comminution circuit configuration, equipment types, and operation. Stages of comminution are discussed from ROM through fine grinding, with sections devoted to special grinding applications, ore characterization and circuit design, and mill liners and media. No attempt is made to cover all comminution machines or flow sheets; however, methods processing the largest tonnages of ore in the metals mining segment are summarized. Selected unit operations in broad use for each stage of comminution are presented in Table 14.2-1, with size ranges for the most commonly used unit operations depicted in Figure 14.2-1. Unit operations are discussed in more detail in relevant sections.

Examples of selected circuit configurations are presented in Table 14.2-2. This selection is not exhaustive; the summary presents both a range of grinding applications and demonstrates examples of selected circuit configurations. Throughout this chapter, commonly used references to describe feed and product sizes are employed; F and P represent feed and product, respectively, with the subscript indicating the percentage of the material passing a given size. For example, a P_{80} of 13 mm describes a size distribution for a material that has 80% of the material finer than 13 mm.

Individual comminution unit operations are well described in contemporary mineral processing textbooks (Wills 2006; Kelly and Spottiswood 1995). Classic works such as Taggart (1945) are still useful and provide perspective, and a number of comminution monographs provide detailed references (including Mular and Jergensen 1982; Napier-Munn et al. 1996). To keep up with changing practices, various forums addressing academic, engineering, and operational aspects of comminution were developed. Perhaps the most focused of these forums have been the International Autogenous and Semiautogenous Grinding Technology Conferences, hosted by the University of British Columbia. Proceedings from these conferences (1989, 1996, 2001, and 2006) are the broadest reference body for case studies on contemporary milling practices. Despite the name, a broad spectrum of mineral processing comminution circuits is addressed.

MINING AND PRIMARY CRUSHING

Because the process of comminution starts with mining, the degree of comminution achieved should be used as a performance indicator for the mining process. Correspondingly, the comminution circuit should also be developed in consideration of the selected mining process.

For surface mines that produce broken ore or muck via drilling and blasting, there are numerous case studies of optimizing drilling and blasting in conjunction with the overall economics of shovel productivity, primary crusher throughput, and downstream comminution efficiency. Efficient blasting is effective at both decreasing top size as well as improved fines generation. In general, the following conclusions can be drawn:

- Staggered patterns (versus square patterns) reduce the maximum distance between drill holes and typically reduces the ROM top size (boulders).

John Mosher, Executive Vice President-Operations, PT Freeport Indonesia, Tembagapura, Papua, Indonesia

Table 14.2-1 Unit operations for stages of comminution

Milling Stage	Typical Top Size	Common Unit Operations	Alternatives
ROM	F_{100}* = 1 m	• Primary crusher (gyratory/jaw) • Secondary pre-crush	• MMD Sizer • McLanahan log washer
Primary	F_{100} = 250 mm F_{80} = 50–100 mm	• AG/SAG/pebble crusher circuits • 2º/3º/4º crushing circuits • Crusher/HPGR circuits	• Rod milling • Impact mills • Dry AG/SAG
Secondary	F_{100} = 13 mm	• Ball milling • Pebble mills	• Attrition scrubbing • Dry ball mills
Tertiary (concentrate regrind, handling, pelletizing)	Nominally –0.2 mm	• Ball mill • HPGR • Vertical shaft mills (screw and pin) • Horizontal shaft mills (IsaMill)	• Roller mills • Vibratory ball mills • Centrifugal mills • Jet mills

*F = feed; subscript represents the percentage of the material passing a given size.

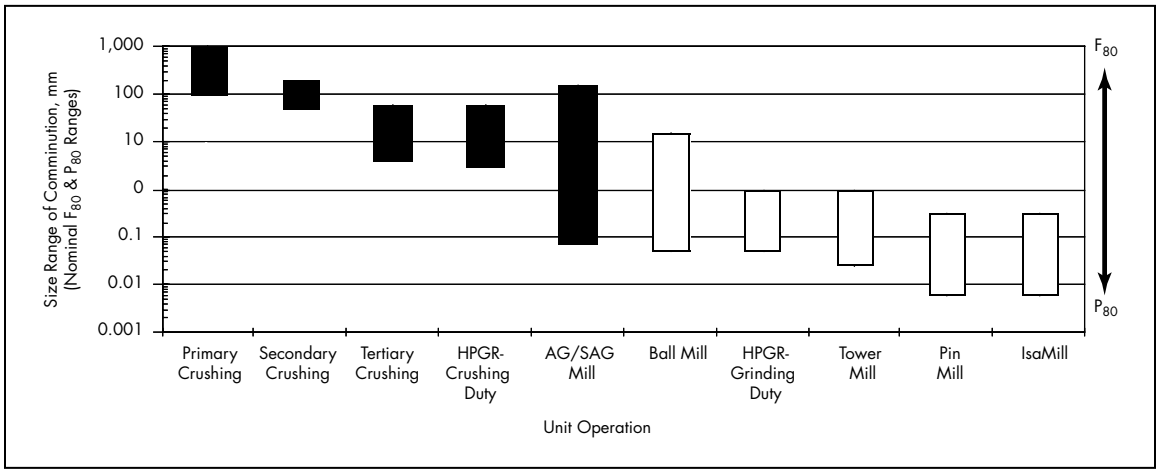

Figure 14.2-1 Size range of common comminution machines

- Quality of drilling in terms of the accuracy of holes in x-, y-, and z-axes improves fragmentation as well as shovel productivity.
- Customized blast designs by material type (burden and spacing, explosive type and amount, and initiation timings) can improve fragmentation and offer cost benefits.
- The effect of blast sequence (including presplitting, production, and trim blasting, where required for wall control), blast size, and pattern geometry should be considered for the effect on comminution.

Additional considerations for underground mines apply. As a consequence of mining through areas previously subjected to ground control, many underground mines produce extraneous metal in the mill feed. Additionally, block cave mines typically produce coarser material at drawpoints early in their development. With higher draw columns, greater AG breakage occurs, and drawn material becomes finer. Block cave mines usually employ secondary breakage to control material hang-ups in drawpoints, as well as mechanical rock breakers and grizzlies to ensure top size control prior to truck loading, before primary crushing is undertaken.

Typically, ROM material must undergo a stage of size reduction to facilitate conveyor transport. Questions to be addressed in circuit development include the size, number, and type of crusher used to produce suitable mill feed, where to place the crushers, and how to feed them. The choice of primary crushing equipment is typically between jaw and gyratory crushers. Jaw crushers can be selected for applications with low throughput, while throughputs greater than 1,000 t/h (1,100 stph) favor gyratory crushers. Gyratory crushers of up to 1.9 × 3.2 m (75 × 124 in.) and installed power of 1 MW or more are currently being marketed. A modern gyratory crusher is depicted in Figure 14.2-2.

The location of primary crushing stations is a critical question. Primary crushers can be permanently located, semimobile, or mobile. Even permanently located crushers can be disassembled and relocated during a mine's life, so the question as to which of the three options to select is one of tradeoffs between the capital and operating cost of the incremental truck haulage fleet required versus mobile or semimobile crushing stations.

Fixed plants simply rely on the haulage fleet to bring ore to the crusher. Mobile and semimobile plants often used tracked crawlers, which have capacities of more than 1,000 t (1,100 st), to periodically relocate the crushing unit. In conjunction with movable conveyors, such systems are placed to shift the haulage burden from a mobile equipment fleet to conveyors and more economically transport material mined to either ore or overburden stockpiles. The evolution of larger truck sizes, along with a general trend of steeper and deeper pits, have tended to disfavor in-pit crushing and conveying. However, these can offer advantages in terms of reduced operating costs, increased availability, and reduced labor requirements compared to a truck fleet; a thorough review of the topic is provided by Boyd and Utley (2002).

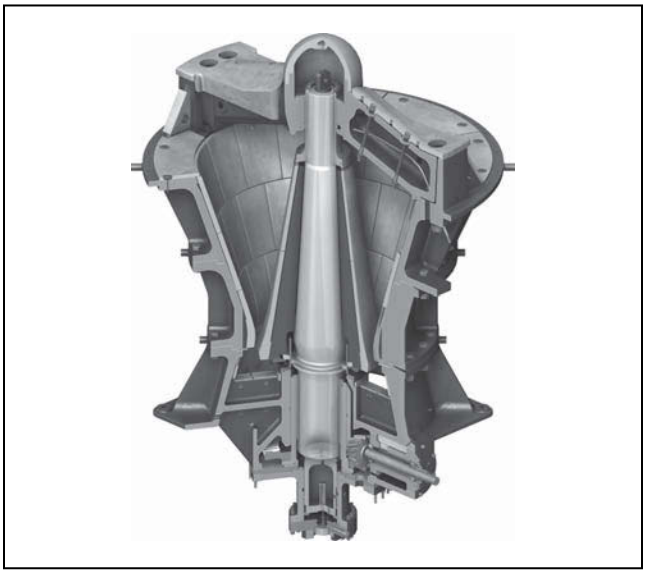

Table 14.2-2 Selected contemporary circuit configurations (all circuits milling ROM ore)

Configuration	Operation*	Major Equipment, Dimensions and Installed Power, kW	Nominal Capacity, t/d	Total Installed Power, MW	P_{80}, μm

Aside from selection of crusher and crusher location and mobility, design considerations include methods to feed the crusher and convey crusher product to the mill stockpile. Crusher feeding considerations include the number of truck dump locations and the size of the crusher feed hopper (and appropriate design for dead beds). Primary crushers can either be fed with direct truck dumping (as in Figure 14.2-3) or by using ore pockets and apron feeders. Direct dumping is the simplest, but it can be more difficult to sustain peak crusher utilization, and truck wait times can be incurred. Apron feeders offer the ability to partially disconnect the crusher from truck dumping (with the idea of both reducing truck queues and improving crusher performance) but introduce additional capital costs, as well as the substantial maintenance costs of operating apron feeders in the demanding duty. Crusher installations should also consider the requirement for mobile equipment to clear dump pockets in case of blockages, rock breaker installations to handle oversize inadvertently fed to the crusher, overhead craneage (fixed or mobile) for maintenance, and overall elevation required for an installation (controlled by crusher dump pocket and product bin dimensions).

Crusher product handling using a bin and apron feeders to place the material on a conveyor belt is effective and allows matching the operation of the semicontinuous, variable capacity crusher (depending on material type) with a conveying system of fixed capacity. Product bin sizing should consider peak flow-through rates observed when crushing fine ore to avoid bin overfilling. In cases with sufficient belt capacity relative to crusher throughput, product can be fed directly to belts via appropriate chutes.

Figure 14.2-2 Primary gyratory crusher

Alternatives to conventional crushing prior to further processing include mineral sizers (whose manufacturers include Krupp and MMD). These machines operate dry, employ horizontal counter-rotating shafts equipped with wear tips, and are alternatives for size reduction of low- to moderate-strength materials with low-head-height devices. A somewhat similar

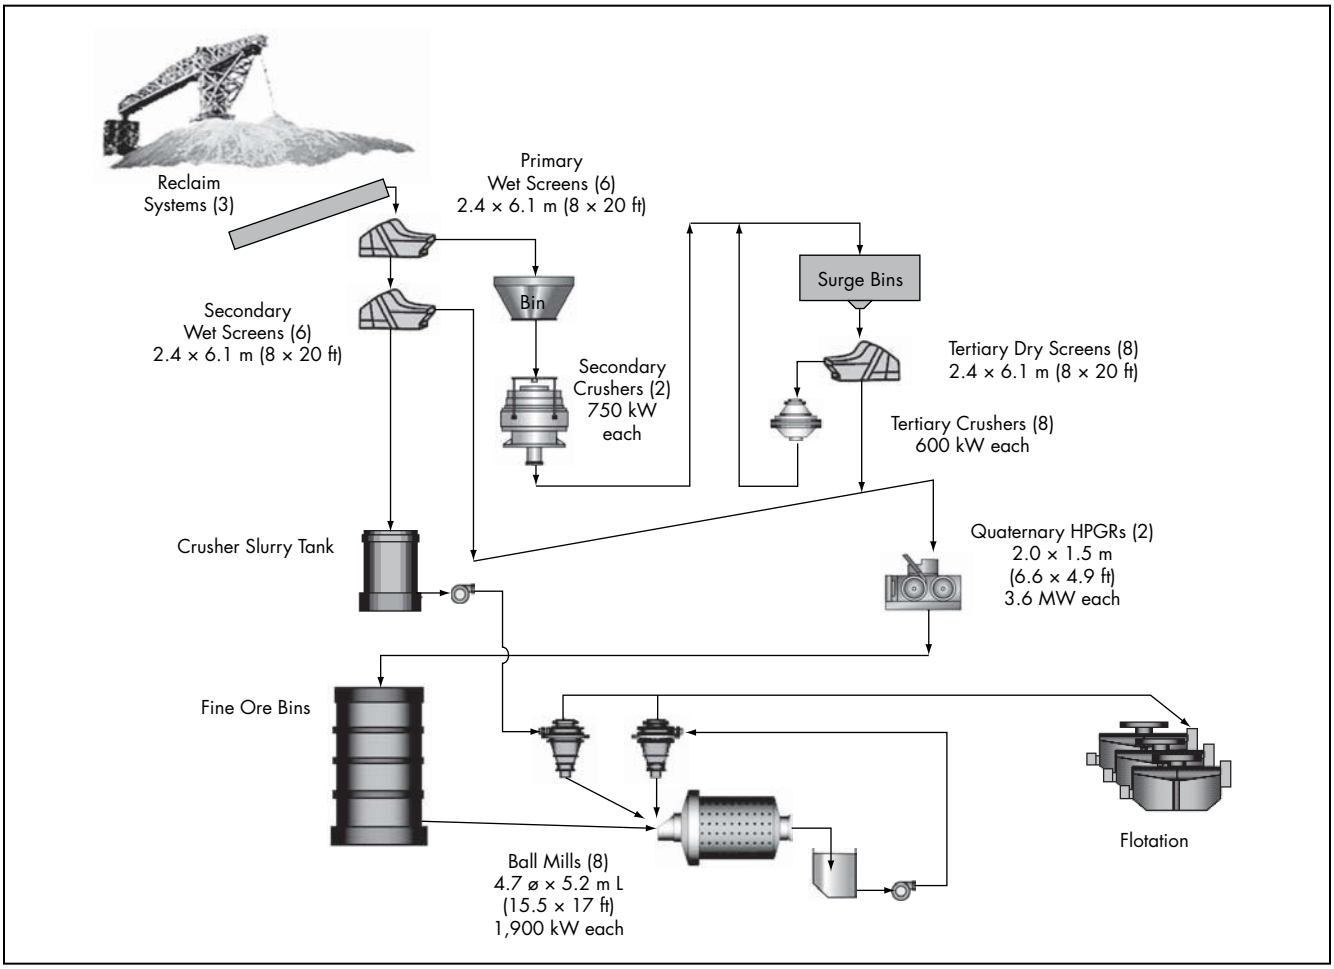
Figure 14.2-3 Direct truck dumping to a gyratory crusher

device, the McLanahan log washer, operates wet and serves to deagglomerate coarse from fines rather than affect true comminution. These devices are well proven and work effectively in appropriate applications. There can be substantial capital cost savings with reduced civil and structural work for these units.

All of these machines are vulnerable to damage through introduction of incompressible foreign objects (notably ground engagement tools and tramp metal). In cases where direct dumping is used, protection is limited to tools such as cameras and image analysis software (useful for detection of the loss of shovel teeth), spotters, and the installation of safety clutches to limit damage for unavoidable events. Where material is reclaimed or dumped to feeders, metal detectors or magnets can be used in some applications.

PRIMARY MILLING

A critical linkage point between the mining and milling operations is the mill stockpile. Most comminution plants reclaim from a stockpile of primary crushed material, and stockpile management is essential to maintain consistent throughput. There is generally some degree of stockpile segregation, with coarse material preferentially accumulating toward the outside of stockpiles. Maintaining a live stockpile and balancing multiple reclaim feeders will result in the highest average (and most stable) throughput. Feed size to a primary milling circuit can have a substantial impact on throughput, particularly for AG and SAG circuits. This underscores the importance of evaluating mining technique and practice, primary crushing, and the downstream comminution circuit. It is also important in terms of nonsteady-state operation, such as stockpile drawdown conditions. As the proportion of material drawn down from the stockpile increases, the feed to the comminution circuit typically becomes coarser, correspondingly requiring a higher unit energy input for comminution. The often observed effect was well quantified by Morrell and Valery (2001); that paper also discusses broadly the effect of SAG feed on circuit performance.



Maintaining reclaim stockpiles at reasonable levels minimizes the effect of load and haul equipment shift changes on downstream operations and decouples the mine and mill from maintenance activities associated with shovel and mill maintenance periods. Stockpile size should be based on anticipated interruptions due to primary crusher maintenance, load-and-haul asset maintenance, mill maintenance downtime requirements, and normal fluctuations due to mine sequencing. Depending on climate, ore moisture, surrounding facilities, dusting characteristics, and regulatory requirements, covering stockpiles may be desired or necessary.

The following sections outline three circuit configurations in broad use as the first stage in a comminution plant (primary milling): (1) standard crushing plants, (2) AG/SAG mills, and (3) the combined application of cone crushers and HPGRs. The latter circuit is now broadly viewed as an alternative to SAG circuits.

Crushing Circuits

The classic crushing circuit prepares primary crushed ore for secondary milling through two stages of crushing. Most typically, stockpiled primary crusher product is reclaimed and fed to a secondary crusher. In turn, the product of a secondary crusher operating in open circuit is screened, with oversize fed to a tertiary crushing circuit operating in closed circuit with screens. The product of a standard tertiary crushing plant is nominally 100% passing 13 mm. The basic design of a tertiary crushing plant (secondary crushers in open circuit with tertiary crushers in closed circuit with screens), along with variations, has been widely used. Such a circuit, inclusive of HPGRs in a quaternary role and follow-on single-stage ball milling, is depicted in Figure 14.2-4; the crushing plant and concentrator depicted has a nominal capacity of 75,000 t/d (83,000 stpd). The plant depicted shows wet primary screening followed by dry tertiary screening. In some applications, this is reversed, and some circuits (particularly for heap leaching) are fully dry. Selection of wet or dry screening is a function of material type, ROM moisture, efficiency of classification required, and the type of follow-on material handling or processing.

The product of such a typical crushing plant can be directly fed to a fine-crush heap leach operation. In milling operations, the product of a crushing plant was historically further reduced in an open-circuit rod mill prior to comminution in a ball mill. However, rod mills are limited to nominally less than 5 m (16.4 ft) in diameter and 6 m (19.7 ft) in length due to practical constraints on mill size before rod tangling occurs—such a mill has a power draw of less than 2.0 MW. As such, economies of scale have largely led mill circuit designers to send crushing plant product directly to ball mill circuits. Doing so may introduce a degree of grinding inefficiency (based on the coarseness of feed to a ball mill or a high reduction ratio in one stage of grinding), but this has been widely accepted as being favorable to a requirement

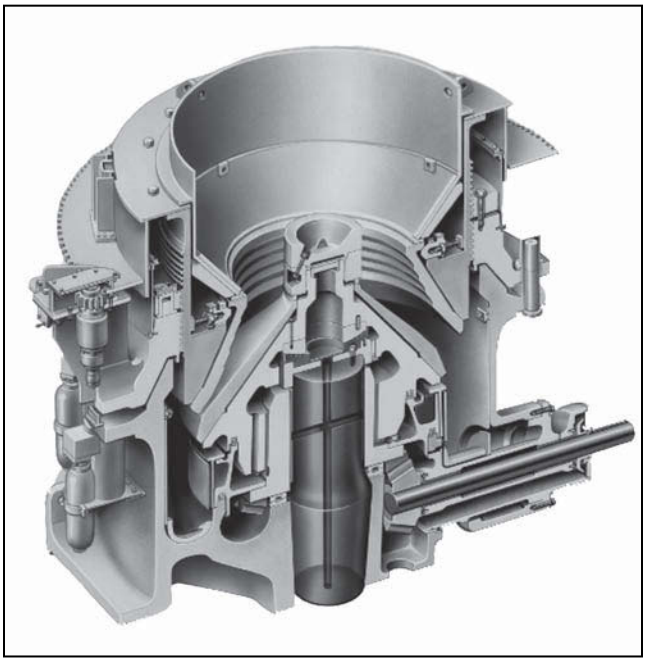

Figure 14.2-4 Crushing ball mill plant

for a large number of rod mill lines and an additional unit operation. As will be discussed in a following section, HPGRs in a quaternary role perform top-size reduction admirably, as well as doing an excellent job of fines generation. Depending on circuit configuration, large single-line secondary/tertiary crushing lines have a nominal installed power of 3 MW and the capacity to crush 25 to 40 kt/d (28,000 to 44,000 st).

Crushers are generally of two types of mechanical design. In the Symons design (Figure 14.2-5), a threaded bowl liner is adjusted to modify the crusher gap. The bowl is threaded to the adjustment ring, which is secured flush against the mainframe through hydraulic accumulators that release in the event of a tramp metal event. In the Allis design (Figure 14.2-6), the crusher mantle is shaft supported against a fixed bowl liner (analogous to a gyratory crusher's concaves) to maintain either a fixed gap or a fixed pressure setting. In the event of tramp metal (or other uncrushable item) entering the crushing chamber, the hydraulically supported shaft drops, allowing the material to pass.

Because crushing plants are well understood, the skill sets required for plant operation and maintenance can be readily sourced or developed. Throughput for the machines used is largely volumetrically controlled; as such, plant throughput is relatively insensitive to changes in feed hardness or feed size distribution (though the amount of comminution work and power drawn by the machines is clearly affected). Power input is a direct result of comminution effort required to effect breakage, unlike tumbling mills, where it is the outcome of the potential energy transmitted to the mill charge.

Crushing plants have some drawbacks relative to other plant configurations. First, particularly for larger plants, they normally require many more units of equipment (bins, crushers, screens, conveyors, chutes, etc.) for an equivalent throughput than other major circuit types. This is due to the fact that the current upper limit for installed power for a conventional crusher is 750 to 1,000 kW, smaller than the average unit installed power for mills. Partially as a result of the number of units in series, and partially due to liner change-outs, crushing plant run time is lower than that of rotating mills. Crushing plants do not produce fines to the same degree as other primary milling options, which increases the amount of comminution effort required in a second stage of milling. The mode of breakage is dominated by compressive fracture, which produces fewer fines, and screening (wet or dry) at finer sizes is not practical at large tonnages; screen area required escalates nonlinearly with decreasing cut size. Finally, crushing plants have material-handling difficulties with sticky ores, significant downtime due to metal detector trips, and potentially a resulting loss in production with ores that contain a high degree of tramp metal or magnetite.

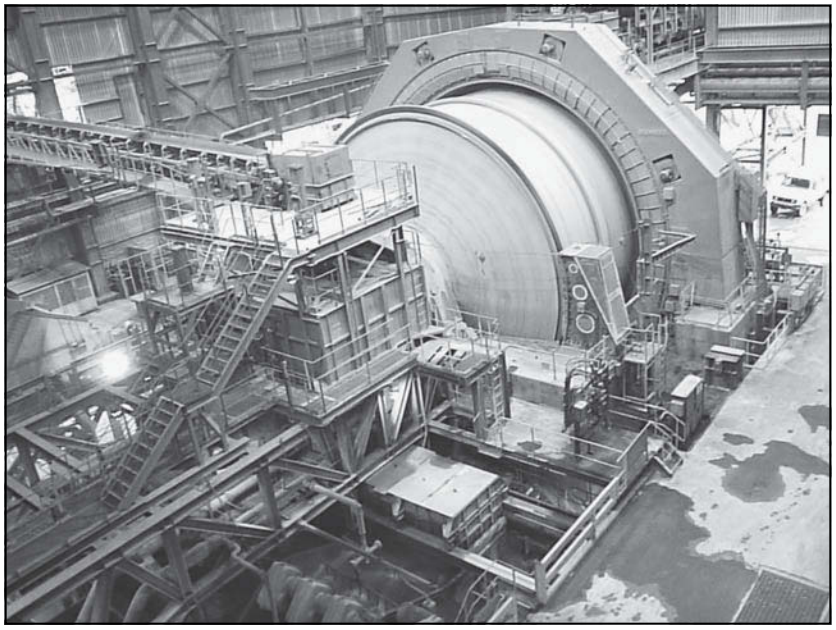
AG/SAG Circuits

Since their early development, AG and SAG mills have become a mainstay of comminution in mineral processing applications. Although crushing-rod mill-ball mill circuits were referred to as "conventional" plants until relatively recently, AG/SAG mills are now the foundation unit operation for most large grinding circuits. The variety of AG/SAG circuits is substantial. The following duties are all well represented:



- Single-stage autogenous/semiautogenous milling
- AG/SAG mills as one stage in a larger comminution circuit
- Inclusion of pebble crushing circuits in the AG/SAG circuit
- Employment of a crushing stage after primary crushing (such that SAG feed has been through two stages of crushing)

Single-stage AG circuits have been installed in relatively high-tonnage, coarse-grind applications such as Iron Ore Company of Canada's (IOC's) Carol Concentrator, and in lower-tonnage, finer-grind applications (closed with hydrocyclones) like Noranda's Brunswick operation in Quebec, Canada. Very high single-line capacities have been demonstrated, with some circuits having up to 70 MW of installed grinding power in a single plant. PT Freeport Indonesia's 11.6-m- (38-ft-) diameter SAG mill in Concentrator 4 (Papua, Indonesia), presented in Figure 14.2-7, has registered monthly tonnages averaging more than 125,000 t/d (138,000 stpd), with single-day performances in excess of 150,000 t/d (165,000 stpd).

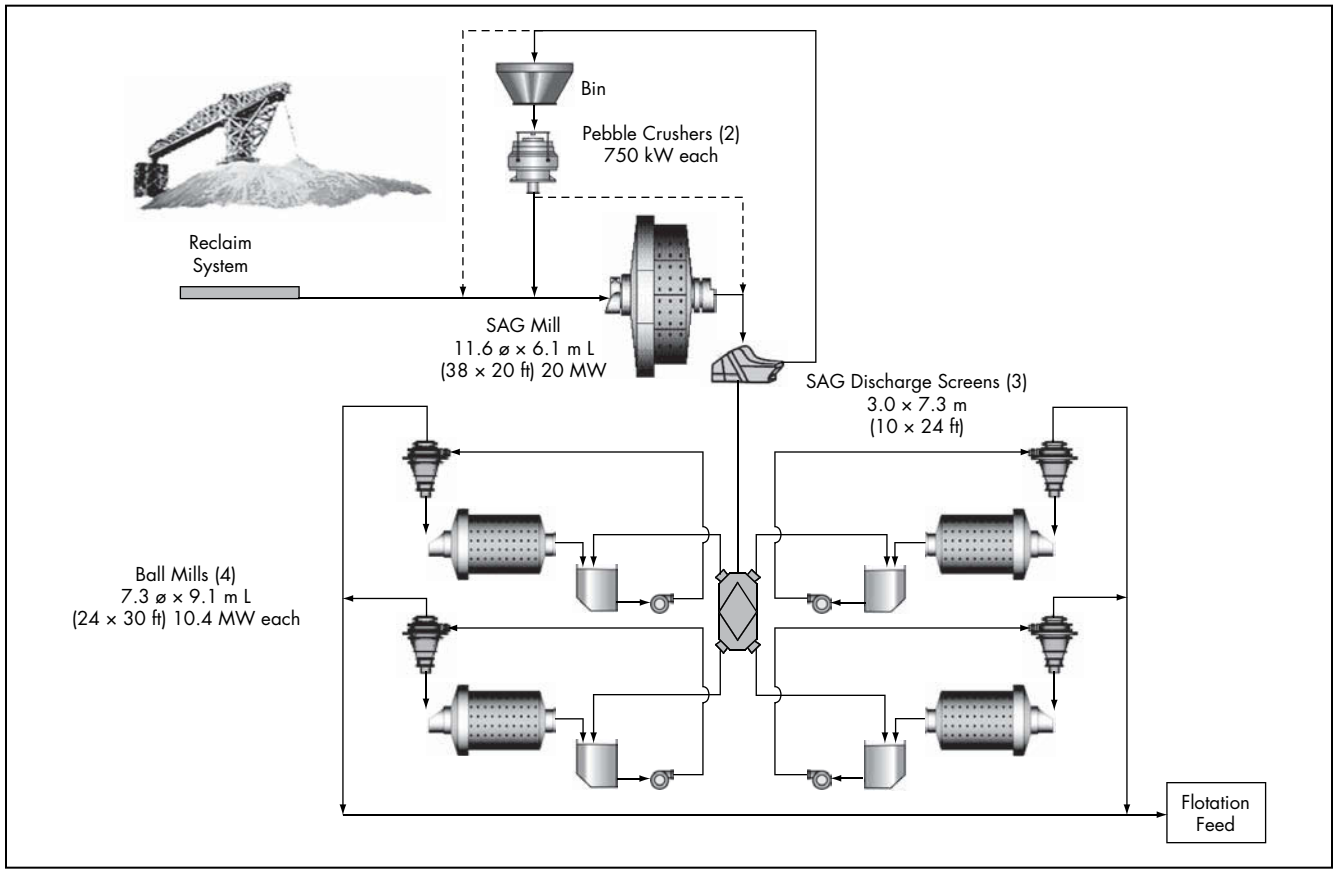
Although common convention generally refers to high-aspect-ratio mills as SAG mills (with diameter to effective grinding length ratios of 3:1 to 1:1), low-aspect-ratio mills (generally, a mill with a significantly longer length than diameter) can also grind autogenously or semiautogenously. Such mills are common in South African operations and are sometimes referred to as tube mills or ROM ball mills. Many of these mills operate at higher mill speeds (nominally 90% of critical speed) and often use grid liners to form an AG liner surface. These mills typically grind ROM ore in a single stage, either autogenously or semiautogenously.

The broad application of AG/SAG mills lies in the large single-line capacity of such plants, the ability of circuits to mill a broad range of feed types, and the variety of circuit configurations. The application of gearless drives has allowed mills to grow beyond sizes allowed by twin-pinion drives; a nominal limitation of 12–16 MW (based on a limit of 6–8 MW per pinion on a twin-pinion drive) results in a restriction of nominally an 11-m (36-ft) diameter SAG mill (based on typical diameter/length ratios) if using geared drives. Many large mills around the world (including Cadia, Collahuasi [New South Wales, Australia] with 12.2-m (40-ft) mills, and Antamina [Peru], Escondida Ph IV [Antofagasta, Chile], PT Freeport Indonesia, and others with 11.6-m [38-ft] mills) have installed SAG mills of nominally 20 MW with gearless drives. A number of mills with 25 MW or higher gearless drives are either under construction or in engineering. Some of these grinding lines have design capacities exceeding 100,000 t/d (110,000 stpd). The process flow sheet for the large SAG installation (with pebble crusher product combining with SAG discharge and feeding screens) depicted in Figure 14.2-7 is presented in Figure 14.2-8.

AG/SAG mills comminute ore through impact breakage, attrition breakage, and abrasion of ore serving as media. AG circuits require an ore of suitable competency (or fractions within the ore of suitable competency) to serve as media. SAG circuits may employ low to relatively high ball charges (ranging from 2% to 22%, expressed as volumetric mill filling) to augment AG media. Higher ball charges shift the breakage mode away from attrition and abrasion breakage toward impact breakage; as a result, autogenous milling produces a

Courtesy of PT Freeport Indonesia.
Figure 14.2-7 Large SAG installation (20-MW gearless drive)

finer grind than semiautogenous milling for a given ore and otherwise equal operating conditions.



With a higher-density mill charge, SAG mills have a higher installed power density for a given plant footprint relative to AG mills. With the combination of finer grind and a lower installed power density (based on the lower density of the mill charge), a typical AG mill has a lower throughput, a lower power draw, produces a finer grind, and has a higher unit power input (kilowatt-hours per ton) than a SAG circuit milling the same ore. In the presence of suitable ore, an AG circuit can provide substantial operating cost savings due to a reduction in grinding media expenditure and liner wear. In broad terms, this makes SAG mills less expensive to build (in terms of unit capital cost per metric ton of throughput) than AG mills but more expensive to operate (as a result of increased grinding media and liner costs). SAG circuits tend to be less susceptible to substantial fluctuations, because of feed variation, than AG mills and are more stable to operate. AG circuits are more frequently (but not exclusively) installed in circuits with high ore density, with iron ore being the classic example. A small steel charge addition to an AG mill can boost throughput and result in more stable operations, typically at the consequence of a coarser grind and higher operating costs.

AG or SAG mills with low ball charges are often used in single-stage grinding applications. Conversely, SAG mills produce coarser grinds than AG mills in equivalent applications. Based on their higher throughput and coarser grind relative to AG mills, SAG mills are more likely to be used as the primary stage of grinding, followed by a second stage of milling. AG/SAG circuits producing a fine grind (particularly single-stage grinding applications) are often closed with hydrocyclones. Circuits producing coarser grinds often classify mill discharge with screens. For circuits classifying mill discharge at a coarse size (coarser than approximately 10 mm), trommels can also be considered to classify mill discharge. Trommels, however, are less favorable in applications requiring high classification efficiencies and can be constrained by available surface area for high-throughput mills. Regardless of classification (hydrocyclone, screen, or trommel), oversize material can be returned to the mill or directed to a separate comminution stage.

The addition of pebble crushing is the most common variant to closed-circuit autogenous/semiautogenous milling (instead of direct recycle of oversize material). The potential efficiency benefits, both in terms of grinding efficiency and in capital efficiency through incremental throughput, has long been recognized, but the challenges of metal removal (primarily grinding media passing mill grates) were perceived to be a substantial hurdle. With time, and after successful pioneer operations, operators and circuit designers became comfortable with the required magnetic separation and metal detectors/bypass chutes required to protect pebble crushers from tramp steel.

Even after steel ball removal had proved to be reliable, pebble crushers installations were still thoroughly scrutinized at the design stage because of the additional cost and circuit complexity. Instead of foregoing pebble crushing completely, though, many operations chose instead to leave provisions in the design for future pebble crushing expansions. Today, every AG/SAG flow sheet conceived is likely to seriously consider the inclusion of a pebble crusher circuit. For certain ore types (particularly those with a chert, andesite, or other hard component that develops a critically sized material that constrains milling rates), a pebble crushing circuit is almost an imperative for efficient circuit operation. For other cases, it is simply a technique to improve circuit capacity. Construction of an AG/SAG circuit without provision for later pebble crusher installation should have a persuasive economic justification. Important aspects of pebble crusher circuit design include

- Preparation of a clean, well-sized, and dry feed;
- Metal removal (with additional protection via metal detectors and bypass);
- Surge capacity (through bins or, more costly, a pebble stockpile);

Courtesy of PT Freeport Indonesia.
Figure 14.2-8 SAG pebble crusher–ball mill circuit

- Sufficient capacity (primarily a concern of large circuits where multiple pebble crushers are required to serve one grinding line);
- Design for bypassing crusher(s) during maintenance; and
- Evaluation of where to reintroduce the crushed pebbles back to the grinding circuit.

The standard destination for crushed pebbles has been to return them to SAG feed. Doing so is often convenient based on conventional plant layouts. However, open circuiting the SAG mill by feeding crushed pebbles directly to a ball mill circuit is often considered a technique to increase SAG throughput. PT Freeport Indonesia's operation has the ability to return crushed pebbles to SAG feed per a conventional flow sheet, or to SAG discharge. By combining with SAG discharge and screening on the SAG discharge screens, top size control to the ball mill circuit feed is maintained while still unloading the SAG circuit (Mosher et al. 2006).

Aside from parameters fixed at design (mill dimensions, installed power, and circuit type), the major variables affecting AG/SAG mill circuit performance (throughput and grind attained) include

- Feed characteristics in terms of ore hardness or competency;
- Feed size distribution;
- Selection of circuit configuration in terms of liner and grate selection and closing size (screen apertures or hydrocyclone operating conditions);
- Ball charge (fraction of volumetric loading and ball size); and
- Mill operating conditions including mill speed (for circuits with variable-speed drives), density, and total mill load.

The effect of feed hardness is the most significant driver for AG/SAG performance, which is the case to a much greater degree than for (compressive) crushing plants; variations in ore hardness result directly in variations in circuit throughput. With AG circuits, the variations can be substantial and occur suddenly. The effect of feed size is also marked, with both larger and finer feed sizes having a significant effect on throughput. A number of case histories of AG mills have failed to consistently meet throughput targets because of a lack of coarse media. Compounding the challenge of feed size is that, for many ores, the overall coarseness of the primary crusher product is correlated to feed hardness. Larger, more competent material consumes mill volume and limits throughput.

To counteract this effect, many circuits (including Troilus [Quebec], Kidston [Queensland, Australia], Ray [Arizona, United States], Porgera [Papua New Guinea], Granny Smith [Western Australia], Geita Gold [Tanzania], St. Ives [Western Australia], and KCGM [Western Australia]) currently use or have used a secondary SAG precrush circuit to further comminute primary crusher product prior to feeding to a SAG mill. The objective of SAG precrush is to increase SAG throughput. Occasionally, secondary crushing is included in the original design but more often is introduced as an additional circuit to

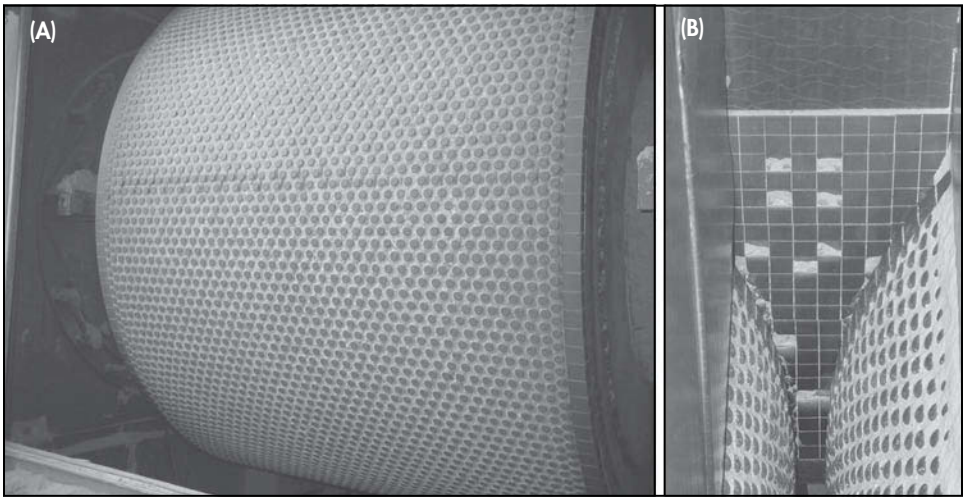
account for harder ore (that proves to be harder than expected or becomes harder as the deposit is developed) or as a capital efficient mechanism to boost throughput in an existing circuit. Such a flow sheet is not without drawbacks. Not surprisingly, some of the advantages of semiautogenous milling are reduced in terms of increased liner wear and increased maintenance costs. Also, precrushing can lead to an increase in midsize material, thereby overloading pebble circuits, and in challenges controlling recycle loads. In certain circuits, the loss of top size material can lead to decreased throughput. It is now widespread enough to be considered a standard circuit variant and is often considered an option in trade-off studies. The concept of feeding AG mills with as coarse a primary crusher product as possible in order to maximize AG mill throughput is obviously at the other end of the spectrum.

To a more significant degree than in other comminution devices, liner design and configuration can have a substantial effect on mill performance. In general terms, lifter spacing and angle, grate open area and aperture size, and pulp lifter design and capacity must be considered. Mill liner designs have moved toward more open shell lifter spacing, increased pulp lifter volumetric capacity, and tailored grate design to facilitate maximizing both pebble crushing circuit utilization and SAG mill capacity (Mosher 2005).

AG/SAG circuits can handle a broad range of feed sizes, as well as sticky, clayey ores (which challenge crushing plants). A range of circuit configurations have been developed, and large single-line plants can be designed with significant economies of scale and streamlined maintenance shutdowns and practices. Compared to crushing plants, wear media usage is reduced, and plants run at higher availabilities. Circuits, however, are more sensitive to variations in circuit feed characteristics of hardness and size distribution. Unlike crushing plants, for which throughput is largely volumetrically controlled, AG/SAG throughput is defined by the unit power required to comminute the ore to the closing size desired. A higher degree of operator skill is typically required of AG/SAG circuit operation, as is more advanced process control to maintain steady-state operation, with different operator/advanced process control regimes based on different ore types. Additionally, very hard ores can severely constrain AG/SAG mill throughput. In such cases, the circuits can become capital inefficient (in terms of the size and number of primary milling units required) and, in some cases, require more total power input compared to alternative comminution flow sheets.

Crusher–HPGR Circuits

Recently, HPGRs have made broad advances into the nonferrous metals mining. Long established in the cement industry, HPGRs first made inroads into diamond processing (where rock fracture along grain lines favored a reduction in diamond breakage during comminution) and in the iron ore industry. Penetration to the hard-rock mining industry was slow and hampered by high maintenance requirements both for wear surfaces in general and high wear on the edge of rolls. The intensity of the maintenance effort (relative to other comminution machines) required for a trial unit at the (then Phelps Dodge) Sierrita operation (Arizona) in 1996 was high.



Significant product improvements since then, however, have increased wear life, improved availability, and decreased the overall maintenance effort required. Incorporation of studs on the surface of rolls to allow formation of AG wear surfaces, as well as implementing edge blocks of a long-wearing material for edge protection, have allowed HPGRs to break into the mainstream of mineral processing. These wear-retarding innovations were the focal point of a full-scale trial at Lone Tree in Nevada, United States (Seidel et al. 2006). Successful completion of this trial marked somewhat of a turning point for interest in HPGRs for hard-rock applications. Manufacturers have also paid special attention to the bearings, wear surfaces, and the handling of tramp metal through the rolls to improve operational reliability, reduce maintenance, and obtain longer service lives. Availabilities are now such that aside from rolls change-outs (akin to a mill liner change), the unit rarely controls circuit availability.

The wear on a roll's surface is a function of the ore's abrasiveness. Increasing roll speed or pressure increases wear with a given material. Studs allowing the formation of an AG wear layer, edge blocks, and cheek plates are depicted in Figure 14.2-9. Development in each of these areas continues, including profiling of stud hardness to minimize the "bathtub" effect (wear of the center of the rolls more rapidly than the outer areas), low-profile edge blocks for installation on worn tires, and improvements in both design and wear materials for cheek plates.

In hard-rock-metals mining applications, HPGRs are currently used in tertiary and quaternary crushing applications, as well as in secondary pebble crushing. In some respects, HPGRs replace crushers as a unit operation. However, from a process standpoint, HPGRs produce a product with substantially more fines (for a given P_{80}) than a crushing circuit. In this regard, the size distribution of an HPGR circuit is much more similar to the product of a SAG circuit than a conventional crushing circuit, reducing the required amount of power in the ball mill circuit (relative to a crushing circuit). Also, an HPGR represents a much larger installation of power in a given footprint relative to tertiary crushers: An HPGR has up to a 5-MW power installation per unit compared to 750 kW for a single large cone crusher. HPGRs have also been cited as crushing more efficiently than rotating mills, as well as generating residual cracks that improve efficiency in subsequent milling operations. This effect is material- and operating-condition specific.

As a result, the number of material handling units (feeders, conveyors, screens, chutes) can be sharply reduced compared to a conventional crushing plant, and plant layouts are also much more straightforward. Freeport-McMoRan's (Phelps Dodge at the time of construction) Cerro Verde operation in Peru was a groundbreaking installation because the combination of secondary crushing (using MP1000s), tertiary crushing using HPGRs, and screens replaced what would have been more typically a large SAG mill feeding a multiple ball mill circuit (Vanderbeek et al. 2006). This was a significant step, as it presented an alternative to conventional crushing plants or autogenous/semiautogenous milling for primary milling applications (see Figure 14.2-10). Newmont Mining Corporation's consideration and ultimate selection of HPGR comminution for its Boddington project in Western Australia, widely documented in the literature, has now been commissioned with a similar comminution flow sheet to the Cerro Verde flow sheet (and also employing four units measuring 2.4×1.7 m).

Although the primary focus of this section is to discuss HPGRs (as they have been combined with crushers and screens) in primary milling roles, the versatility of the HPGRs in grinding applications must be noted. Though limited in top size they can accept (based on nip angle and resultant stud

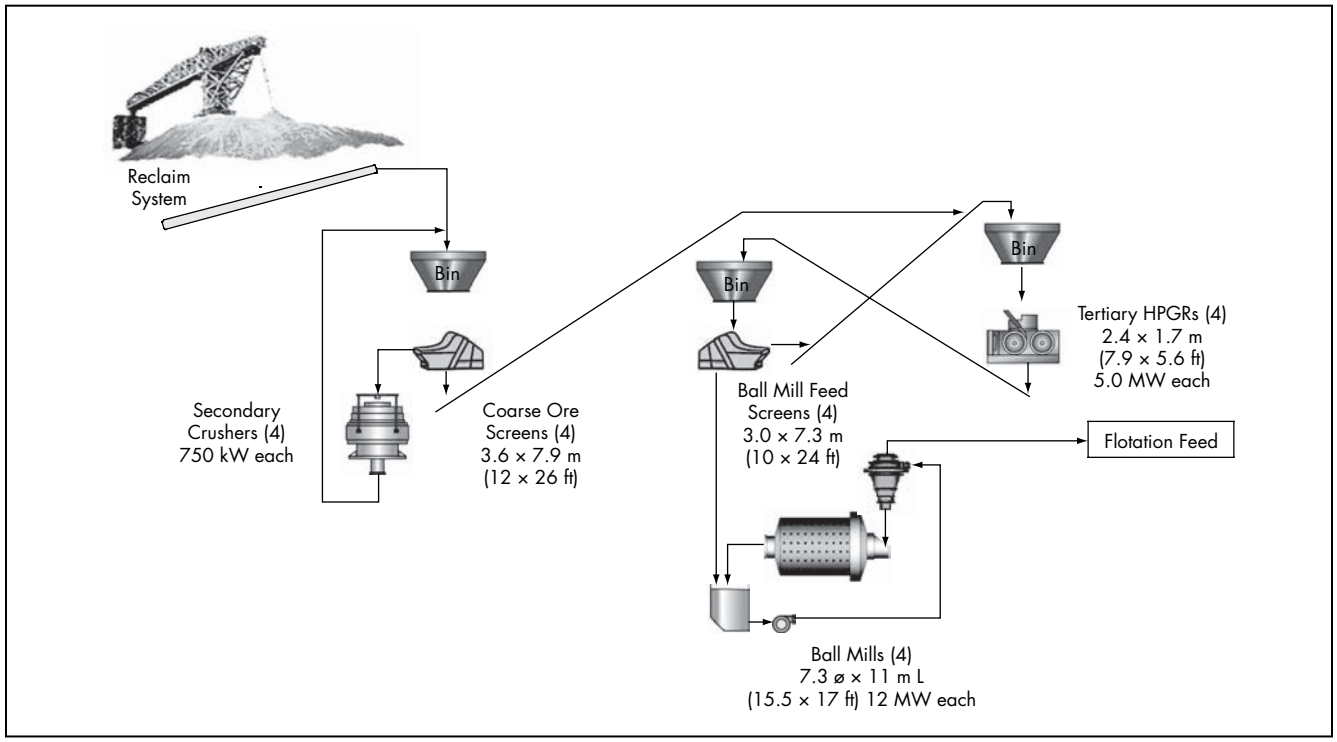
Courtesy of PT Freeport Indonesia.

Figure 14.2-9 HPGR roll (2.0 × 1.5 m diameter) with (A) studs and edge blocks and (B) cheek plates

breakage, leading to selection in tertiary rather than secondary roles), the machines are quite versatile because they have been installed in tertiary, quaternary, second-stage pebble crushing roles, and a number of finer grinding applications. In the fine-grinding role, HPGRs are widely used in pelletizing operations. One area not currently applicable to HPGRs is secondary milling in a wet process. In the cement industry, it is common practice to use HPGRs in closed circuits with a dry air classifier for finish grinding (S. Kirsch, personal communication). However, wet classification and subsequent dewatering does not compare favorably to the use of ball mills for wet processes most commonly used in mineral processing. A summary of the broad range of comminution applications of HPGRs is presented in Table 14.2-3.

SECONDARY MILLING

For those circuits requiring secondary grinding (most circuits aside from heap leach operations and single-stage AG/SAG circuits), the use of wet ball mills has remained the standard unit operation. Most such circuits use ball mills in closed circuit with hydrocyclones. However, closing circuits with fine screens is becoming more common, particularly in the iron ore industry (Valine et al. 2009). The majority of applications grind from a typical range of F_{80} values of 1–13 mm to P_{80} values of 300–37 μm. Pebble mills are also used in a number of applications.



Ball mills as large as 8.5 m (28 ft) in diameter are now being constructed. As with SAG mills, twin pinion and girth gears can be considered for mills with power input up to at least 15 MW (generally mills with a diameter of 7.3 m [24 ft] or less). Wraparound drives are the standard for larger mills.

In general, given a mill of suitable power and operated with an appropriate feed size, reduction ratio, media size selection, and the use of efficient classifiers, accurately predicting grinding circuit response is relatively straightforward. These principles apply for either wet or dry milling.

Aside from the widely used Bond equation (discussed later in the "Circuit Design" section), Bond used eight factors to "correct" for the power required for grinding in different operating scenarios (Rowland 2002). Bond's work to develop criteria for use in designing grinding circuits has proved to be enduring and useful, even with the contemporary availability of powerful simulation tools. Although the utility of correction factors for quantitative contemporary use in formal design is debatable, using the factors for qualitative evaluation of aspects affecting grinding efficiency can have value. Two of the eight correction factors apply strictly to rod milling, with the remaining six to ball mill grinding. Of greatest interest for current applications are corrections for coarse feed (with the definition of what is excessively coarse being a function of ore hardness), open-circuit milling (vs. closed-circuit), grinding to a P_{80} finer than 75 μm, and excessively low reduction ratios. One correction factor was developed to correct for inefficiency of large ball mills; many mill designers today believe that this factor had more to do with inefficiencies of classification in large hydrocyclones in early mill installations than in any actual milling inefficiency. The last factor for ball milling applies to dry grinding. In summary, although using these factors as originally developed for design may not be relevant, using them qualitatively to assess efficient operating conditions can be a useful tool.

By far the largest tonnages processed through secondary milling today are classified using hydrocyclones. Specialized low-tonnage operations may use screens, selected contemporary operations still employ screw classifiers, and dry operations generally use cyclones. A detailed discussion of the appropriate design for recirculating load is beyond the scope of this chapter. Milling efficiency typically increases with closed-circuit operation and will often increase to a certain level with increasing circulating load. After a certain point, the grinding efficiency declines with increasing recirculating load. Also, at a certain point, the power required for pumping for increased recirculation is not offset by improved grinding efficiency.

Some circuits perform grinding in one step, others in multiple stages (though rarely exceeding two), and occasionally with beneficiation integrated into the grinding circuit. The use of gravity concentration integrated into the mill recirculating load is common for the recovery of gold, flash flotation is often seen in sulfide mills, and recovery efforts after each stage of grinding are common for recovering platinum group metals and certain iron ore operations relying on magnetic separation.

TERTIARY MILLING

In the context of this paper, the term *tertiary milling* is used to describe concentrate regrind, grinding conducted for materials handling (iron ore pelletizing and pumping of mineral concentrates, for example), and fine grinding for specialized metallurgical applications. The border between a typical tertiary milling application and fine grinding is not distinct. However, as the methodologies for sizing change substantially at nominally 37 μm (400 mesh, and switching from conventional sieving practice toward subsieve analysis and alternate techniques at finer sizes), designating grinding to a P_{80} <37 μm as fine grinding is a useful designation.

Most grinding circuits are developed with the concept that the mill feed will be ground to an economic optimum such that further grinding expense (in terms of energy and media wear) is not justified based on the additional liberation and recovery of additional value units. In many cases, grinding 100% of the bulk mill feed to this size represents the optimum in terms of overall project economics and simplicity. In some circuits, it is desirable to have multiple stages of liberation and beneficiation. Since physical mineral separation processes have an optimum size range for efficiency, and essentially all lose efficiency at very fine particle sizes, this sequence can allow recovery of value minerals as they are liberated and before they are overground. Particularly in flotation, value minerals are often recovered to rougher concentrates when only partially liberated. Further grinding of such concentrates is employed to increase liberation and facilitate production of concentrate at a salable grade. Aside from liberation and recovery considerations, material handling of concentrates may dictate further size reduction. Examples include grinding of concentrates to allow pumping without pipeline wear or grinding of iron ore concentrates prior to pelletizing operations.

The field of options for fine grinding is diverse, with many originally developed to fulfill a specific need and subsequently marketed. Although not all operations require this stage of grinding, for those that do it is often a critical unit operation. Although the mills are smaller in size than mills for primary and secondary grinding, unit energy input (ranging from 5 to 40 kW·h/t) for tertiary mill feed often exceeds the total unit energy requirement for the bulk feed. In broad terms, the equipment field can be classified into rotating mills, stirred mills, and a general category of specialized mills. In general, the stirred mill category has the ability to grind finer with a higher efficiency than rotating mills. Specialized mills can cover a broad range of sizes but tend to be more focused to specific applications. Options for fine grinding are summarized:

- Conventional rotating mills (ball mills)
- Stirred mills
  - Vertical shaft mill (screw type). Also referred to generically as tower mills, after an early manufacturer, the Japan Tower Mill Company. Similar mills are now made by several manufacturers, with perhaps the most common being the descendant of the original mill design (by Nippon Eirich Co. Ltd.) by the trade name of Vertimill (marketed by Metso) (Lynch and Rowland 2005).
  - Vertical shaft mill (pin type). One trade name is the Metprotech mill (marketed by Bradken); another with a higher tip speed is the stirred media detritor (SMD) (marketed by Metso).
  - Horizontal shaft mill. The IsaMill has made broad inroads into fine grinding.
- Other specialized mills
  - Jet mills
  - Vibratory ball mills
  - Roller mills
  - Centrifugal mills

These machines are classified primarily by their mechanical configuration. Lichter and Davy (2002) provide another useful distinguishing feature for stirred mills—the charge motion. They cite a distinct difference between mills in which the charge is stirred (tower mills and some pin mills) and those in which the charge is fluidized (some pin mills and IsaMills), indicating that stirred mills are more efficient with coarse, hard feeds and that fluidized mills are more efficient with relatively finer, softer feeds.

Conventional rotating (tumbling) ball mills are often used to grind concentrates down to sizes of nominally –37 μm. Common applications include tertiary milling with multiple stages of grinding, in regrind applications, and in preparation of iron ore concentrates for pelletizing.

Stirred mills are often used for fine grinding. Mills in this category are sometimes more commonly referred to by their trade names. Stirred mills offer a higher power density (kilowatts per cubic meter), which, combined with the fact that they are filled with media (as opposed to tumbling mills, where the charge volume is nominally 35% of the total mill volume), means that these mills are compact in terms of installed power. Tower mills are occasionally used as way to retrofit additional grinding power with a small footprint and low capital for civil works; in this capacity they are often used for additional secondary or for tertiary grinding. They are widely used in lime slaking and in concentrate regrind applications. Pin mills (of either nonfluidizing or fluidizing tip speed) are generally the next mill considered at progressively finer grinds to a nominal grind size with a P_{80} of 5 μm. IsaMills are established as a versatile fine grinding mill, having been commercialized after being developed at Mount Isa Mines (Queensland, Australia). The IsaMill has demonstrated an ability to grind sizes with a nominal P_{80} of 5 μm. IsaMill models with up to 3 MW of installed power have broadened the mill's usage to regrind applications where higher tonnages dictate larger mill sizes (Burford and Niva 2008).

Grinding energies required (sometimes judged by the calculation of an operating work index, Wi_o, at coarser sizes, and at finer sizes by the specific energy input required to attain the target grind) often increase substantially as grinds get progressively finer. This can be due to a combination of factors, including higher energy required as the mineral grain size is approached, the number of micro-imperfections in the particle structure to exploit decreases, and, not insignificantly, the efficiency of classification is reduced. The required energy inputs can vary substantially based on mill type, media type, and the efficiency of classification employed. Tests should be conducted with a variety of machines and with a variety of media types to measure the specific energy input required to attain the target grind. Media types and sizes are summarized in a subsequent section ("Media and Liners"), but it is worth noting that the energy efficiency of fine grinding is strongly influenced by the media type selected (Gao et al. 2001). Additionally, based on the high unit power input, the integrity of media is also critically important. At very fine grind sizes, and depending on the material ground, the energy input can modify the reactivity of the material, and this can be a consideration in the chosen grinding methodology.

There are number of specialized fine-grinding applications, particularly in the fields of industrial minerals, powders, and the like. Fine grinding in specialized applications is often conducted dry and using either ceramic media or autogenously to avoid iron contamination. Examples include jet milling, centrifugal mills (including the nutating mill), vibratory ball mills, and roller mills. The reader is directed toward manufacturers and the body of literature for detailed coverage of these applications.

No discussion of ultrafine grinding would be complete without touching on the method of particle size analysis. At extremely fine sizes, particle size determination is not always straightforward. The measurements used are often indirect measurements from which particle size is estimated, with different techniques resulting in a different size being inferred. Additionally, the intense energy input can change the surface chemistry of the ground material, which can have effects including agglomeration or increased galvanic activity. For example, the use of specialized electroformed nickel subsieves (which offer precisely sized apertures for sieves at sizes less than 20 μm) is restricted for copper concentrates because of rapid galvanic action with the sieve itself.

Techniques often used include conventional sieves, specialized subsieves (generally available at 15, 10, and 5 μm) made of textile or electroformed and photo-etched nickel, and indirect methods, which employ material properties. Techniques rely on measurements of settling velocity (by means of elutriation, sedimentation, or centrifugal sedimentation), light dispersion characteristics, or both. Examples include the Warman Cyclosizer, the Malvern Mastersizer laser analysis, Microtrac's laser unit, Quantachrome's Microscan

units, as well as others including the Coulter counter and surface area techniques. Regardless of technique, it is important to use the same one throughout a study. It can also be worthwhile to confirm sizing calculated via a certain technique using microscopy, either direct or in combination with image analysis software. Though this is unlikely to have any benefit for a circuit in operation, it can be useful in comparing size distributions of different machines. Comparing numbers derived using different techniques should be performed only with great caution.

SPECIAL APPLICATIONS

This chapter has focused largely on the comminution means employed by the majority of mineral processing operations (as judged by the tonnages processed). A number of special considerations apply either to specific industries, minerals, or focused applications. Comminution to develop a specific size distribution (rather than the simpler approach of assessing the size distribution through the use of a single data point) and a certain shape of particle (rather than using liberation as the goal), along mineral boundaries, and beneficiation steps integrated in the comminution process are all often considerations.

Beneficiation during comminution is often employed. The concentration of heavier specific gravity minerals in hydrocyclone feed or more often in hydrocyclone underflows is well documented and is used as a preconcentration step in flash flotation and gravity concentration units in a number of grinding circuits. The addition of reagents and lixiviants to grinding mills is commonly practiced, either for conditioning (commonly in flotation) or to increase leach residence time.

In certain applications (typically aggregate or industrial minerals), the particle shape resulting from comminution can be important and is a criterion in the selection of certain types of comminution machines. Examples include vertical shaft impact crushers or Gyradisc (marketed by Metso) crushers, which are examples of machines sometimes selected for comminution to a specific particle shape. Similarly, in certain applications, minimizing fines generation while attaining a grind below a maximum particle size is important. When this requirement is overriding, certain grinding equipment (listed in order of coarser grinds and lower fines generation) can be used: center discharge rod mills, end-peripheral discharge rod mills, overflow rod mills, and grate discharge ball mills. In quarrying and certain other applications, maximizing yield in certain size fractions preferentially over other size fractions can add significant value. For specialized applications such as this, close consultation with vendors and thorough testing are recommended.

Dry grinding is an important, albeit niche, application. For any pyrometallurgical operation, dry grinding is an obvious consideration. Newmont's Carlin mill and Barrick's Goldstrike mill in Nevada both have roaster facilities fed by Krupp double-rotator dry mills. The double-rotator mills consist of a twin chamber mill (with sides for coarse and fine milling), with both sides discharging to a common air classification system. Operation of Goldstrike's system is well described by Thomas et al. (2001). Newmont's Minahasa gold operation in Indonesia employed an Aerofall SAG mill followed by dry ball milling prior to decommissioning. The IOC's Carol Concentrator in Labrador (Canada) formerly milled iron ore for gravity concentration using dry Aerofall AG mills; Chung et al. (2001) demonstrated substantially better energy efficiency in grinding using dry milling. Energy costs for drying, particularly for a wet downstream process, contributed ultimately to the full conversion of the Carol Concentrator to wet AG. Richards Bay Minerals uses an Aerofall mill for dry grinding of titanium slags. Dry grinding with air classification should be considered in applications where the follow-on process is pyrometallurgical and drying would be required anyway, minimization of fines during comminution is critical (with air-sweep and classification assisting in this regard), or an ore's aggressive soluble components make dry grinding more cost-efficient than construction of a wet milling circuit made from corrosion-resistant materials.

A number of other specialized grinding units are referenced in this chapter based on their comminution range (primary, secondary, or tertiary grinding). Media selection to avoid contamination is also a consideration, referenced later in the "Media and Liners" section. Finally, certain applications find that media selection can impact metallurgical performance (through the interaction of redox potential and dissolved oxygen); for certain applications, AG, high chrome, or inert media can be preferred.

ORE CHARACTERIZATION, CIRCUIT DESIGN, AND CIRCUIT SELECTION

Many ore bodies can be successfully processed using a range of comminution circuit configurations. In some cases, however, certain types of circuits are favored over others. Ore characteristics (competency, density, work index, abrasivity, chemical composition), plant capacity, downstream processing requirements, mine life, capital costs, operating costs, delivery time for major components, and plant location are all factors in process selection. Given ore characterization data, alternative circuit designs to accomplish the required comminution can be developed. Capital and operating cost estimates for each circuit alternative allow for trade-off studies. Ore characterization, circuit design, and circuit selection are summarized briefly, with each addressed in depth in the broader literature.

Before an effective study culminating in a circuit design can be commissioned, a sufficient knowledge of the deposit and the mining method and sequence must be defined to allow development of a sampling design. Sampling of a greenfield deposit via drilling can be an expensive undertaking, and collection of a bulk sample for pilot testing (if desired or required) often exceeds the cost of the testing itself. Knowledge of the overall range of comminution characteristics within a deposit can be useful, but, as a guideline, the testing effort based on ore type should be proportional to the representation in the overall reserves. If ore types have divergent characteristics and/or will be mined at different periods in the mine life, it may be prudent to consider construction of a modular plant.

In some cases, blending of samples may also be considered. If so, blending should be done in a fashion consistent with the planned mining sequence. For instance, blending two samples that will be milled together may make sense. However, compositing of an entire drill core consisting of different horizons almost never makes sense and typically results in misleading data. Many designers prefer to blend the results of testing (mathematically) of individual ore types rather than blending a sample for testing. Both approaches have advantages and disadvantages. Obviously, testing for circuit design should be performed on ore and not waste; too many projects have had initial characterization done on waste (with waste samples being more readily available). Efforts in reasonable ore-body definition and the planned mining sequence to allow

development of a rational sampling program is almost always a good investment.

Ore Characterization

Bench-scale breakage characterization tests are the basis for circuit design. Such tests fall into three broad categories: (1) grindability, (2) single-particle breakage, and (3) standard materials. Pilot-scale testing has long been considered the most reliable way to perform test work. However, the cost of testing, the difficulty in getting representative samples, advances in design methodologies, and greater experience with newer comminution circuits have tended to decrease the importance of pilot testing.

Typically, grindability tests rely on (1) a known size distribution of feed, (2) the application of a known or measured amount of energy to (3) a measured feed rate, and (4) a measured product size distribution. Based on these four items, an index is then calculated. The traditional Bond work index is perhaps the best known, but similar indices are calculated by other tests. Grindability tests that reach a locked cycle equilibrium or steady-state continuous operation are a better indicator of actual mill performance than batch tests. The design methodology for HPGRs using a bench-scale test (such as Polysius' LABWAL test) is largely analogous to this approach, except that primary index is a specific throughput, with measurements for specific energy input and the comminution outcome of that energy input also measured.

Single-particle breakage tests typically endeavor to quantify breakage as a function of energy input. Regardless of the test, using a breakage energy regime as close to the actual milling conditions as possible is preferred. Single-particle breakage tests provide fundamental data critical for a simulation effort; traditional grindability tests are unable to generate this data. Unfortunately, tests of this type cannot reliably predict the steady-state mill load; for autogenous/semiautogenous milling, the composition of the mill load defines mill performance.

Some comminution machines use conventional civil engineering measurements of strength as a direct basis for design, such as unconfined compressive strength. This is particularly true for crushers. Aside from the comminution tests presented, other indicative data can be used to map the overall comminution profile of an ore body, particularly rock quality designation and point load testing. Such tests, though not directly usable for design, can prove beneficial in determining the distribution of ore regimes. In some cases, correlations to comminution tests using these (inexpensive and quick) test results can prove constructive.

In addition to breakage tests, because media and liner costs represent significant operating costs, tests to determine wear rates are often conducted. The Pennsylvania abrasion test (often called the Bond abrasion test) is the most widespread. However, plant correlation with test results is often not particularly good. Because the test is conducted dry, it does not measure corrosion, a significant source of media consumption in wet grinding circuits. Abrasion data can also be obtained using specialized equipment, such as Polysius' ATWAL test for HPGRs, or by direct measurements of wear in pilot testing. A good approach is to use these tests to determine the relative wear of an ore type to others, then to benchmark with similar circuits and similar ores in operation.

Pilot testing involves larger-scale, steady-state testing at a range of operating conditions (including a feed size similar to the anticipated design) to evaluate potential design and operating scenarios. The response is then either directly scaled from pilot-sized to full-scale equipment using either a volumetric or a power basis. Pilot testing offers a high degree of confidence but can be inadequate in actual utility because of the limited number of variables that can be reasonably tested, the amount of sample required, and the logistics and expense of sample acquisition.

A number of tests have been developed over the years with various strengths and weaknesses. This is partly a reflection of proprietary design approaches by various companies and designers, and perhaps also a reflection of the never-ending quest for a test that can fully define the comminution response of an ore type quickly, with little sample, and at low cost. A summary of selected ore characterization tests are presented in Table 14.2-4. Most of the tests summarized are conventional comminution tests relevant for primary and secondary grinding operations. Bench-scale and pilot-scale HPGR tests are included, with direct consultation with manufacturers recommended for tertiary grinding tests (most of which rely on direct scaling based on unit power input). All testing (to include the benchmark of pilot testing) presents trade-offs, in terms of data developed, with the time, effort, and cost of sample collection and testing. In many cases, factoring how representative the samples tested are of the ore body presents its own challenges. Fundamentally, a large number of poorly selected samples cannot overcome a lack of sample design. Data developed from testing samples that poorly represent the intended population are at best useless and at worst damaging in that they can contribute to incorrect designs or performance projections.

Ore testing should also consider the methodology of the subsequent circuit design. Traditional power-based design methods are generally based on work indices measured during grindability tests. Then these data are typically scaled based on power input. Simulation circuit design generally relies on the results of single-particle tests. A combination of computational mathematical modeling (circuit simulation) and use of traditional work indices are generally used in current practice. Additionally, to broaden the applicability of certain tests, some designers have developed correlations (some with defined bands of variance) that allow prediction of single-particle test parameters from grindability tests (particularly the SMC Test; Morrell 2006) and vice versa.

A sound approach for ore-body comminution is an integrated test program using both well-designed steady-state tests and single-particle breakage tests. These tests may be complemented with other tests to map a deposit and with equipment-specific tests (i.e., bench-scale tests for specific comminution machines) supplanting or replacing portions of the test program. Simulation of bench- and pilot-scale mill tests via discrete element modeling or other high-definition models is well within the scope of today's technology. Perhaps single-particle ore characterization in conjunction with high-definition modeling and scaling of steady-state bench-scale tests will become the norm for future design work.

Circuit Design

Given a design throughput, grind size target, and ore breakage characteristics for an ore body (most appropriately evaluated as a range and ideally based on a preliminary mine plan), a number of circuit designs can be prepared for evaluation. Based on circuit specifications, ore characteristics, downstream processes, location, operator preferences, and scoping

Table 14.2-4 Summary of ore characterization tests

Test	Mill Diameter, m	Top Size, mm	Core Size, Standard Reference	Peak Energy*, J/kg	Peak Energy, J	Sample Requested, kg	Sample Used†, kg	Closing Size, mm	Type
AG/SAG pilot	1.83	100–150	N/A‡	50	150	~10,000/test	Varies	Varies	Continuous

*Peak energy is estimated as the nominal maximum impact breakage energy input based on the highest energy event on the coarsest size range used in the test.

†Sample is the amount typically used in conducting the test and typically still usable for metallurgical testing if required. The amount is typically less than requested based either on the amount required for sampling purposes or to allow for repeat testing by the laboratory.

‡N/A = not applicable.

§S. Morrell (personal communication).

**Diameter for HPGR tests specifies rolls diameter.

and prefeasibility studies, a short list of comminution circuit types can generally be developed that merit development of a process design.

Fundamental to achieving size reduction is the application of power; applying power at peak efficiency reduces unit operating costs and ensures efficient utilization of capital. The machines most widely used to apply comminution energy have been discussed in previous sections. The machines described apply energy via two mechanisms:

1. Directly through devices that break particles through compressive force (crushers, for example)
2. Initially to impart motion to a grinding charge, a portion of which energy is then translated into particle breakage

For the first case, the machines are generally controlled by volumetric throughput. The amount of power drawn to impart compressive forces is a direct function of the hardness of the material being broken by compression. As a result, the unit power can vary based on material type at a fixed throughput. For a given material type and circuit/machine configuration, the size distribution of the product tends to be fairly consistent.

In contrast, application of power in tumbling mills is somewhat more complex. Once power is drawn in a rotating mill, a portion of the power is applied to the charge, resulting in breakage through the mechanisms of impact, abrasion, and attrition. With a steady-state charge, the power imparted is constant, regardless of material hardness or throughput. In overflow mills, the throughput through the mill can be readily varied, and there is a degree of control over the unit power input. A SAG mill's throughput, though, is volumetrically controlled based on the mill's discharge grates. As throughput decreases in a tumbling mill with a constant power draw, the unit power increases, and a finer grind results.

In both cases, though, the fundamental driver of the amount of breakage achieved is the amount of power delivered to each unit mass of material. Therefore, in designing for volumetric throughput machines, it is essential to have a firm understanding of throughput and how much power will be drawn under the operating conditions used. In tumbling mills, it is essential to understand the power draw that the mill will achieve and the range of throughput that can be expected under such conditions.

Historical articles on comminution circuit design have presented tabulations of power draw estimates for mills and machines of a given size. Indeed, substantial effort by mill designers went toward understanding how the power installed on a mill would be drawn. In numerous case studies, the installed motor power was inadequate for operation at the desired operating conditions. Conversely, motors with rated power outputs larger than could ever be drawn have been installed, leading to confusion on the part of designers and operators who believed that this power should be available for grinding.

Much of the art of power estimation was converted to direct computation through the development of a mathematical model by Morrell (1996). His model is an outcome of modeling the physics of the power required to impart charge motion and lift; fundamentally, a mill's power draw is the sum of the power (applied over time) required to impart kinetic and potential energy to the mill charge. The power draw of a mill is a function of (1) the charge shape (including the volumetric filling of the mill, the charge density, amount of slurry pooling, etc.), (2) charge position (particularly top [or shoulder] and bottom [or toe] position of the charge), and (3) the mill speed. It is evident to practitioners that these three fundamental variables of mill power draw are interrelated—for example, charge shape and position are impacted by changes in mill speed.

The critical question in design is the efficient application of power. As with ore characterization, there are a number of design techniques. The use of power-based, simulation-based, and direct-scaling benchmarking with existing plants

or (preferably) a combination of techniques can be used to develop circuit designs for evaluation. Regardless of methodology, a key metric of the design process is the design power input (kilowatt-hours per ton) for each ore type. Designers often evaluate (and sometimes rank) circuits in terms of unit power input; mill operators more commonly reference circuit performance based simply on throughput at target operating conditions.

In power-based designs, the Bond equation continues to be a fundamental tool. The correlation between the power applied in a grinding operation and the amount of size reduction attained has long been intuitively known, with several relationships between the two proposed through the years. Over decades of application, F.C. Bond's third-theory equation has an established track record for both design and analyses of conventional grinding circuits. The standard Bond equation is presented in Equation 14.2-1 (Bond 1960). The equation can also be used to evaluate the relative power efficiency of simulated and operating circuits. By rearranging the formula to Equation 14.2-2, the operating work index (Wi_o) of an existing grinding circuit can be calculated, given known mill power draw, throughput, feed, and product size distributions. The use of operating work indices can be useful for forecasting future mill performance and as a benchmark to compare against laboratory measured work indices.

$$\text{kW} \cdot \text{h/t} = Wi * \left(\frac{10}{\sqrt{P_{80}}} - \frac{10}{\sqrt{F_{80}}} \right) \tag{14.2-1}$$

$$Wi_o = \frac{\text{kW} \cdot \text{h/t}}{\left(\frac{10}{\sqrt{P_{80}}} - \frac{10}{\sqrt{F_{80}}} \right)} \tag{14.2-2}$$

where

kW·h/t = power applied per ton of feed to the grinding unit
Wi = standard Bond work index of the ore
P_{80} = 80% cumulative passing size of the product, in μm
F_{80} = 80% cumulative passing size of the feed, in μm

Care must be employed in using the Bond equation for sizing individual unit operations when the feed and product particle size distributions are not parallel; this challenge is an artifact of describing a particle size distribution through the use of one number (represented by the P or F size). For example, SAG mills and HPGRs both produce substantially more fines than a traditional crushing plant for a given F size. As a result, an operating work index of a ball mill following a SAG mill or an HPGR is substantially lower than the operating work index of a ball mill following a rod mill or crusher. Similarly, the operating work index of the unit preceding the ball mill will be higher for those machines producing substantial fines than for crushers or rod mills. The apparent advantage in ball mill efficiency is a misnomer; the ball mill simply has less work to do with greater proportions of fines in the feed. This effect can be addressed in a number of ways, but recognizing it is essential in design (McKen et al. 2001).

Power-based designs rely on circuit configurations that will deliver the targeted energy input. As such, sound use of computational methods, tables, or benchmarking to ensure that the designed mill/motor configurations will draw and apply the target power is essential. Aside from proper equipment sizing, the most critical pitfall of a power-based design is ensuring that the design is achievable in terms of the assigned power split for each grinding stage. Many designs have relied on arbitrary power allocation between grinding stages. When commissioned, it was found that throughput constraints between units would either prevent the design throughput from being achieved, most often while attaining a finer grind than designed, or vice versa.

Simulation-based designs use a set of mathematical models to calculate the anticipated response of a circuit under a set of operating conditions. A number of commercial and proprietary simulation packages are available. Major equipment manufacturers often use in-house simulation models. Many of these packages are based on a combination of empirical and fundamental models, and correlations with observed plant performance.

Simulation is a powerful tool that offers the ability to evaluate circuit response for a range of operating conditions and of a given circuit for a range of feed types, and readily compare a number of circuit options. It can also provide a great deal of useful process information (in terms of the volumes and size distributions of intermediate flows) that is unavailable from power-based designs. Notably, simulation offers the ability to evaluate the impact of classification on the comminution circuit, something that cannot be done with power-based techniques. In addition to computer simulation to model steady-state comminution circuit performance, discrete event simulation can be useful in evaluating overall circuit response with respect to linkages with discontinuous (truck dumping) or semicontinuous (such as a crushing plant with periodic stops due to metal detects) processes.

When conducting a design exercise, it is critical to validate that the circuit being modeled is within the boundaries of the underlying model. Although this is generally the case for typical processing plants, the use of models outside of the operating window for which the model was developed can be misleading. Calculating the operating work index of circuits developed using circuit simulation can provide a cross-reference (reality check) and can be useful for evaluating the relative efficiency of circuits.

Direct scaling is employed for a number of comminution machines and, depending on the design approach, can be based on achieving a target unit energy input (kilowatt-hours per ton) or on a specific throughput determined in laboratory testing. For single unit operations, and when used in conjunction with a good database of existing plant operations, robust designs can be produced. However, examples frequently emerge of direct scaling and commissioning of plants that could not achieve the design throughput but are capable of grinding finer than target grind, or vice versa—that is, they exceed nameplate throughput but do not achieve the target grind.

Regardless of the design technique, benchmarking is a useful tool. Frequently, comparison of ore breakage characteristics and circuit design parameters can yield a list of relevant similar operations. In fact, although this approach may not be bankable, it is widely used for low-risk, self-financed expansion projects or when scaling the anticipated throughput of a new deposit in an existing mill. Using it as the sole basis for design, however, can introduce a higher degree of uncertainty in the design outcome.

An additional consideration is the question of how to integrate the stages in a comminution circuit. Primary grinding units, whether they are crushers, AG/SAG mills, or HPGRs, arrive at their unit power input largely based on the volumetric throughput at which they are operated. For AG/SAG mills at a given operating condition of speed and load, the power input

is fixed, so the only variable is feed rate (which will change based on ore hardness and size distribution). For crushers or HPGRs, though, the feed rate is fixed based on volumetric throughput at a given aperture, and the power drawn varies as a function of the ore characteristics. Regardless, a design methodology that considers designing the primary milling stage based on the required throughput, with the secondary stage based on the amount of power required to finish grind the design throughput, is more successful than a methodology that counts on a set amount of power input in the primary grinding stage.

For power-based designs, determining the appropriate and efficient way to input the design grinding power is the core question. For simulation-based designs, determining the amount of power drawn under a given set of simulated conditions is required. Cross checking this value with calculated power requirements or benchmarking with operating circuits is wise. For scaled designs, it is essential to ensure that power input scales similarly to volumetric throughput, or the unit power inputs will not match, and consequently the desired size reduction may not be attained at the target throughput.

Most modern circuit designers consider the various design techniques to be complementary. Although various designers may have preferences, a robust design will consider several different approaches. A higher degree of confidence can be assigned to a design that is confirmed based on traditional power-based approaches, with various operating conditions investigated and evaluated by simulation, and which benchmarks and scales favorably with similar operations. Although any of the techniques can be used independently, the most robust design will eventuate through the combination of these techniques.

Circuit Selection

Staged crushing plants are favored in cases of low-tonnage operations where little fines generation is desired and a dry, coarse product is required (heap leaches), or in moderate tonnage operations with hard ore. Plants that will be fed sticky ores, with large amounts of tramp metal, or high-tonnage operations are generally less favorable for a traditional crushing plant. A benchmark for annual run time (including mechanical availability and all other factors) for a well-maintained and run modern crushing plant is 85%. Lower availabilities are typical in more-demanding applications.

Semiautogenous milling is favored for high-capacity plants, soft to moderately hard ore types, sticky or clay-bearing ores, and ores containing significant amounts of tramp metal or magnetite. Ores with a competent fraction, particularly higher-density ores, can be amenable to autogenous grinding. This is particularly true for small to medium throughputs with a long mine life. Because AG mills tend to have a lower unit power input for a given mill size, they can be more expensive to construct but much less expensive to run (when compared on unit cost basis) compared to a SAG mill. Circuits designed for autogenous grinding are often designed to accommodate semiautogenous grinding either for operational flexibility or with the anticipation of milling future ore bodies; a case study of an operation with a versatile single-stage AG/SAG circuit is Brunswick (Larsen et al. 2001).

When using the largest mills available, a single SAG mill often produces feed for secondary grinding two or more ball mills. In a typical SAG–ball mill circuit, the SAG circuits should generally be designed for the target throughput, with the ball mill circuit designed to achieve the target grind. Based on ore breakage characteristics, feed size, grate aperture, and circuit closing size, the ability to shift the transfer size substantially between the SAG and ball mill circuits is often limited. Though exposure to significant downtime for a failure in a single line is often considered a drawback, SAG plants have demonstrated annual run times of 95%.

HPGRs are considered favorably as a circuit alternate to autogenous/semiautogenous milling. Such a circuit must be designed in conjunction with secondary crushing to reduce ROM ore to a size suitable for HPGR feed. HPGRs, in closed circuit with screens, then produce ball mill feed. HPGRs were selected for the Cerro Verde Cu-Mo project commissioned in 2006 and have also been specified for the Boddington project. Particularly in the case of hard and abrasive ores, HPGRs can offer operating cost benefits relative to SAG. Depending on the delivery time for large SAG mills (and often its accompanying wraparound electric motor), delivery and construction of HPGRs may be executed more quickly than for a SAG mill circuit. The largest HPGRs can be reasonably sized with a single large crusher to feed one ball mill for typical circuits. A crusher and closed-circuit HPGR grinding line feeding a ball mill will typically have lower availability and more unit operations than a similar SAG/ball mill line.

Substantial progress has been made in terms of availability and reliability. Preventive maintenance periods are required for cheek plates and inspections, but HPGR maintenance is rarely the controlling factor in overall circuit maintenance. Aside from rolls changes (akin to a mill reline and typically occurring between 2,000 and 15,000 running hours, depending on the material and application), more often circuit availability is controlled by belt, chute, screen, and conventional crusher maintenance. Circuit availabilities between a traditional crushing plant and a SAG mill should be expected for circuits where a secondary crusher/screen/HPGR replaces a SAG mill, with 90% run time a nominal benchmark. Aside from the fact that the degree of ancillary equipment (belts, transfer chutes, additional pumps, etc.) can increase the maintenance demand relative to a SAG plant, the additional unit operations also drive up capital costs.

Circuit selection is typically based on the calculation of the net present value of various circuit options (implicitly incorporating both differences in capital and operating costs and in performance between plant types). Qualitative considerations include location, operator preference, equipment lead times, and the like.

Selection of motor and drive types for tumbling mills is a specialized topic in itself. For larger mills (nominally more than 7.2 m [23.6 ft] in diameter for ball mills and more than 9.8 m [32.2 ft] for SAG mills), gearless (wraparound motor) and geared (pinion/bull gear combinations) drives are normally compared. Gear manufacturers indicate that geared drives with up to 10 MW per pinion are feasible (Hankes 2001). Failures with both large wraparound motors and large gears have occurred in the industry, and engineering trade-off studies will likely continue for those mills where either geared or wraparound motor drives could be used.

MEDIA AND LINERS

Table 14.2-5 summarizes the typical media sizes and types in the broadest use for mills discussed in this chapter. Contemporary practice in tumbling mills is to add a single-size makeup ball mass to maintain constant power draw. Ball

Table 14.2-5 Typical media sizes and types

Media	Size*	Type
SAG mills	127 mm (100–150 mm)	Forged steel
Ball mills	50–65 mm (25–100 mm)	Forged or cast steel
Regrind/fine-grind ball mills	25 mm (9–40 mm)	Forged or cast steel
Tower mills	12 mm (6–25 mm)	Forged, cast, or other (e.g., shot) steel
Pin mills	12 mm (3–12 mm) (Metprotech) 3 mm (SMD)	Steel or ceramic Ceramic or sand
IsaMills	3 mm (1–6 mm)	Sand, slag, ceramic

*Common makeup ball sizes indicated, with a typical range indicated in parentheses; coarser or finer sizes may be found in certain applications.

charging should be done on a daily basis or, more ideally, on a shift-wise basis. Some plants with a mechanized ball charging system (typically for SAG mills) have adopted continuous charging (at a rate matching the mill's steel consumption) to facilitate operating at peak conditions. As steel media most often have a hardness profile with a softer center, once balls reach a certain size, they tend to wear very quickly.

The use of a mixed-size makeup ball charge has been repeatedly demonstrated in laboratory studies to offer incremental efficiency benefits, but the benefits have been difficult to document at plant scale. Selected operations have adopted mixed-sized makeup ball charging for SAG mills, but it remains uncommon for ball mills. There is little reason to believe that the steady-state media size distribution resulting from the wear rate of the makeup ball size corresponds to the optimum ball size based on the mill's feed and target grind.

The concept of selecting a makeup ball size based on the coarseness of feed has long been recognized (Taggart 1945). In general, a mixed makeup ball charging regime improves grinding efficiency, with greatest potential benefit for single-stage milling applications with large size reductions. McIvor and Weldum (2004) suggests that the benefits from graded charges extend to pebble mills and hypothesizes that this is a fundamental reason for improved efficiency (relative to laboratory-measured work indices) at the Empire mill. Nonetheless, most operations tend to use a single-sized makeup ball size for reasons of convenience. In practical terms, for grate discharge mills, there is essentially zero grinding media smaller than the grate aperture at any given time. For overflow mills, the lower media size is constrained by the size at which media flow out of the mill (which, in turn, is effected by volumetric throughput, pulp density, and media size and density).

The use of ore as AG media was reviewed previously in the "AG/SAG Circuits" section. Pebble milling (a form of secondary milling) most often uses oversize material extracted from the primary milling circuit as media. This is most often done in applications with higher ore densities and can represent a substantial savings in milling costs. With ore densities lower than steel densities, larger mills are often required, and some degree of flexibility may be needed when the generation and consumption rates of AG media do not match.

The use of recycled SAG scats (worn and broken media recovered via magnets from SAG mill grate discharge) in ball mills has grown in application. The balls are direct charged to ball mills as a replacement for new grinding balls. The larger soft core of SAG media (as a result of larger size and requirements for ball durability) means that the recycled media wear more quickly than a typical like-sized new ball mill ball. Discussion of the use of alloys, cast/forged or other types of media, or whether to effect improved wear life through surface hardness, hardness profile, or improved resistance to corrosion is outside the scope of this chapter.

Liner innovation has contributed substantially to comminution performance. Nowhere has this been more evident than in semiautogenous milling. After early work that tended to focus more on maximizing life, current best practice is focused on maximizing total productivity over the life of a liner set. Generally this means development of a shell lifter set that facilitates (within the constraints of original mill shell drilling) a quick startup period with little to no lifter packing and for which full power draw can be maintained over the planned life of the liner set. Critical aspects of shell lifter design include lifter spacing, height, and face angle. In general, common practice has evolved toward operation with liner sets that are more open (have greater spacing between lifter bars relative to lifter heights). In general terms, this philosophy leads to less liner packing, the shortening (or elimination) of a break-in period with new liners, and higher mill performance over the liner set. Going too far can lead to short liner life offsetting performance benefits and, in extreme cases, insufficient charge lift to achieve baseline mill performance. Design of pulp lifters and discharge grates has been an area of intense effort by mill operators, particularly large, high-volumetric throughput mills.

Because of the HPGR's role in replacing duties performed by mills, HPGR liner wear is often relevant in comparison with liner and media cost. Cost savings relative to the overall costs of liner and media consumption in a rotating mill can often be realized. Relative to mill liners and grinding balls, HPGR wear surfaces are much lower volume and a more highly engineered product. The unit cost of media wear, generally in terms of dollars per metric ton (at equivalent kilowatt-hours per ton) is a good metric for comparison.

The use of liner handlers to reline mills is now standard practice, and the use of larger machines has facilitated consolidation of liner parts. The world's current largest liner handler is in use at PT Freeport Indonesia; the machine's 7,250-kg capacity has allowed consolidation of parts and reduction in the number of units requiring handling during a reline. Progressive refinements, with each pushing the then-existing technology's capacity in terms of casting integrity and liner handlers, now facilitates the use of 40% fewer liner pieces than the original design in PT Freeport Indonesia's 10.4-m (34-ft) and 11.6-m (38-ft) SAG mills. The use of a sound, integrated, and well-resourced maintenance approach can lead to annual run times in the 95%–96% range in even the most challenging environments. Such techniques can also be applied to ball mill liners or to primary crusher concave relines (e.g., with larger castings, reducing the number of rows from a typical five-row installation to three-row).

LOOKING FORWARD

This chapter has summarized a range of comminution options for mineral processing applications. Although machine design, performance, maintenance, and other aspects have been touched upon, the focus has been on the process. Since the last comminution chapter in the previous edition, the range of equipment options for mineral processing comminution plants

has broadened. AG/SAG circuits as well as circuits incorporating HPGRs are in wide use. In particular, AG/SAG mills and HPGRs have blurred the distinctions of using a certain machine for a certain feed size.

The low fraction of total power input in the crushing and grinding process that actually goes toward size reduction (with the balance being dissipated largely as heat and noise) has long been cited (Kelly and Spottiswood 1995). Despite intense research efforts with both public and private sponsorship, no viable commercial processes with markedly better efficiency are on the horizon. With increasing focus on energy input, from both high energy cost aspects but also considering the embodied energy and greenhouse gas impacts of various products, these efforts will continue. Interestingly in the case of energy input in mineral processing applications, the effects of increased energy input for liberation are offset by the benefits of improved resource recovery.

To the extent that the marketplace can accurately assign a value to the material produced and a cost to the negative impacts, assessing the benefits of increased comminution to affect increased recovery versus the costs of higher energy consumption should be clear. The focus on comminution as often the highest-cost category of mineral processing (both in terms of capital and operating) is likely to increase given continuing demand for resources and increasing awareness and attempts to mitigate the impact of the human carbon footprint. At first glance, decreasing the comminution effort may seem to be an easy target to achieve both cost and carbon footprint benefits. In many cases, though, the incremental comminution effort required for the incremental value recovery is less than the energy requirement to recover a like quantity of values from a freshly mined ton of ore. From an energy perspective, increasing comminution will in many cases be favorable to mining and milling new ore tons. Thorough study and cost quantification are required for a true optimization of the overall process.

CHAPTER 14.3

Classification by Screens and Cyclones

Brian Flintoff and Ronald Kuehl II

INTRODUCTION

The classification of particles based on size is an important step in almost all mineral processing flow sheets. Although the technical focus in plant design, control, and optimization is most often on comminution (e.g., size control and mineral liberation) and/or separation equipment (e.g., recovery/yield and grade), classification plays a critical role in optimizing process efficiency. This chapter focuses on two major classes of classification unit operations: screens and hydrocyclones.

SCREENS

Matthews (1985) said, "Screening is defined precisely as a mechanical process that accomplishes a separation of particles on the basis of size and their acceptance or rejection by a screening surface. Particles are presented to the apertures in a screening surface and are rejected if larger than the opening or accepted and passed through if smaller." The screening process has been a part of mineral processing flow sheets for a long time, and like many other unit operations, screening has seen some interesting mechanical and process developments over the past few years.

Looking across all of the process industries, there are many different kinds of screens and applications. However, the authors have restricted the discussion to the most common applications in the mining industry. Figure 14.3-1 is a generic graphical representation of the major applications of screening in mining: scalping, size control, and sorting.

Table 14.3-1 provides more amplification on the type of screen one might find in given applications.

Screen types can generally be categorized as follows:

- **Fixed types:** grizzlies, riffles, sieve bends, and so forth
- **Moving (linear) types:** vibrating, reciprocating, and resonance
- **Moving (rotating) types:** cylindrical trommels

Figures 14.3-2 through 14.3-6 are photographs of a grizzly screen, vibrating screen, trommel screen, Stack Sizer, and sieve bend. In general, these are the workhorses of the mining industry, with the vibrating screen standing out as the most widely employed screening unit operation. It is for this reason that most of the chapter is devoted to the vibrating screen.

Vibrating Screen Basics

The vibrating screen is ubiquitous in mineral processing plants. One would imagine that with this breadth and history of application and its apparent simplicity, there would be few remaining unknowns in the screening process. However, the design and operation of screening systems remains a blend of art and science—a statement used by many other authors (e.g., Mathews 1985). It is interesting to note that the screening process is enjoying something of a renaissance today, as new simulation tools offer a closer examination of the physics of the process, providing quantitative insights into mechanisms and their relation to design variables. In addition, new instrumentation offers real-time modulation and measurement of mechanical and process condition. The following section deals with vibrating screen basics and introduces some of the latest tools and techniques in the design, analysis, control, and optimization of vibrating screens.

Principles of Operation

The vibrating screen is used here as a proxy for all other screens, as the basic operating principles are similar or the same. In the screening process, a feed material comprised of particles of varying sizes is presented to the screen media (collectively, the screen deck) in such a way that those particles finer than the screen aperture fall through to the undersize stream, and those that are larger than the screen aperture continue moving along the screen surface to eventually report to the oversize stream.

Screening can be carried out with wet or dry feeds, although coarser particle separation (greater than a 5-mm aperture) is usually performed dry (at the surface moisture of the feed). Wet screening usually involves either sticky/clayey feeds or finer particle sizes where the solid material has been slurried to facilitate transportation and processing. In dry applications, some combination of vibration and gravity are responsible for particle transportation. In wet applications,

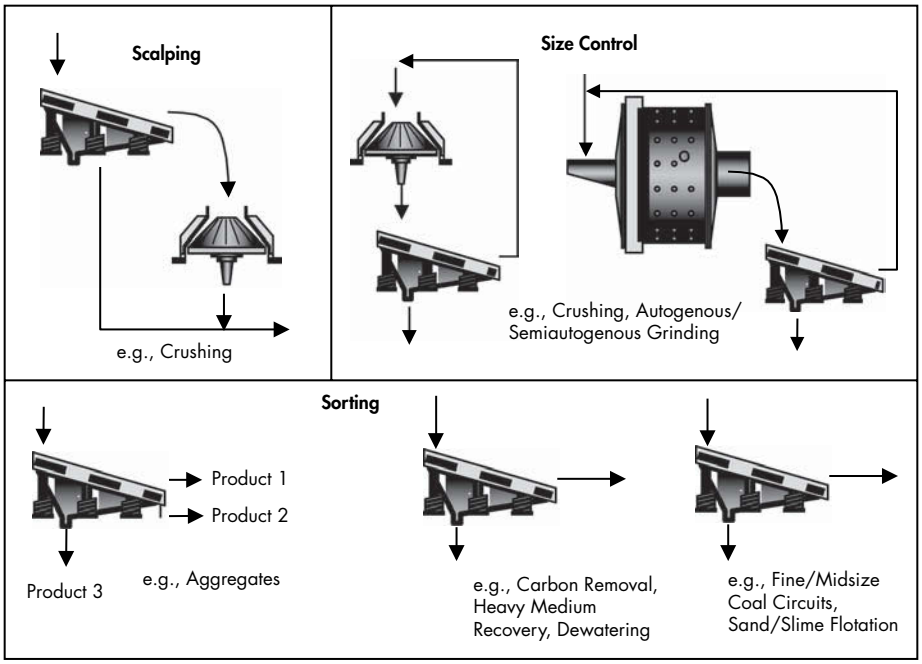

Figure 14.3-1 Examples of the application classes for screening in mining

Table 14.3-1 Types of screening operations

Operation and Description	Type of Screen Commonly Employed
Scalping: Scalping is strictly the removal of a small amount of oversize from a feed consisting predominantly of fines. Scalping typically consists of the removal of oversize from a feed with a maximum of 5% oversize and a minimum of 50% half size. Coarse scalping is typically smaller than 150 mm (6 in.) and larger than 50 mm (2 in.).	Coarse (grizzly), fine (same as fine separation), and ultrafine (same as ultrafine separation). *Example*: Grizzlies are usually used to scalp oversize material from primary crusher feed or are used to scalp fines from the feed to crushers or grinding rolls.
Course separation: Consists of making a size separation smaller than 50 mm (2 in.) and larger than 5 mm	Vibrating screens (banana, incline, and horizontal) and trommel screens. *Examples*: The removal of pebbles from a semiautogenous grinding discharge stream, sizing material for the next crushing stage, and sizing material for leach pile or product pile.
Fine separation: Consists of making a size separation smaller than 5 mm and larger than 0.3 mm (48 mesh)	Vibrating screens (banana, incline, and horizontal), which are typically set up with a high speed and a low amplitude or stroke; sifter screens; static sieves; and centrifugal screens. *Examples:* Sorting coal into ±28 mesh fractions for washing, and iron ore processing
Ultrafine separation: Consists of making a size separation smaller than 0.3 mm (48 mesh)	High-speed, low-amplitude vibrating screens; sifter screens; static sieves; centrifugal screens. *Example:* Size control on grinding circuit product
Dewatering: Consists of the removal of free water from a solid-water mixture and generally limited to 4 mesh and above	Decline vibrating, horizontal vibrating, inclined vibrating (about 10°), and centrifugal screens. *Example:* Wet quarrying operations
Trash removal: Consists of the removal of extraneous foreign matter. This is essentially a form of scalping operation, and the type of screen depends on the size range of the processed material.	Vibrating screens (horizontal or inclined), sifter screens, static sieves, and centrifugal screens. *Example*: The removal of extraneous organic and other matter from the leach feed in a gold plant
Other applications: Other applications include desliming (the removal of extremely fine particles from wet material by passing it over a screening surface), conveying (in some instances, the transport of a material may be as important as the screen operation), dense media recovery, a combination washing and dewatering operation, and concentration.	Vibrating screens (banana, incline, or horizontal), oscillating screens, and centrifugal screens. *Example*: Dense medium recovery in a coal washing plant, a wobbler feeder for conveying, and classifying sticky materials to a crusher

some form of vibrator mechanisms dictates the movement of material. However, hydrodynamic (drag) forces are introduced. In wet applications, deck water sprays or flood boxes are sometimes used to aid in classification. Spray selection is chosen based on two criteria: it must be decided whether the goal is to flush material through the deck or to wash off the fines. A general guideline is that water added to the feed is more effective than water sprayed on the deck in improving the classification.

Figure 14.3-7 is a schematic representation of the results of an experiment with a small horizontal vibrating screen having a screen aperture of 10 mm. (This particular screen and test [from Hilden 2007] is referenced throughout the text.) The shaded bars depict the relative mass flows, and the annotations show the mass mean size for each stream. As the feed is introduced onto the deck, it forms a bed that is usually several times the screen aperture in thickness. The bed moves

Source: Hilden 2007.
Figure 14.3-7 The relative mass flows and mean particle sizes for a horizontal vibrating screen

under the influence of gravitation and vibrational motion, and in the process, the particles stratify as the finer materials move quickly through the interstices of the larger particles and find their way to and then through the screen apertures. In this initial zone on the screen, rapid segregation means there is always sufficient fine material in the layer next to the screen deck that the flow through the screen apertures is more or less constant. This is said to be typical of crowded or saturation screening. However, as the fines are depleted, the bed height is reduced, and at some point the particles begin to act more or less as individual entities. This is the zone of separated or statistical screening, that is, each time the particle approaches the deck it has a chance (or a statistical trial) to pass through the aperture. (This notion of repetitive trials underpins many semi-empirical screen models.)

Figure 14.3-7 shows that the greatest flow of material to the undersize stream occurs closest to the feed end, which is typical of crowded screening. Segregation ensures that these particles presented to the apertures are small enough that the probability of passage to the undersize stream is ~1.0. The mass flow to the undersize stream decreases along the length of the deck, which is typical of the transition to separated screening, more typical of the coarser particles (the so-called "nearsize," as it is near to the size of the aperture) that remain in the bed. For these particles, the probability of passage on any one trial is significantly less than 1.0. The increase in the mass mean size along the deck also reflects the fact that the remaining material on the deck becomes coarser as it moves from the feed end to the discharge. This helps to explain why screen length governs efficiency. On the other hand, screen width is related to the amount of material that can be fed to the screen and be effectively separated, and therefore this is the major factor governing capacity.

On this latter point, a guideline for good dry-screen operation is for the bed depth at the discharge point to be three to four screen apertures in thickness. A guideline for wet screening is to design for a bed depth of four to six times the opening. With anything larger, the efficiency of removal of the particles close to the aperture size is reduced, as segregation is more difficult. This suggests that multiple screen decks probably should be considered, using a larger aperture size on the top deck to scalp out much of the larger oversize and reduce the loading on the lower deck for the final classification. Anything less and these particles will probably bounce excessively, reducing the number of trials and the screen efficiency. (It is

Table 14.3-2 Design and operating variables for vibrating screens

Figure 14.3-9 Blinding on a screen deck

also sometimes useful to install weirs on the deck's surface to hold back the flow as an aid to sustaining an active bed.)

Screen design and operation is about matching the screen characteristics to the (range of) feed conditions. Table 14.3-2 provides a summary of the important variables for each.

When focusing on design variables, screen area is important because capacity is proportional to width (W) and efficiency is proportional to length (L). It is common for $L \approx 2$ to 3 W. Because of the mechanical fittings on and around the screen decks, the effective area is often approximated as 90% to 95% of the actual area (LW). Screens are standard products, so the manufacturers dictate the actual sizes. It is therefore common to require more than one screen, operating in parallel, to effectively separate a feed.

Open area (OA) is expressed as the ratio of the total area of the apertures over the total active area of the screen deck. Figure 14.3-8 illustrates this for the screen in Figure 14.3-7 with a square aperture of 10 mm in a wire mesh screen with a wire diameter of 2 mm. From the explanations of screening mechanism, it is clear that the greater the OA, the greater the capacity of the screen. In practice, OA is limited by the need for sufficient mechanical strength and wear resistance of the deck and is a function of the media materials of construction, for example, wire mesh versus perforated plate.

This is a good point to introduce some common, and occasionally confusing, jargon associated with phenomena that act to reduce the OA and, hence, the capacity. The first is pegging (also called blinding or plugging), which occurs when a nearsize particle becomes firmly lodged in an aperture effectively eliminating it from the screening process. The second is blinding (also called bridging), which is the phenomena whereby smaller particles aggregate in such a way that they combine to block up the aperture, having the same overall effect as pegging, as shown in Figure 14.3-9. Blinding is more of a problem with moist or sticky materials and small aperture sizes.

The aperture size is, by convention, the minimum linear measurement in an opening; for example, the diameter for a round hole and the width (where width ≤ length) for a slot or a square. (Because screen performance assessments start with sieving samples of process streams and because the sieve has square apertures, the best correlations occur with square apertures in the screen media.) What is perhaps more important is the so-called throughfall size, h_T, which accounts for the change in effective opening as the screen is inclined. This is illustrated in Figure 14.3-10, where the angle of inclination is exaggerated to show the difference between the aperture size, h, and the throughfall size for a wire mesh screen surface. (There is a similar effect for rectangular slots.)

Although square apertures may be the most common, there is a multitude of aperture shapes. Some of the more common shapes are illustrated in Figure 14.3-11. Square or round shapes generally allow for better control of the separation size, although circular apertures are most often used in coarse-screening applications. Longitudinal slotted apertures allow slabby particles into the undersize stream. This increases capacity and reduces pegging and blinding. Transverse slots are mainly used in dewatering applications. (For steel or polymeric screen media, it is possible to design tapers and other forms of relief into the apertures to minimize pegging—see the insert in Figure 14.3-11 for an example.) Finally, the screen deck or panel is designed to withstand the load and maximize wear life. Therefore, in the case of a large spread in feed particle sizes and/or some large particles in the feed, it is common to use multiple screen decks to satisfy both mechanical and process requirements.

Inclining a screen deck increases the slope and causes the feed material to move more quickly on the deck, reducing the residence time and increasing capacity and sometimes efficiency. Vibration motion on a horizontal screen deck usually means that material velocities of 10 to 16 m/min (33 to 52 fpm), with an inclination in the neighborhood of 20°, will increase this into the range of 20 to 28 m/min (66 to 92 fpm). Generally, inclinations range from horizontal to as high as 30°, although ~20° is the usual limit. This led to the evolution of the multislope screen (also commonly known as a banana

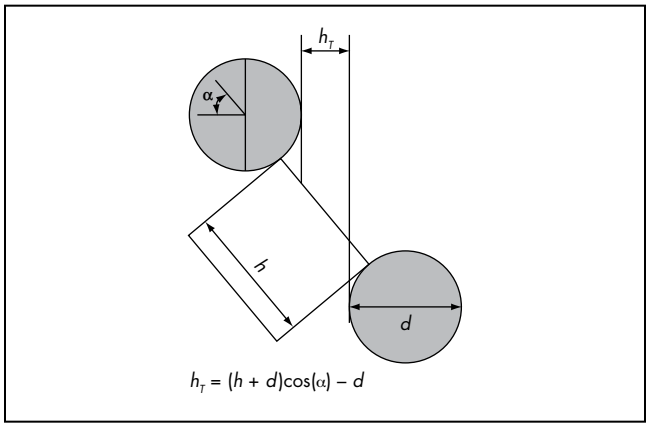

Figure 14.3-10 The relation between the throughfall size (h_T) and the aperture size (h)

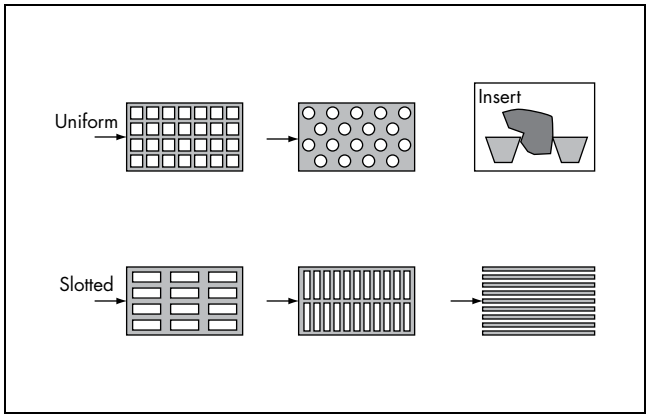

Figure 14.3-11 Common screen aperture shapes

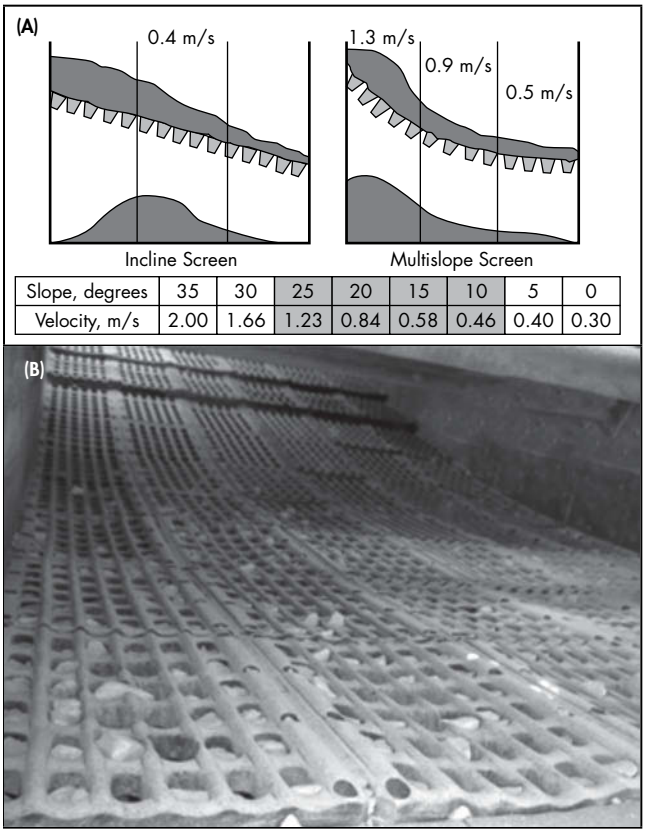
screen). The banana screen (Figure 14.3-12) has a relatively high slope in the initial screening zone, which takes advantage of the fast kinetics of fine particle removal. The slope then decreases, which slows particle movement and offers an additional G-force to accelerate removal of the larger fine material. In the final section, the slope is relatively flat, yielding minimal velocity and maximum residence time, for finer nearsize particle removal to the undersize stream.

Vibrating screen deck motion is circular, elliptical, or straight line, with the vibrating mechanism rotating in the direction of flow or counter to the flow. Strokes are usually in the range of 3 to 20 mm (0.118 to 0.787 in.) and speed ranges from 650 to 950 rpm. A key parameter here is the G-force (G), which is computed by Equation 14.3-1.



$$G = \frac{N^2 S}{1{,}789{,}129} \qquad (14.3\text{-}1)$$

where

G = the G-force (also known as the throw number)
N = speed (rpm)
S = stroke (mm)

Typical G-forces are in the 3.5-to-5.0 range, tending to higher values with heavy loads, sticky materials, or where pegging and blinding are issues. The G-force is usually higher in a horizontal screen, as it must provide the means for both stratification and material movement. (For example, with the horizontal test screen in Figure 14.3-7, the speed was 981 rpm and the stroke 5 mm [0.197 in.], giving a G of 2.69.) Table 14.3-3 amplifies on the conditions prevalent over a broad range of G-forces.

Figure 14.3-13 is a simplified graphic of particle motion with different trajectories, and Figure 14.3-14 shows how deck motion can be induced using weights on the shaft. Of

Slope, degrees	35	30	25	20	15	10	5	0
Velocity, m/s	2.00	1.66	1.23	0.84	0.58	0.46	0.40	0.30

Figure 14.3-12 Banana screen deck

Table 14.3-3 G-force implications in inclined vibrating screens

G-Force	Comment
<1.5	Practically no movement on the deck, so it is of no use.
1.5–2.5	The stratification is limited and the relative velocity between the particle and the deck is low. These parameters are suitable for soft screening and where size degradation is problematic and there is a low tolerance to impact.
3.0–3.5	The particle is presented to the screen deck at its maximum relative velocity and offers the best screening condition for inclined screens. The stratification is adequate.
4.0–5.0	The stratification is good, but the relative velocity between the deck and particle is low, offering poor screening efficiency. Bearing life is shortened.
5–6	The stratification is good, but the particle projection is in excess of the pitch (particles are in flight too long) and screening opportunities are lost. The relative velocity between the screen and particle is low, combining to give poor parameters for efficient inclined screening. The high acceleration forces can act negatively on the screen structure, and bearing life is further shortened.

Source: Moon 2003.

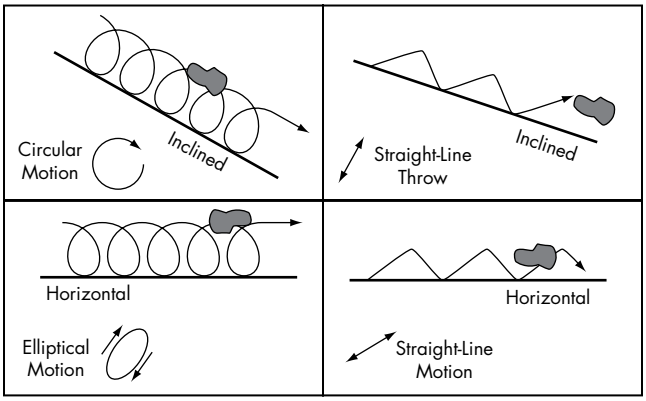


Figure 14.3-13 Particle motion as a function of the deck orbit

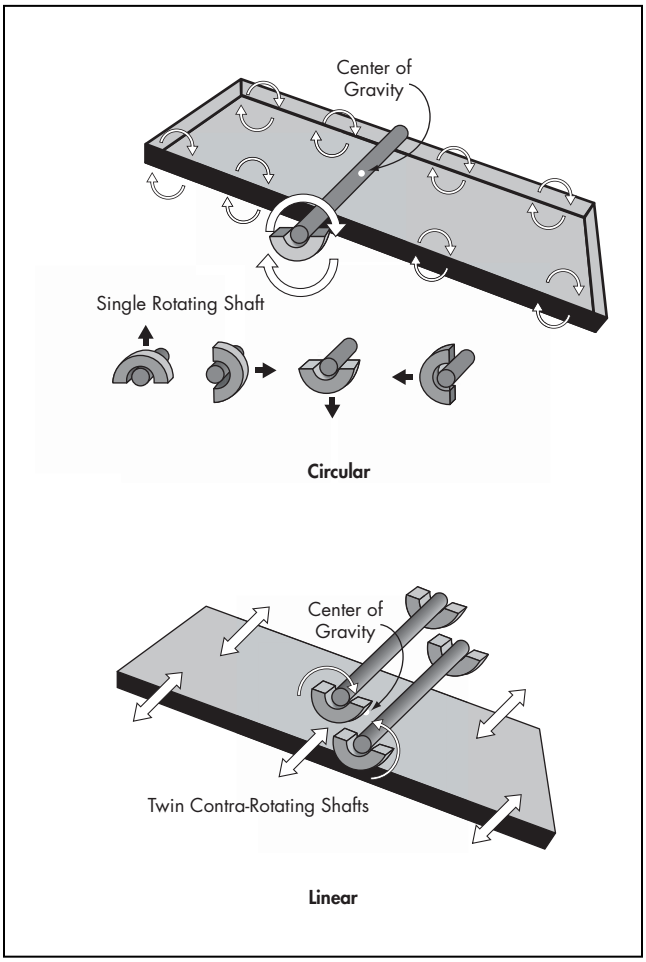

Figure 14.3-14 Using weights to induce specific orbits

course, there are other methods to induce motion and other, more complex orbits.

The stroke angle, measured relative to the length of the deck and in the direction of flow, can affect efficiency and capacity. Very low (~0°) or high (~180°) angles do little other than accelerate wear. For other angles, there is a component of vertical movement (aiding stratification) and a horizontal component aiding (<90°) or retarding (>90°) material flow. (For the screen in Figure 14.3-7, the stroke angle was 50°.)

Table 14.3-4 Process matrix for a vibrating screen*

Design Variable	Screen Capacity	Screen Efficiency	Undersize Mean Size	Pegging/ Blinding
Screen area	+	0	0	0
Open area	+	+ or 0	0	0
Aperture size	+	+	+	–
Aperture shape (increasing nonuniformity)	+	+ or 0	+	–
Deck inclination	+	– or 0	–	– or 0
Speed	+	+	0	–
Stroke angle	–	+	0	– or 0
Stroke	+	+	0	–
Orbit (from linear toward circular)	–	+	0	+

*All other factors being equal, an increase in the design parameter will cause an increase (+), a decrease (–), or no change (0) in the performance metric.

The designer for the screening application chooses the orbit motion (circular, elliptical, or linear) based on a compromise between material movement (capacity), which emphasizes linear motion, and efficiency, which emphasizes circular motion. The ellipse is an optimized solution. All give good stratification with the correct stroke angle. For horizontal and banana screens, linear motion is the defacto standard as material movement is critical. For inclined screens, circular or elliptical orbits are more common.

Finally, there is the matter of feeding the screen. Here, there are the following three general rules:

1. It is important that the feed be uniformly distributed across the width of the screen for the unit to achieve rated capacity.
2. It is important that feed rate be modulated where possible (e.g., using belt feeders) to ensure that the screen works efficiently in the face of changing feed conditions.
3. Where possible, it is good to introduce the feed having a motion opposite to the eventual material flow, which helps in distribution and avoids flooding in the initial zone of the screen deck.

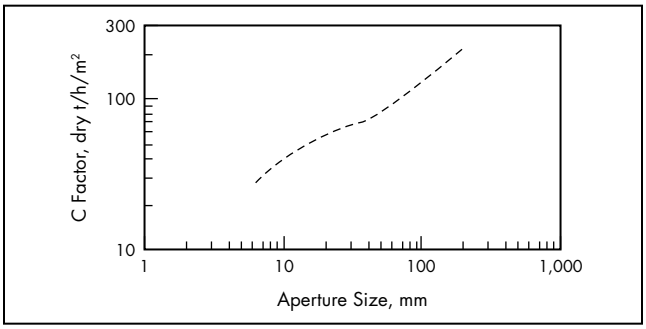

Table 14.3-4 provides a review of the major design variables of a vibrating screen and indicates usual design ranges where appropriate. This "one-variable-at-a-time" approach does not always take into account the myriad interactions among these variables.

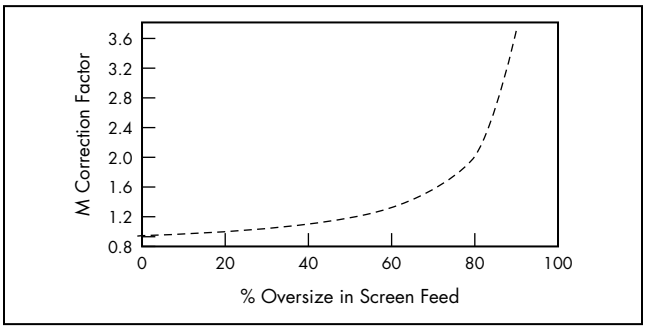
Screen Selection

Many opinions and methods of screen selection suggest fertile ground for development and refinement. Three general selection method classes follow:



- *Class 1:* Empirical methods based on correlations derived from extensive databases of industrial experimental results
- *Class 2:* Lab screening tests with empirical model-based scale-up procedures
- *Class 3:* Fundamental model-based methods (these are relatively new and are described later in more detail)

Class 2 methods have been used sparingly in the past, but recent work (Hilden 2007) suggests there is good scope for improvement and further suggests there is room to combine Class 2 and Class 3 methods very effectively. Despite the

Figure 14.3-17 Correction factor (K) as a function of percent half size

potential of using Class 2 and Class 3 methods, most industrial vibrating screens are still selected using Class 1 methods. Because in most cases these screens operate more or less as designed, it is understandable why these methods have survived with a few improvements for 70 years.

Class 1 selection methods employ empirical correlations to deduce screen area. The design process can begin once the application (e.g., a pebble screen on a semiautogenous grinding [SAG] mill discharge), the design feed rate of solids, and the typical feed particle size distribution are given. Early decisions on the number of decks, inclination, motion, lo-head or hi-head screens, and so forth, come from the design basis documents and past practices in similar applications. Once these parameters are set, the correlations can be used to compute screen area requirements, and the deck with the largest area determines the screen size. The task is then to match one of the standard products to the design. This often is an iterative design process.

Two usual approaches can be used to solve the Class 1 design problem—one based on the total solids feed rate to the screen and the other based on the solids feed rate of undersize material to the screen. Not surprisingly, this is also an area of debate, as the scientific community tends to prefer the latter method, yet the former is very commonly used. The former method will be described in an abbreviated way simply for illustrative purposes. To provide a real example, the data for the screen shown in Figure 14.3-7 is used.

The fundamental equation for determining the screen area required is given in the Equation 14.3-2 (Allis Chalmers, n.d.)

$$A = \frac{T}{CMKQ_1Q_2Q_3Q_4Q_5Q_6} \tag{14.3-2}$$

where

A = required screen area
T = mass flow of feed to screen
C = basic capacity factor
M = oversize factor (percent larger than aperture size in feed)
K = undersize factor (percent smaller that ½ aperture size in feed)
Q_1 = bulk density factor (usually ~60% of rock density)
Q_2 = aperture shape factor
Q_3 = particle shape factor
Q_4 = OA correction factor
Q_5 = wet or dry screening factor
Q_6 = surface moisture factor

Figures 14.3-15 through 14.3-17 provide the basis for estimating the factors C, M, and K, respectively. Table 14.3-5 provides the means for estimating the Q factors. (OA and aperture shape come from Figure 14.3-8.) Table 14.3-6 presents the summary data for the calculations, showing both the input data required and the empirical corrections, as deduced from the previously mentioned graphs and tables (which are adapted from Allis Chalmers, n.d.). The required area allows for a 6% loss due to mechanical fittings and so forth. Following the rough rule that $L = 3W$, this screen would have the approximate dimensions of 0.34 × 1.03 m (1.12 × 3.38 ft). In fact, the screen in Figure 14.3-7 is 0.34 × 1.67 m (1.03 × 5.48 ft). The width is the same, but the test screen has extra length, so a higher classification efficiency might be expected. This topic is discussed in the following subsection.

Performance Assessment

Mechanical and process performance can be distinguished, but this subsection only focuses on the latter.

A single parameter can be calculated in several ways that will quantify screen performance. Among these, the most common are E_u, which is defined as the efficiency of removal of undersize material from the oversize stream, and R_u, which is defined as the efficiency of undersize removal from the feed stream. Referring to Figure 14.3-18, Equations 14.3-3 and 14.3-4 are used to compute numerical values:

$$E_u = \frac{F(1-\hat{f}_u)}{O} = (1-\hat{o}_u) \tag{14.3-3}$$

Table 14.3-5 Q correction factors

Bulk Density Factor	Value

$$R_u = \frac{U}{F\hat{f}_u} = \frac{(\hat{f}_u - \hat{o}_u)}{\hat{f}_u(1 - \hat{o}_u)} \qquad (14.3\text{-}4)$$

where

F = feed rate
O = oversize mass flow rate
U = undersize mass flow rate
$\hat{f}_u$ = cumulative mass fraction in the feed passing the aperture size
$\hat{o}_u$ = cumulative mass fraction in the oversize stream

To utilize these performance measures, one is required to perform a sampling experiment around the screen while it is running at steady-state conditions. This raises topics beyond the scope of this chapter (e.g., experimental design, sampling theory, sample preparation and analysis, and data massage). Fortunately, for the screen shown in Figure 14.3-7, the balanced data are already available and are summarized in Table 14.3-7.

Using these results, E_u = 77.9% and R_u = 93.5%. The data suggest that there is a considerable amount of finer (less than the aperture size of 10 mm [0.4 in.]) nearsize material in the oversize stream. In terms of assessing performance, the manufacturers have a curve that relates E_u to the rated capacity of the screen. This is shown in Figure 14.3-19, and the rated capacity is the ratio of the actual tonnage (or area) to the calculated tonnage (or area) from Equation 14.3-2. The respective area figures for the example are 0.35 and 0.57 m^2,

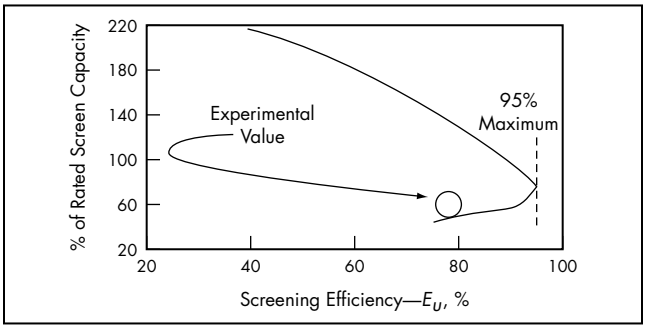

Figure 14.3-19 Percent of rated capacity versus E_u

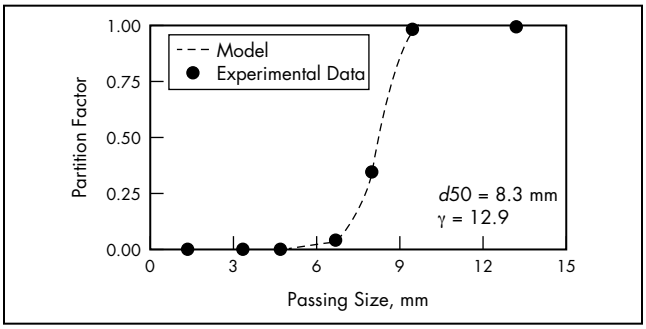
which give a rated capacity of 59.9%. This point is plotted on the curve for reference.

This comparison indicates that the test screen in Figure 14.3-7 is not performing as well as would be expected at the given operating conditions, and further analysis of the situation would be required to validate the result and improve performance.



Another very common measure of efficiency is to use the data in Table 14.3-7 to compute an experimental partition curve, which can then be modeled with any number of simple functional forms. The model parameters are efficiency measures. Again, looking to the example in Figure 14.3-7, the experimental partition factors for the various size fractions are computed from Equation 14.3-5 and are defined as the mass fraction of material in a certain size fraction in the feed that reports to the oversize stream:

$$p_i = \frac{Oo_i}{Ff_i} \tag{14.3-5}$$

where

p_i = observed partition factor for size class i
f_i = mass fraction retained in the ith class of the feed
o_i = mass fraction retained in the ith class of the oversize stream

A very common model and one that will be further discussed later is the so-called Rosin–Rammler curve, and

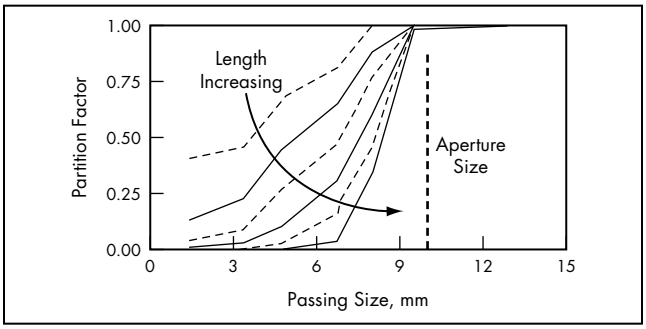
Source: Data from Hilden 2007.

Figure 14.3-20 Experimental and modeled partition function data

the estimated partition factors are computed according to Equation 14.3-6:

$$p_i = 1 - e^{-0.693\left(\frac{d_i}{d50}\right)^{\gamma}} \tag{14.3-6}$$

where



p_i = calculated partition factor for size class i
d_i = the characteristic size for size class i
$d50$ = cut size—particles of this size have an equal chance (50/50) of going to the undersize or oversize
γ = sharpness of separation (larger values mean better separation)

The parameters ($d50$ and γ) are obtained by minimizing a least-squares objective function using nonlinear regression (e.g., Solver in Microsoft Excel). That is, the parameters are selected in such a way that the sum of the squares of the differences in the observed and calculated partition factors is minimized. Figure 14.3-20 presents the results for the screen in Figure 14.3-7.

One would normally expect the cut size to be close to the throughfall aperture size, and it is clear that the value is a little low here (in part because of the way the characteristic size was defined for this study). The sharpness of separation for screens cutting in the aperture size range is usually around 6, so a value of close to 13 suggests that efficiency is high. Taken together, the implication is that the screen is not processing the finer nearsize material very well, which would require further investigation.

Interestingly, the data acquired for the screen in Figure 14.3-7 permit the calculation of the cumulative partition curve as a function of the position along the length of the deck. The experimental results are shown in Figure 14.3-21. Given the explanation related to crowded and separated screening given previously, it is no surprise to see that the fine material moves quickly through the screen—collectively, particles do not have to progress far down the deck before all of the very fine material has passed through the apertures (and the corresponding $p_i = 0$). For the fine, nearsize material, it is clear that the process is a lot slower.

The periodic measurement of screen efficiency is as important to the maintenance of process performance as the periodic measurement of, for instance, bearing condition is to the maintenance of mechanical performance. Unfortunately, it is often the case that the process aspects of screens are

Source: Data from Hilden 2007.

Figure 14.3-21 Partition factors as function of position on deck

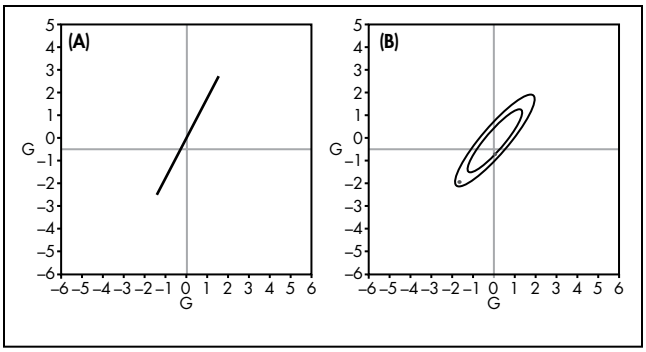


Figure 14.3-22 Feed end orbits in (A) normal and (B) abnormal operation

ignored. However, they are robust devices, and they often have a direct impact on the performance of comminution and separation equipment, for which a systems thinking approach must be applied.

Recent Developments

This subsection provides a brief introduction into some of the developments emerging in the vibrating screen market.

Real-time condition monitoring. Using vibration, thermographic, and occasionally other specialty sensors to automate the more usual manual inspections of predictive maintenance is becoming increasingly commonplace. Where it is done, this is still usually reserved for the typical applications of monitoring bearing health. Manufacturers such as Metso (Screen Security Package) have taken this a step further by using additional accelerometers to compute screen orbits, which can then be compared to expected values from run-in tests and/or to finite element modeling to analyze the mechanical and process health of the screen. Figure 14.3-22 is an example of normal orbits and the kinds of trends that develop when there is a problem, such as with the supporting springs. Loose media on the screen deck and other kinds of serious problems have their own orbit "signature."

In the case of the normal orbits (Figure 14.3-22A), both are linear and superimposed, showing the same stroke and angle. In the case of the abnormal conditions (Figure 14.3-22B), the orbits are now elliptical and the strokes are different.

The frequency spectrum of the accelerometers also provides useful information on the mechanical state of the deck, loading, and other interesting performance parameters, Moreover, when these signals are combined with others (e.g., from load cells and vision systems) in a kind of sensor fusion approach, the analytical detail and reliability can be dramatically increased.

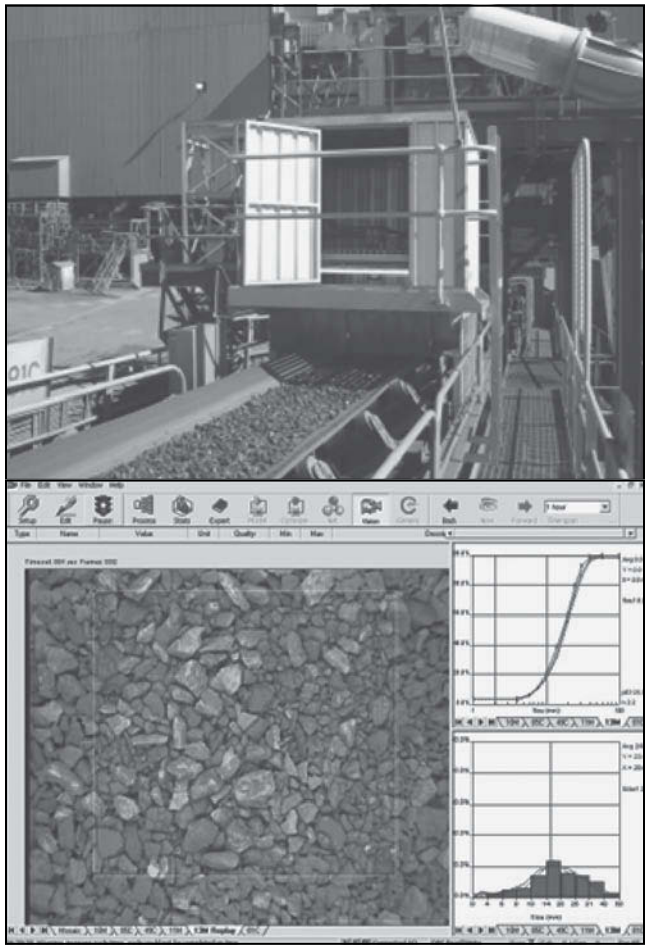

Figure 14.3-23 VisioRock installation and typical output display

Real-time deck motion modulation. As seen in the process matrix of Table 14.3-4, deck motion (stroke, angle, and orbit) all affect performance, and in light of the fact that screen feeds often change (mass flow and particle size distribution), there is a school of thought that says the ability to modulate these parameters on line would support real-time screen performance management. A number of manufacturers are implementing this kind of solution on selected screen models.

Instrumentation. One of the exciting areas of potential for performance monitoring is "machine vision," primarily as applied to measuring feed or product size. Typically, dry screening is very dusty and requires hoods covering the entire screening surface for effective dust control. Therefore, applications on the deck itself (oversize velocity, load, etc.) are challenging. However, in the case where the product streams are discharged onto belts, the standard technology, such as Metso's VisioRock, can be applied. For example, in the production of iron ore, lump size control is very important, and the early warning of a problem is essential if, for example, the screen media is broken, thereby producing off-spec material in the undersize stream. One operator is now using machine vision to detect and react to these types of quality-assurance events, and Figure 14.3-23 shows the VisioRock installation

as well as the output from data processing. In this case, images are analyzed at a rate of approximately 10 per second, which is more than sufficient to monitor everything that passes.

Acoustics also offer interesting potential for analyzing screen performance, but it is very early for research in this area.

Population balance simulation methods. Population balance methods (PBMs) are not new, having been in use for at least two decades, but as the design and operations needs turn increasingly toward simulation to accelerate the activities, higher and higher fidelity is required. These are an element of the Class 2 methods previously mentioned in the "Screen Selection" subsection. Although the industry is moving in this direction, older approaches are still in use in most of the simulation packages. One of these is the model by Karra (1979), which is based on a Class 1 selection method, although in this case it is based on the method of sizing relating to the mass flow rate of undersize in the feed stream.

Using the model in Equation 14.3-6, Karra developed a correlation based on the empirical screen sizing factors used in the screen selection approach. The factors have been modified over time, and their estimation is described elsewhere (e.g., King 2001), but the equation for computing $d50$ is

$$d50 = \frac{G_c h_T}{\left(\frac{\left(T_u/H\right)}{ABCDEF}\right)^{0.148}} \qquad (14.3\text{-}7)$$

where

$d50$ = cut size
G_c = nearsize correction factor
h_T = throughfall aperture (King 2001)
T_u = tons of undersize in the feed (dry t/h)
H = effective screen area (m^2)
A = basic capacity factor
B = oversize factor
C = fine size factor
D = deck location factor
E = wet screen factor
F = bulk density factor

Because a number of the properties for the screen in Figure 14.3-7 have been given, Table 14.3-8 is a shortened summary of the Karra calculation of $d50$. The agreement with the experimental value in Figure 14.3-20 is good.

Karra assumes γ is a constant at 5.9, and in the authors' experience, numbers in the region are pretty typical for coarse screening. This number does not agree very well with the value in Figure 14.3-20, which highlights that Karra's simple two-parameter model approach probably requires additional parameters.

Nevertheless, using the model of Equation 14.3-7 and the feed data in Table 14.3-7, Karra's model can be used to predict the expected size distributions for the undersize and oversize products, and these are shown in Figure 14.3-24 along with the actual experimental results. The predictions are satisfactory, but the importance of γ is clear. The calculated fractional mass splits of 0.26 and 0.74 compare well with the product mass flows reported in Table 14.3-7.

Discrete element simulation methods. In the pursuit of higher-fidelity simulation of screen performance, the ultimate tool is probably discrete element modeling (DEM). Very briefly, this approach is based on fundamental models drawn from physics (e.g., Newton's laws of motion.) Using a mathematical description of the body and motion of the screen; some typical physical properties; and the feed size distribution, flow rate, and particle shapes, the DEM simulation can be run from only first principles (e.g., no correlations and no parameters drawn for experimental data). Although this sounds simple in concept, solving the problem is onerous, as there are millions of particles, each requiring several differential equations to describe translational and rotational motion in time and space. Because of the interactions of the particles among themselves and with the screen itself, the integration intervals are very short—on the order of one millionth of a second. Simulating several seconds of real-time operation can take days, weeks, or months, depending on the problem size, the computational capability, and the simulation code efficiency. It is for this reason that the goal is to combine DEM and PBMs, the former to work out the real mechanisms and the latter to abstract these and provide speedy calculations.

Because of the vast quantities (gigabytes or even terabytes) of numerical data generated in such simulations, it is common practice to use visualization techniques to "see the results." However, the numerical data must be used for any calculations. Figure 14.3-25 presents a snapshot of visualization, and Figure 14.3-26 shows the predicted (lines) and measured (bullets) particle size distributions from a simulation of the banana screen pictured in Figure 14.3-12B. The agreement in Figure 14.3-26 is very good, which provides some insight into the power this tool will bring to screen modeling.

Table 14.3-8 Computing Karra's *d*50 for the screen in Figure 14.3-7

Symbol	Factor	Units	Result
T_u	Feed	dry t/h	15.67
H	Effective screen area	m^2	0.57
h_T	Throughfall aperture	mm	10

Screen Media

Because screen media is often the single largest operational expense for a vibrating screen, this chapter would be incomplete without a brief discussion on this topic. The governing objective here is the absolute lowest total cost, which implies that availability, cost, wear life, downtime, and so forth must be considered in making the final media selection.

Three major materials of construction for screen media are steel (punched plate or wire mesh), rubber, and polyurethane. The polymeric compounds of rubber and polyurethane are usually more expensive, but they tend to exhibit superior wear performance in those applications that permit alternatives. Service life can be extended by factors of more than five with polymerics.

Figures 14.3-27 through 14.3-29 show wire mesh, rubber, and polyurethane media, respectively. Media specialists often break down the applications as scalping, standard production (size control and sorting), and washing (sorting).

Wire mesh can have standard weaves, as shown in Figure 14.3-27A, or slotted antiblinding or even custom weaves, as shown in Figure 14.3-27B. The wires are normal high-carbon or stainless steels.

Typical applications for rubber screen decks (Figure 14.3-28) include high-impact scalping type duty or situations where abrasion and/or blinding are a serious concern. The decks are manufactured by punching or molding.

Polyurethane decks (Figure 14.3-29) are usually found in standard production applications and in washing or dewatering applications. They are manufactured by casting or injection molding processes.

The polymeric materials lend themselves to modular installation or paneling. Table 14.3-9 weighs the pros and cons of steel versus the polymerics.

As a cautionary note, although there might be a tendency to choose thicker panels to increase wear life, this will reduce capacity and accuracy and will induce higher levels of pegging and blinding. Media suppliers familiar with best practices can be very helpful in these selections, and it is also recommended that the original equipment manufacturer (OEM) is consulted when changing the design of media.

Standard Screen Sizing and Relative Pricing

Table 14.3-10 provides a glimpse of a typical vibrating screen product line, and while the price data supplied here is somewhat out of date, the relative pricing of the screen equipment is more or less the same.

Fine Screening

In general, wet fine particle classification is achieved by mechanical/hydraulic means (e.g., rake or spiral/screw

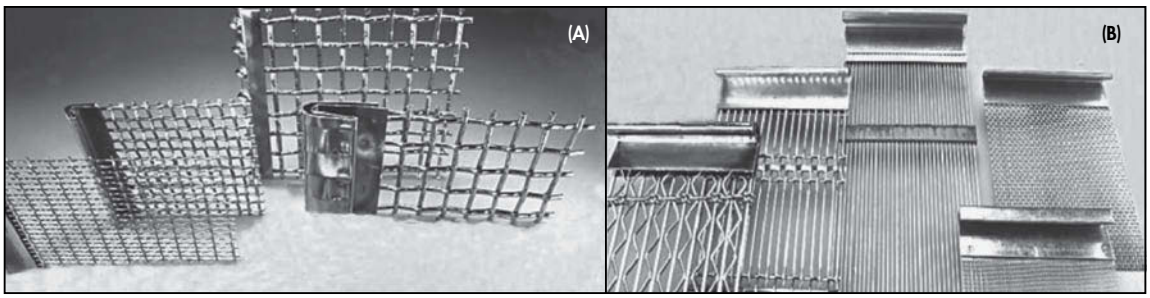

Figure 14.3-27 Wire mesh media

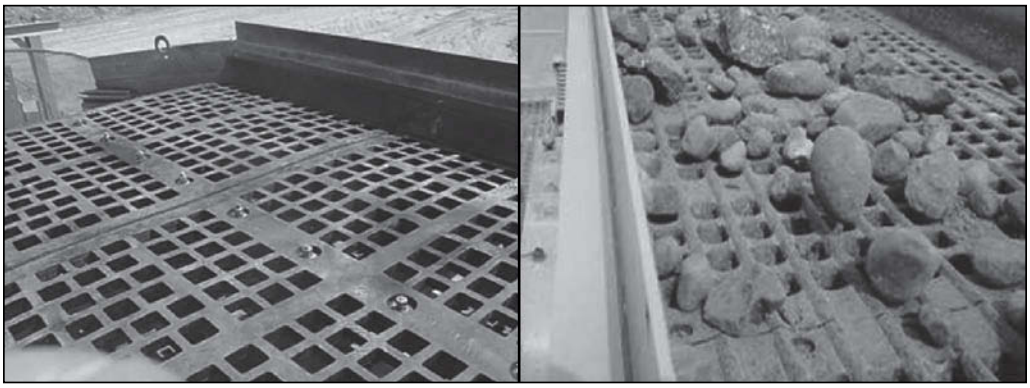

Figure 14.3-28 Rubber screen decks

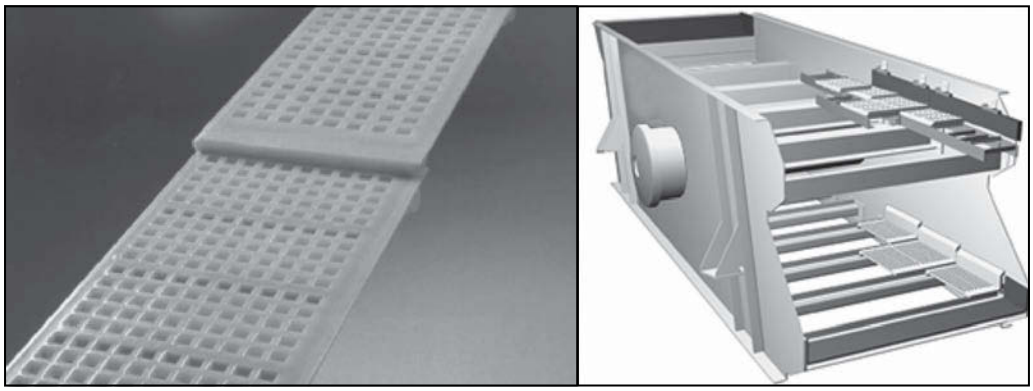

Figure 14.3-29 Polyurethane panels

classifiers), hydrocyclones (discussed later in this chapter), and fine screens. Although the mechanical devices still have their place, fine screens, and especially hydrocyclones, dominate fine and ultrafine classification. Fine screening is the term generally reserved for fine and ultrafine separations, as defined in Table 14.3-1. It is performed dry or wet, although in most mining or quarrying applications, this is a wet process. Consequently, the emphasis here is on wet fine screening.

The principles described previously for vibrating screens apply to most screening processes. One notable difference is that fine screening generally involves much higher rotational speeds (e.g., ~3,600 rpm). Therefore, much smaller strokes are required. Another major difference for fine screening is that the selection of the appropriate screen is as much an art (i.e., past practices in similar applications) as it is a science (i.e., laboratory testing of specific screens on the expected feed material and supplier databases). This complexity is due in large measure to the critically important aspect of fluid mechanics, as drag forces tend to govern wet fine and ultrafine separations. Suffice it to say, the expertise in fine-screen design generally lies with the major supplier organizations, such as Derrick Corporation, Conn-Weld Industries, Kroosh Technologies, Pansep, Multotec Group, and Wedgewire.

The two most common wet fine screening devices are the sieve bend (i.e., a stationary version of the banana screen, Figure 14.3-6) and the more conventional, high-frequency fine screen (i.e., having a more conventional geometry and represented herein by the Derrick product line, including the Stack Sizer [Figure 14.3-5], the multifeed screen, and the repulp screen). Wet fine screening is essentially the only flow-sheet option in a number of applications (see sorting class in Figure 14.3-1), for example, in coal preparation desliming and iron ore coarse silica removal. (A more complete review on this topic is available in Valine and Wennen (2002).

Table 14.3-9 Advantages and disadvantages of steel versus polymeric screen decks

Wire	Rubber/Polyurethane
Advantages • Price • Accuracy of cut • Open area is high (on installation)	Advantages • Longer life • Less downtime • Shock resistance • Accuracy • Reduced pegging • Reduced blinding • Open area (in operation) • Noise reduction
Disadvantages • Shorter life • More downtime • Pegging problems • Blinding problems • Reduces open area (in operation) • Noise levels	Disadvantages • Price • Open area (on installation) (e.g., although these screens tend to have lower open areas out of the manufacturing process than wire mesh, they retain open area much better)

Many other applications provide wet screening as an alternative to hydrocyclones or other mechanical devices, as it offers some significant advantages in classification efficiency (as measured by γ or E_u). In some applications, both sieve bends and high-frequency screens are used in conjunction with hydrocyclones to exploit the physical and classification

attributes for each type of separator. In other instances, it may also be possible to feed a wet screen by gravity, rather than the pumping systems more commonly associated with hydrocyclone batteries. Nevertheless, in these kinds of trade-off studies, it generally comes down to the footprint advantages of hydrocyclones versus the process efficiency advantages of wet screening. For example, one study (Vince 2007) in coal indicated that purely from a capacity perspective, two to three Derrick Stack Sizers were the equivalent of one 900-mm (35.4-in.) classifying hydrocyclone. Interestingly, that same study came to the conclusion that the Stack Sizer should be considered for coal-preparation applications with cut points in the 100-to-350-µm range, while sieve bends could be considered for cut sizes in the 250-to-350-µm range. Of even greater interest was the observation that "similar" equipment made by different suppliers can have quite different performance characteristics—*caveat emptor* (buyer beware).

One area of growing interest for fine screening is close fine-grinding (ball mill or even stirred-mill) circuits (e.g., see Wennen et al. 1997). The opportunities to exploit improved efficiency to reduce specific energy and media requirements and to improve downstream metallurgical efficiency (e.g., by minimizing the overgrinding of valuable minerals) are very appealing, both technically and economically. In addition, while hydrocyclones separate based on particle mass (i.e., particle size and density are first-order effects), wet fine screens separate predominantly on size (i.e., density is a higher order effect, mainly related to particle stratification). For example, in iron-ore grinding, the cut size on a screen is the same for the iron minerals and silica, whereas in a hydrocyclone, the cut size for the iron minerals is about one-third of that for silica,

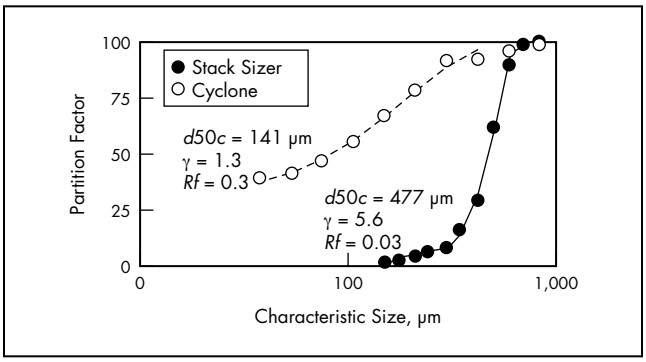

Figure 14.3-30 Partition curves for a 254-mm (10-in.) hydrocyclone and a Derrick Stack Sizer

which is to say that a lot of fine liberated iron mineral can be sent back to the grinding mill by a hydrocyclone.

Consider the partition curves shown in Figure 14.3-30. (The parameter *Rf* is defined later in Figure 14.3-49 and in Equation 14.3-17, but it effectively represents the very fine material hydraulically entrained in the oversize stream—the bypass.) Although there are some "apples to oranges" comparisons in terms of the cut sizes, these example are drawn from the same plant in similar applications (Aquino and Vizcarra 2007); the real interest comes from the comparison of the sharpness of separation (γ) and the efficiency (here inversely related to *Rf*). The benefits of wet screening are obvious, which makes it a technical option to cut sizes ranging down to 100 µm. For the hydrocyclone partition curve, the inflections

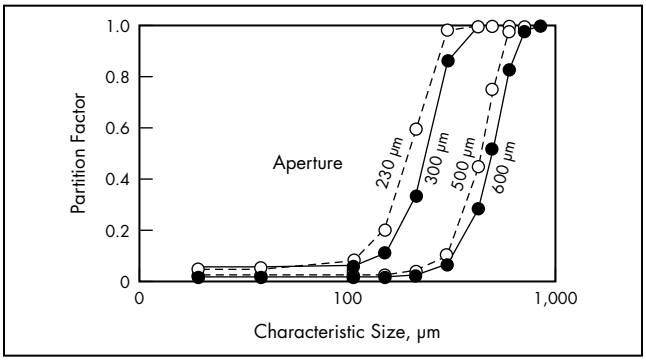

Figure 14.3-31 Partition curves for a Derrick Stack Sizer with different screen apertures

and rather poor sharpness of separation are a partial consequence of the existence of liberated heavy and light minerals in the feed (i.e., the density effect).

Finally, Figure 14.3-31 provides a glimpse of the ability of this fine screen to preserve efficiency over a range of aperture sizes (i.e., the sharpness in separation is good and the bypass is low).

CYCLONES

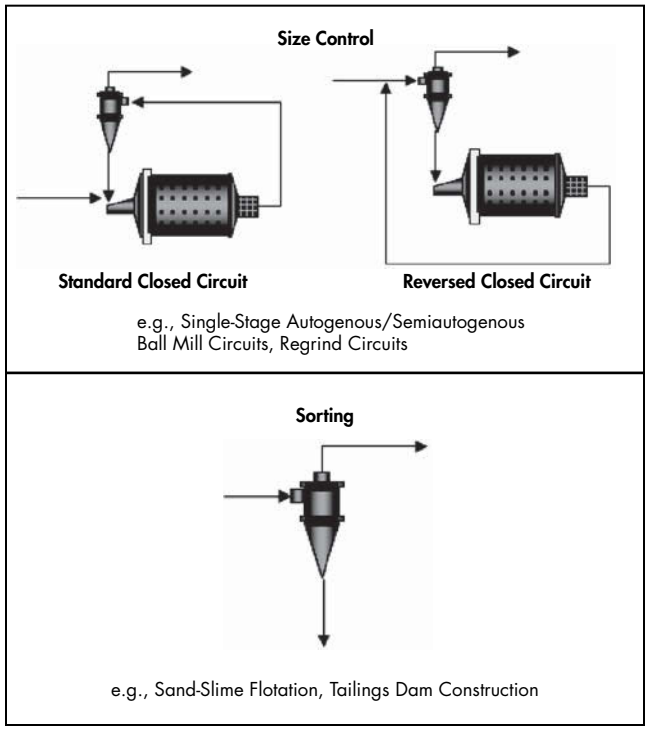
Cyclones (named for the spiraling motion within the body of the device) are one of a large number of classification devices aimed at separating fine particles in a fluid (water or air). For examples, see Kelly and Spottiswood (1982) or Svarovsky (2000). Cyclone classification is generally reserved for the separation of particles on the basis of size. For this reason, other applications for cyclones, such as thickening and dense-medium separation, are not considered here. Broadly speaking, cyclone classifiers can either treat dry feeds (the air classifier or air separator) or wet/slurry feeds (the hydrocyclone). The emphasis here will be on wet applications.

Unlike the vibrating screen, which employs a physical means (the screen media) to effect a separation, the cyclone classifier uses differential settling properties of particles of different mass. The cyclonic action within the body of the device develops G-forces significantly greater than gravity, which accelerate the separation process. In general, cyclones are robust, compact (small footprint), and relatively efficient size-separation devices.

Figure 14.3-32 shows the most common applications of wet cyclones in mining. Air classifiers are also commonly used in these applications, for example, as a size-control device in dry grinding (most notably in refractory gold, coal-fired power plant pulverizers, or cement clinker applications) and as sorters (usually in de-dusting applications).

Figure 14.3-33 shows the geometry of a standard hydrocyclone, the shape of which clearly resembles the natural phenomenon that gives rise to the name. The separator comprises a feed section, cylindro-conical section, discharge spigot, vortex finder, and overflow. In some cases, usually with larger diameters, each of these is supplied as a separate entity, whereas in others they may be cast into a single unit (i.e., with smaller diameters).

The capacity of a hydrocyclone is a function of its size and, subject to operational constraints, the rate and solids concentration at which the feed (slurry) material is supplied. In some cases, hydrocyclones are gravity fed from surge tanks,



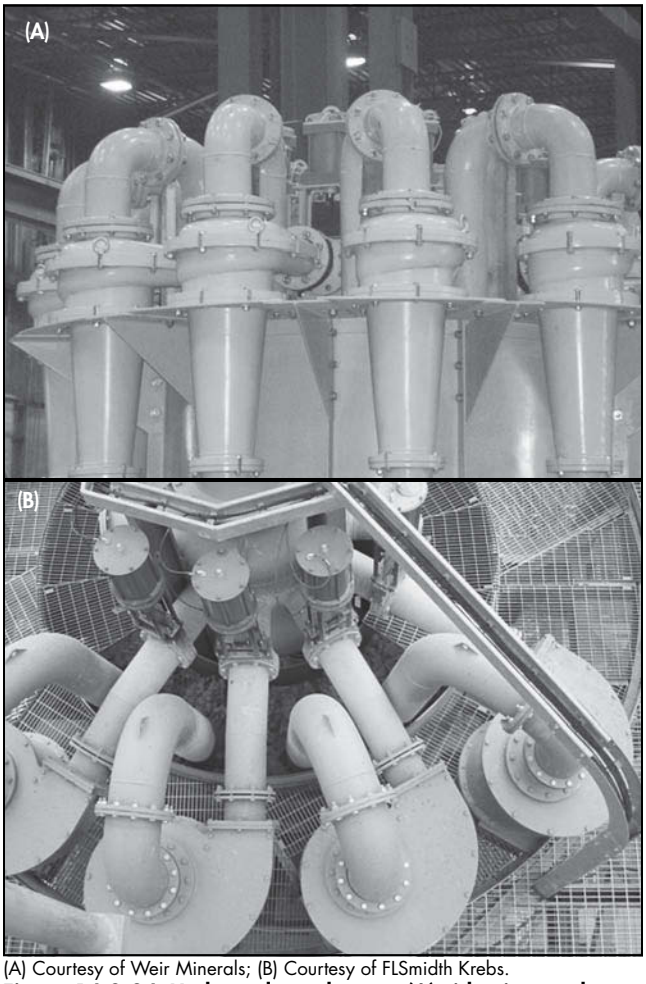


Figure 14.3-32 Examples of the application classes for hydrocyclones in mining

Courtesy of Weir Minerals.

Figure 14.3-33 Hydrocyclone

but the majority of applications use a feed sump and pump arrangement. Consequently, it is common to utilize a group of hydrocyclones operating in parallel to achieve the required process throughput capacity. As Figure 14.3-34 shows, the compact design of the units permits the use of a radial header to distribute feed to a number of hydrocyclones. This is commonly called a hydrocyclone cluster or battery, or a Cyclopac. Moreover, as Figure 14.3-34B highlights, the use of knife-gate valves to open or close a hydrocyclone is very convenient, both from an online process control point of view as well as for maintenance purposes. On the latter point, and given the relative cost of a hydrocyclone, it is typical to remove a

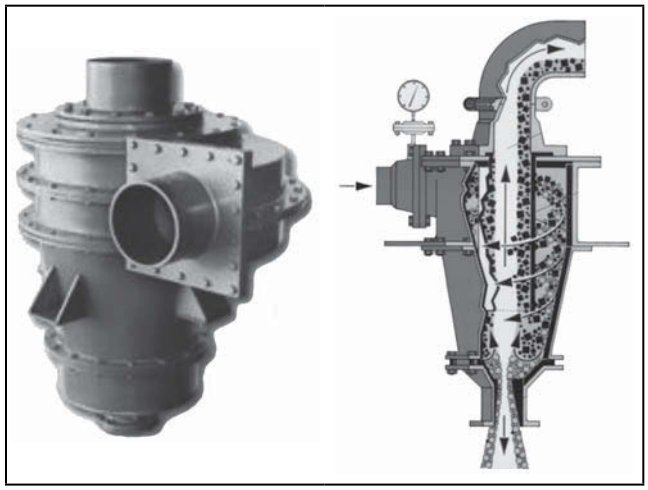
Figure 14.3-34 Hydrocyclone clusters: (A) side view and (B) top view

hydrocyclone for maintenance and simply replace it with a refurbished spare.



There are a number of variants on the more typical hydrocyclone geometry of Figure 14.3-33. Figure 14.3-35 shows the water-only or automedium cyclone that is frequently used in washing fine (–0.6 mm) coal. (The truncated lower cone section is employed to set up a secondary density separation in a rotating particle bed.) The flat-bottomed hydrocyclone occasionally used in mineral processing applications has a very similar kind of body geometry.

Air separators tend to be designed to treat the whole feed flow, so they are larger units, as shown in Figure 14.3-36. These devices can be either static (such as the hydrocyclone) or dynamic (including moving blades, and so forth, to enhance separation).

Figure 14.3-36 illustrates a typical dry grinding circuit with the air separator used for classification and a cyclone used for solids recovery. The cutaway view on the right illustrates the internals and the drive for this dynamic air separator.

Hydrocyclone Basics

The hydrocyclone evolved into its current role in mineral processing in the period from approximately 1950 to 1970, by which time it had become a key element in the design of most

Courtesy of FLSmidth Krebs.

Figure 14.3-35 Water-only cyclone

large-scale grinding circuits. The hydrocyclone offers high capacities in small footprints and arguably enabled the ongoing development of very large grinding circuits. Although they still have their place, mechanical classifiers were effectively rendered obsolete in plant design by the hydrocyclone. Despite the numerous benefits of hydrocyclones, there have always been issues with efficiency, as introduced earlier in the discussion on fine screening. As today's operators look for ways to address energy efficiency and as competitive technologies emerge, hydrocyclone manufacturers have redoubled their development efforts. As is the case for screens, they are using the very latest simulation tools to help refine existing designs and develop new ones for specific applications, with good success. The following subsections provide a refresher on hydrocyclone basics and introduce some of the latest tools and techniques for the design, analysis, control, and optimization of hydrocyclones.

Principles of Operation

Figure 14.3-37 provides a sketch of a typical hydrocyclone showing the main design components. The principal dimensional variable is the diameter of the upper cylindrical section of the hydrocyclone body, D_c. The inlet (D_i) and discharge (D_o and D_u) dimensions usually lie within some ratio of D_c, (e.g., $0.2D_c \leq D_o \leq 0.45D_c$). Because the inlet is usually more rectangular in nature, to facilitate a reduction in turbulence on entry (involute designs—see Olson and Turner 2002), D_i is defined as the diameter of circle with an area equivalent to the actual inlet area. In the past, smaller hydrocyclones have had lower cone angles (~10°), but because of headroom considerations, larger hydrocyclones tend to have larger cone angles (~20°). Some typical dimensions for a hydrocyclone with D_c = 760 mm (30 in.) are shown in the figure.

The feed enters the hydrocyclone near the top of the cylindrical section, usually through some sort of involute inlet design, which is intended to introduce the slurry into the hydrocyclone with a minimum of turbulence, as this can have a deleterious effect on efficiency and wear. Figure 14.3-34A clearly shows this involute design. The rotational motion set up in the body of the hydrocyclone

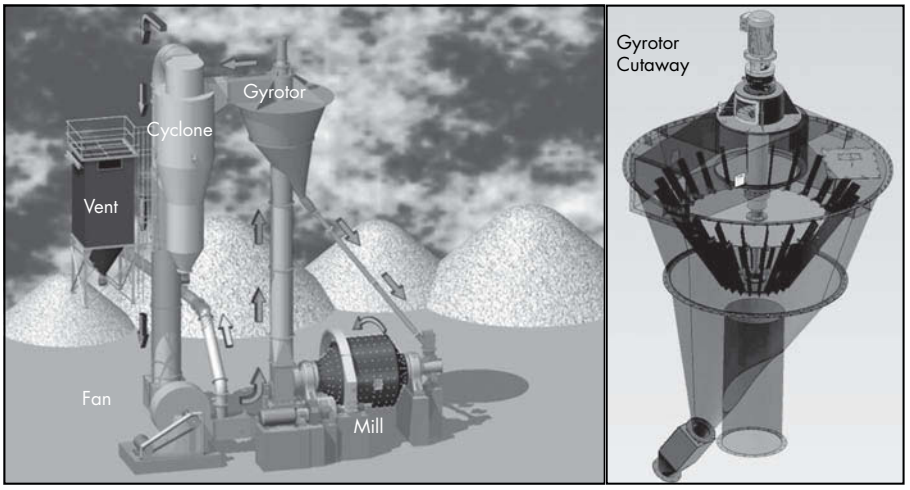


Figure 14.3-36 A Gyrotor air separator in a typical dry grinding circuit

gives rise to the G-forces that accelerate the particle separation process. All of the particles are subjected to the centrifugal forces directing them to the wall of the hydrocyclone, where this material moves downward in a helical fashion to be discharged through the apex, as *underflow*. However, as the particles migrate to the outer wall of the hydrocyclone, they necessarily displace the fluid, which must move inward. The fluid exerts drag forces on the particles and retards their outward motion and, in the case of the finer particles, actually causes them to move inward. This stream moves upward in a helical path to be discharged through the vortex finder, as *overflow*. When the hydrocyclone is operating normally, the centrifugal forces acting on the slurry create low pressure along the central axis, establishing the conditions necessary for development of the characteristic air core.

To look more closely at the separation process, consider Stokes' law for laminar settling, given by Equation 14.3-8. (Whether it is Stokes' law, Newton's law, or something else—as experimental data would seem to indicate—the trends predicted by Stokes' law are seen in practice.)

$$v_t = \frac{(\rho_s - \rho_l) g d^2}{18\mu} \qquad (14.3\text{-}8)$$

where

v_t = terminal settling velocity
ρ_s = solids specific gravity
ρ_l = carrier fluid specific gravity
g = gravitational or centrifugal force acting on the particles
d = particle diameter
μ = carrier fluid viscosity

From the explanation given previously, anything that acts to increase the particle settling velocity increases the chances of particle reporting to the underflow stream. Clearly, the larger the particle, the more likely it is to go to the underflow. Similarly, higher G-forces (meaning higher feed flows or pressure drops) will also act to increase the probability that a particle will find its way to the underflow stream. Particles with higher specific gravities will also have a higher probability of reaching the underflow stream.

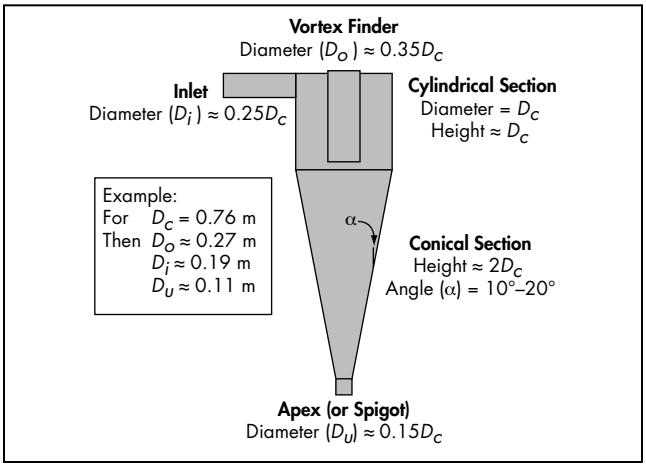

Figure 14.3-37 Principal design elements of a hydrocyclone

However, if the feed material contains a lot of very fine clay material, thereby increasing the effective viscosity, the particles will be less likely to reach the underflow stream. Similarly, with high-density hydrocyclone feeds, there is a significant concentration of fine particles in the carrier fluid, which increases the fluid specific gravity and makes it less likely for particles to reach the underflow stream.

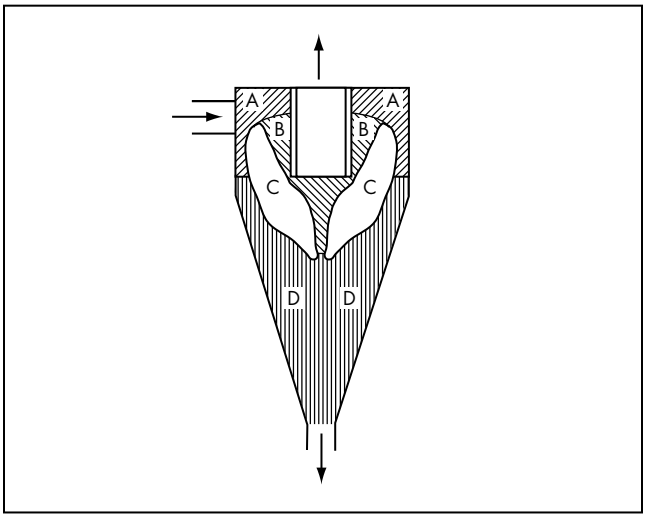
To further complicate things, the size of the vortex finder also has an influence on the separation outcome. Smaller vortex finders will create a finer particle overflow stream, and vice versa. Although to a lesser extent, the apex size will also have an impact, as a smaller apex tends to limit the underflow capacity, diverting some coarser particles toward the upper regions of the hydrocyclone, the finest of which will then be entrained in the overflow stream.

Figure 14.3-38 (absent the air core) was developed by Renner and Cohen (1978) and shows roughly the main regions inside a cyclone. Region A is relatively narrow area in the vicinity of the inlet that is characterized by a size distribution similar to that of the feed. Most of the conical section is Region D, which is characterized by a coarser size distribution similar to the underflow. Region B is the finer material with a size distribution very similar to the overflow product.

Region C is perhaps the most critical region, as it was found to contain significant quantities of nearsize particles, which suggests that they tend to accumulate here until physical capacity constraints force them to move to one product zone or the other. Arguably, this is the region of active classification, and poor operation would be expected if it fails to form properly, possibly because of poor design or excessive feed solids concentrations.

Rather than produce a process matrix for the hydrocyclone, the authors have chosen to illustrate these concepts with the Plitt model (see Flintoff et al. 1987) given in Equation 14.3-9. This is the correlation for the corrected cut size, $d50_c$. For example, increasing the hydrocyclone diameter, D_c, would be expected to lead to a coarser cut size. Similarly, increasing the feed flow, Q, would lead to a finer cut size.

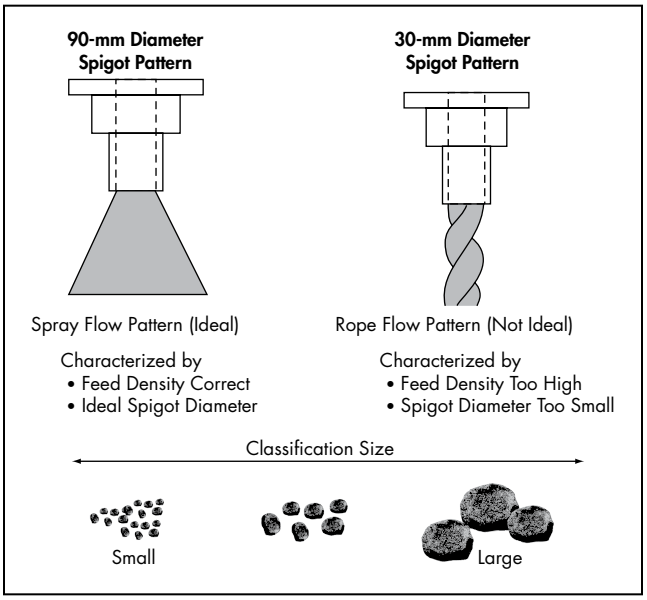
$$d50_c = \frac{CD_c^{0.46} D_i^{0.6} D_o^{1.21} \mu^{0.5} e^{0.063V}}{D_u^{0.71} h^{0.28} Q^{0.48} \left[\frac{\rho_s - \rho_l}{1.65}\right]^k} \qquad (14.3\text{-}9)$$



where

$d50_c$ = corrected cut size
C = a calibration constant
D_c = hydrocyclone diameter
D_i = inlet diameter
D_o = overflow apex diameter
V = volume percent concentration of solids in hydrocyclone feed
D_u = underflow apex diameter
h = free vortex height
Q = feed volumetric flow rate
k = settling exponent (e.g., 0.5 in Equation 14.3-8)

A correlation exists for γ as well, but it is much weaker, generally indicating that γ will improve at lower flows (longer residence times) and lower feed solids volumetric concentrations, both of which are intuitively acceptable.



A couple of phenomena are worthy of some amplification. The first is the phenomenon known as roping (a name based on the appearance of the underflow stream in this regime). Roping occurs when the volumetric flow rate of the underflow stream causes the air core to collapse. When this happens, the usual helical spray from the apex alters appearance, as shown in Figure 14.3-39. Consequently, roping will increase the flow of coarser particles to the overflow stream (i.e., a coarser cut size). The impact on efficiency (as measured by γ in a partition curve) appears to depend on the hydrocyclone feed density—higher densities having a more deleterious effect. Roping does tend to maximize the underflow density. Thus, it minimizes the fraction of fine material that reports with the carrier liquid to this stream.

The other phenomenon is particle density. There are many cases (coal, iron ore, massive sulfide ores, and so forth) where liberated particles of widely different densities exist. Equation 14.3-8 indicates that, for a constant settling velocity, the particle size is related to solids specific gravity as $d \propto (\rho_s - \rho_l)^{0.5}$. In practice, and because of other phenomena such a secondary density separation occurring in the rotating bed, the exponent is usually much greater than 0.5, which means that density effects are exacerbated in the hydrocyclone. To illustrate, consider Figure 14.3-40, which shows coal slurry being processed in a hydrocyclone. Sink and float analysis

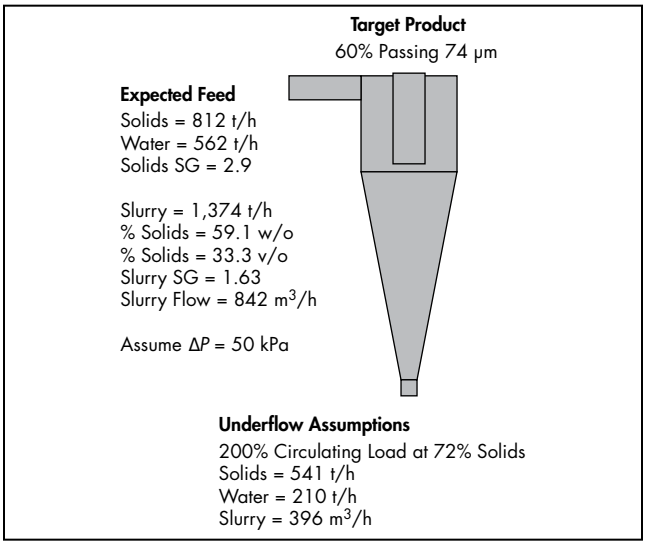
Figure 14.3-39 Spray and rope discharge



on the products allows the reconstruction of separate partition curves for each specific gravity (SG) class, all of which have a reasonable shape. However, looking only at the overall curve could suggest poor classification.

The last item of interest is hydrocyclone mounting. With the development of larger and larger hydrocyclones, mounting them in a vertical orientation puts a significant head on the underflow stream, which can influence wear and separation. However, tilting these hydrocyclones (usually at ~45°) allows operation at lower pressures while still producing a good underflow product, albeit at a coarser cut size. Maintenance-saving claims for wear in the lower region of the hydrocyclone are impressive (80%, e.g., Schmidt and Turner 1993), but it can be more difficult to perform in-situ maintenance for this kind of installation.

Hydrocyclone Selection

The selection of hydrocyclones is normally a task best performed with a supplier, as these firms possess the knowledge, expertise, databases, and tools to ensure that the best results are achieved. In most cases, it is possible to avoid pilot testing. However, there are some instances where this is preferable and even inevitable. One of the more challenging design problems is the closed-circuit grinding application, illustrated on the left in Figure 14.3-32. This is challenging because the hydrocyclone feed characteristics depend very much on mill performance, which in turn depends on the hydrocyclone underflow characteristics, which in turn depend on the feed. Experience has given most suppliers a very good understanding of this problem; nevertheless, circuit simulation tools can be useful adjuncts in developing a hydrocyclone design basis. (Public domain hydrocyclone models, e.g., Equation 14.3-9, include most of the basic design parameters, yet these are seemingly not commonly used in the design process, which underscores the experience factor necessary in this process.)

For the purposes of this chapter, the techniques of hydrocyclone design documented by FLSmidth Krebs are briefly reviewed (for more detail, see Arterburn 1982 and Olson and Turner 2002). The required information is summarized in Figure 14.3-41.

A set of standard tests under very specific design and operating conditions was performed to develop a relationship between what is called the base corrected cut size ($d50_{c\text{-}base}$) and the principal dimensional variable, the hydrocyclone diameter, D_c. The outcome of this work is captured in Figure 14.3-42, based on Equation 14.3-10, and is also given in the alternate form as Equation 14.3-11.

$$d50_{c\text{-}base} = 2.84D_c^{0.66} \tag{14.3-10}$$

$$D_c = 0.206d50_{c\text{-}base}^{1.515} \tag{14.3-11}$$

Table 14.3-11 Empirical correlation between the reference size and $d50_{c\text{-}actual}$

Required Overflow Size Distribution (Percent Passing) of Specified Micrometer	Multiplier (To Be Used to Factor the Specified Micrometer Size)
98.8	0.54
95	0.73
90	0.91
80	1.25
70	1.67
60	2.08
50	2.78

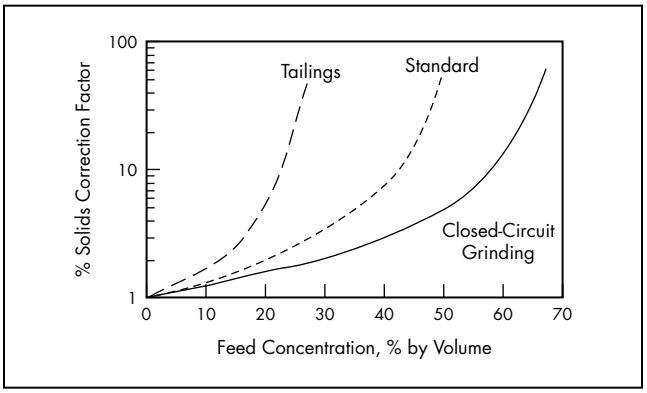
Not unlike the screen design methodology introduced earlier, the hydrocyclone design approach illustrated here relies on a number of empirical correction factors to scale the performance of the standard hydrocyclone to the expected industrial operation. In this case, the key scaling parameter is the $d50_c$, and the key design formula is given by

$$d50_{c\text{-}actual} = d50_{c\text{-}base}(CP1)(CP2)(CP3)(\ldots)\,(CD1)(CD2)(CD3)(\ldots) \quad (14.3\text{-}12)$$

where

$d50_{c\text{-}actual}$ = the expected corrected cut size in industrial operation
$d50_{c\text{-}base}$ = the corrected cut size for the standard hydrocyclone
$CP1, CP2, CP3\ldots$ = process related correction factors (e.g., feed volume [~ viscosity] correction factor)
$CD1, CD2, CD3\ldots$ = design-based correction factors, (e.g., vortex finder diameter)

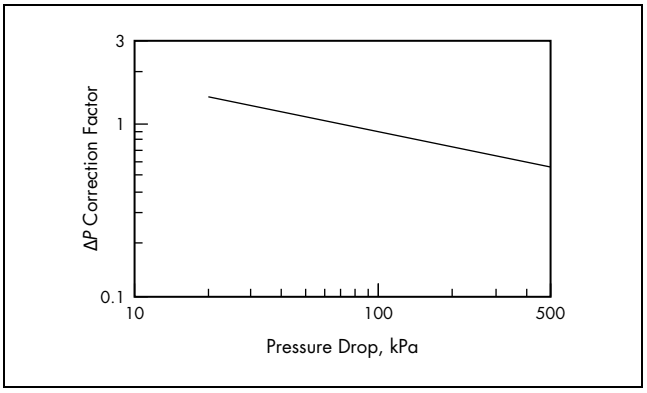
In practice, Equation 14.3-12 is rearranged and used in the form of Equation 14.3-13:



$$d50_{c\text{-}base} = \frac{d50_{c\text{-}actual}}{(CP1)(CP2)(CP3)(\ldots)\,(CD1)(CD2)(CD3)(\ldots)} \quad (14.3\text{-}13)$$

With this short introduction, the basic steps in hydrocyclone design are as follows.

Step 1—Estimation of the $d50_{c\text{-}actual}$. Table 14.3-11 provides the relationship between the overflow size specification and $d50_{c\text{-}actual}$. For the overflow specification in Figure 14.3-41, 60% corresponds to a factor of 2.08, which when multiplied by the reference size of 74 μm gives the estimate for $d50_{c\text{-}actual}$ of 154 μm.



Step 2—Calculation of the correction factors and estimation of $d50_{c\text{-}base}$. Three important published process-related correction factors are the solids feed volume concentration ($CP1$), the operating pressure drop ($CP2$), and the solids specific gravity ($CP3$).

$CP1$ is the correction for the feed volumetric concentration, which is in effect a first-order approximation to viscosity. Of course, viscosity also depends on water temperature, clay concentrations, particle shape, and other factors—clays in fine tailings is what gave rise to the tailings curve in Figure 14.3-43. In this figure, Olson and Turner

Source: Olson and Turner 2002.

Figure 14.3-43 Correction factors for hydrocyclone feed solids volumetric concentration

Source: Arterburn 1982.

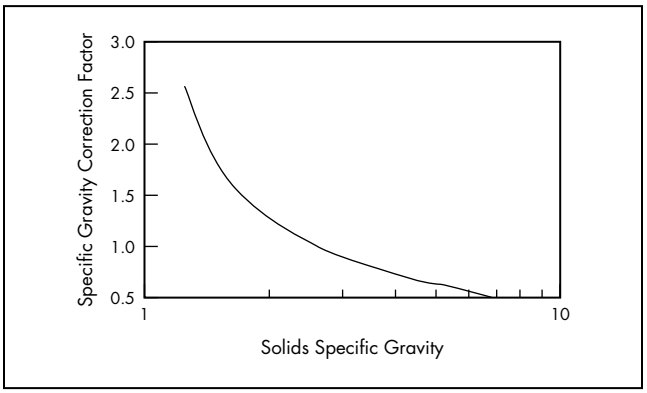
Figure 14.3-44 Pressure drop correction factor

(2002) extended Arterburn's method, which was based on the standard curve in Equation 14.3-14.

$$CP1 = \left[\frac{53 - V}{53}\right]^{-1.34} \quad (14.3\text{-}14)$$

In this example the standard curve is assumed, and with V = 33.3%, then $CP1 = 4.09$.

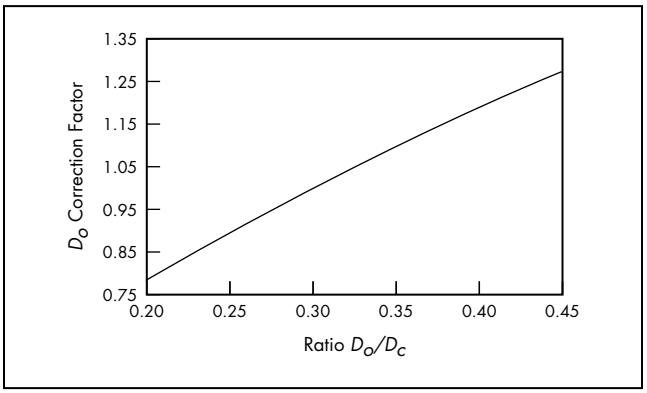
$CP2$ is the correction factor for the operating pressure drop—usually the difference between the measured pressure in the radial header and atmosphere. Larger hydrocyclones tend to run at lower pressures, and vice versa. Figure 14.3-44 and Equation 14.3-15 show this relationship.



$$CP2 = 3.27\Delta P^{-0.82} \quad (14.3\text{-}15)$$

where ΔP is the pressure drop in kPa.

In this example, it was assumed that ΔP = 50 kPa (7.25 psig), which should give relatively good hydrocyclone performance while minimizing wear. From Equation 14.3-15, $CP2 = 1.09$.



$CP3$ is the correction factor for the solids specific gravity and is shown in Figure 14.3-45 and Equation 14.3-16. For a solids specific gravity of 2.9, the correction factor $CP3 = 0.93$.

$$CP3 = \left[\frac{1.65}{\rho_s - \rho_l}\right]^{0.5} \quad (14.3\text{-}16)$$

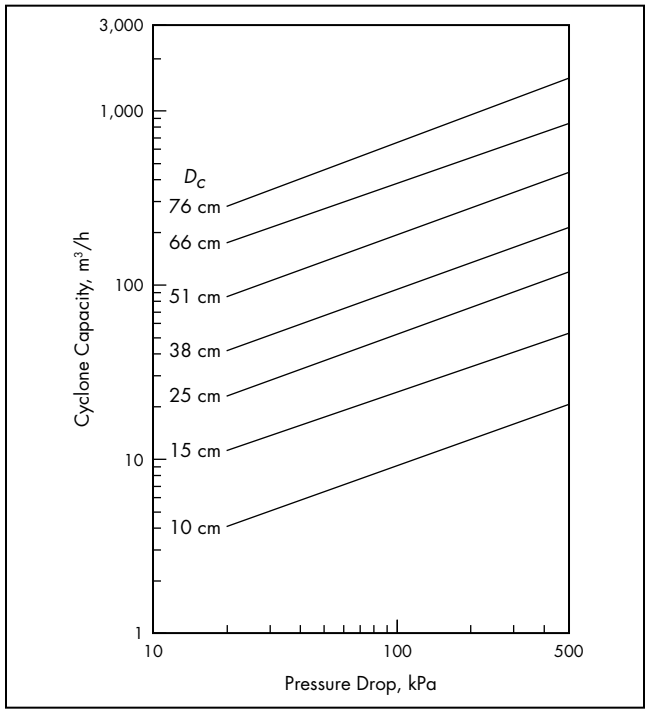
Source: Arterburn 1982.

Figure 14.3-45 Specific gravity correction factor

Source: Olson and Turner 2002.

Figure 14.3-46 Vortex finder correction factor

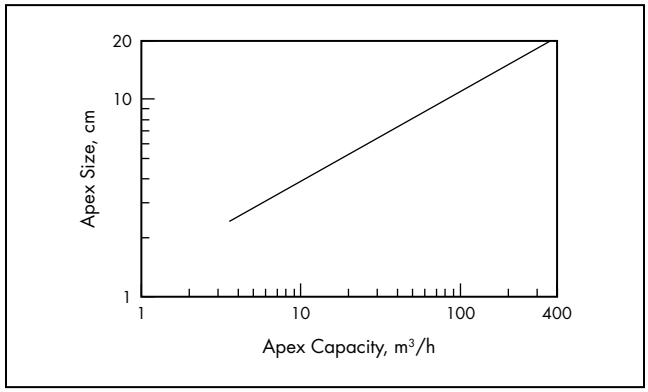
$CD1$ is the correction factor for the vortex finder diameter. In this example the default design of $D_o = 0.3D_c$ is used, but Figure 14.3-46 and Equation 14.3-17 illustrate the nature of the correction.



$$CD1 = \left[\frac{D_o}{0.3D_c}\right]^{0.6} \qquad (14.3\text{-}17)$$

Equation 14.3-11 then solves as

$$d50_{c\text{-}base} = \frac{154\ \mu m}{(4.09)(1.09)(0.93)(1)} = 37\ \mu m \qquad (14.3\text{-}18)$$



Step 3—Select size and number of hydrocyclones. From Equation 14.3-11 or Figure 14.3-42, the diameter of the hydrocyclone required to give this $d50_{c\text{-}base}$ is 49.1 cm (19.3 in.). Hydrocyclones, like screens, come in certain standard sizes, usually defined by D_c. As seen in Figure 14.3-47, the closest size to the "theoretical" value computed previously is a hydrocyclone with D_c = 51 cm (20.1 in.).

For a pressure drop of 50 kPa (7.25 psig), the capacity of a single 51-cm (20.1-in.) hydrocyclone will be approximately 140 m^3/h (616 gpm). From Figure 14.3-41, the total feed volumetric flow is 842 m^3/h (3,707 gpm), so approximately six hydrocyclones will be required in operation. In practice, two or three additional hydrocyclones would be added to accommodate maintenance as well as peaks in the feed flow rate. It is also not uncommon to provide an additional off-take valve in the radial header to be used for sample-collection purposes.

Source: Arterburn 1982.

Figure 14.3-47 Hydrocyclone capacity correlation

Source: Arterburn 1982.

Figure 14.3-48 Apex size correlation

Step 4—Select apex size. The last step is to determine the apex size, and that comes from Figure 14.3-48. For a total underflow rate of 396 m^3/h (1,744 gpm), the flow through each apex would be ~66 m^3/h (291 gpm), corresponding to an apex size of ~9.3 cm (3.66 in.). The manufacturer's closest size would be chosen, if possible tending to a smaller size in anticipation of wear.

Of course, after the hydrocyclones are installed and in operation, the reality of the application is known, and the optimization process (process variables and design variables such as D_o and D_u) can be modified as required.

Although the suppliers have undoubtedly added many refinements to their proprietary methods for hydrocyclone design, such as screens, the published methods for design have changed little since the 1980s. However, with the advent of some of the new, more efficient hydrocyclone technology

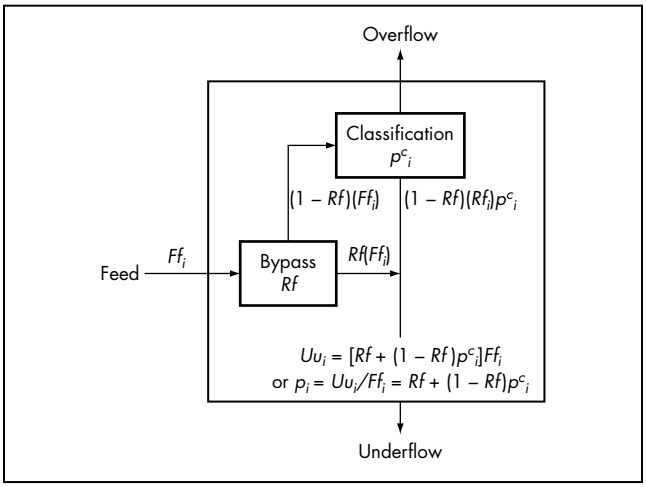


Figure 14.3-49 Conceptual model of hydrocyclone operation

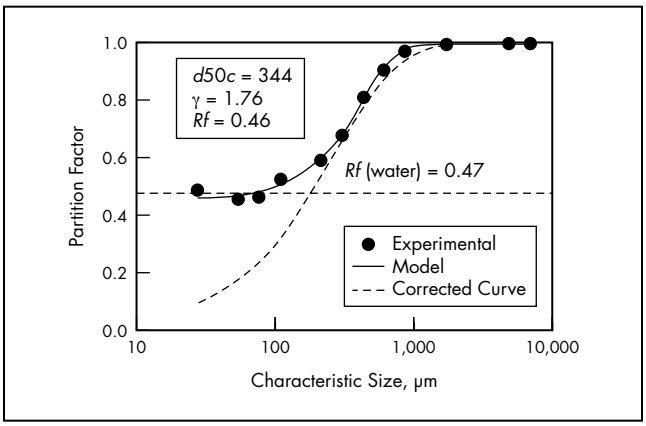

Figure 14.3-50 Partition curve for an inefficient hydrocyclone

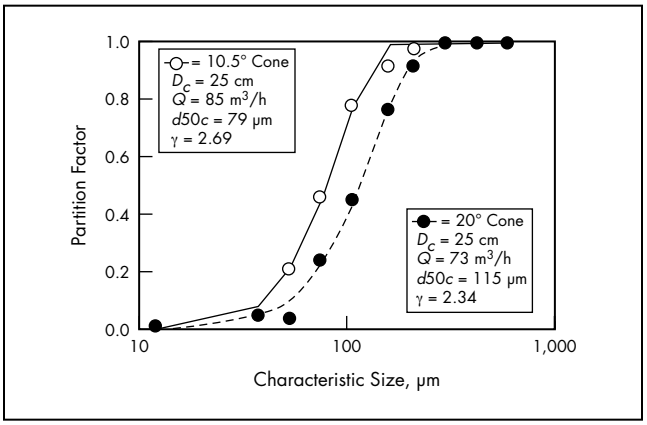
to be discussed later, these published methods will require an adaptation.

Performance Assessment

Hydrocyclone efficiencies are usually assessed through the partition curve, and this implies a sampling experiment to acquire the necessary data. However, unlike screens, the fact that hydrocyclones are treating fine particles in slurries introduces another dimension to the simple modeling approach used for screening (Equation 14.3-6). The liquid phase reporting with the underflow stream carries with it fine particles that should have otherwise reported to the overflow stream. A common conceptual model is illustrated in Figure 14.3-49. It is assumed that a fraction of the feed material is bypassed directly to the underflow stream and the rest of the material is then subjected to the classification process (characterized by γ and $d50c$). (In this figure, upper case letters F and U are mass flows in the feed and underflow, while f_i, and u_i are the mass fractions retained in the ith size class. $p^c{}_i$ is the corrected partition factor for the ith size class, usually given by Equation 14.3-6. Modeling convention is to number the size classes from 1 (coarsest size fraction) to N (the so-called pan fraction) from the sieve analysis. For example, in Table 14.3-12, the particles greater than 6,730 μm will be size Class 1, those falling into the interval 6,730 × 4,760 μm, will be size Class 2, and so on.

Thus, the basic partition curve model for hydrocyclones is given by

$$p_i = Rf + (1 - Rf)\left[1 - e^{-0.693\left(\frac{d_i}{d50_c}\right)^{\gamma}}\right] \qquad (14.3\text{-}19)$$



where Rf is the the bypass fraction.

Table 14.3-12 provides some experimental data for an operating hydrocyclone. Figure 14.3-50 compares the experimental data with modeling results with Equation 14.3-19, and the fit is seen to be very good. (The inefficient hydrocyclone was chosen for this illustration as the data are used to explore other measures of efficiency.)

The corrected partition curve (the term in the braces in Equation 14.3-19) is shown as the dashed line in Figure 14.3-50. Removing the effect of Rf in this way permits a more objective assessment of $d50_c$ and γ. The $d50$ for the experimental data in Figure 14.3-50 is about 106 μm, not very close to the $d50c$ value of 344 μm. Of course, this finer cut is because of the large number of fine particles carried to the underflow by the water—the Rf factor.

To amplify on Rf, the very fine particles ($d_i \rightarrow 0$ mm) are assumed to be more or less trapped in the water by virtue of the extraordinary drag forces. Hence, it is expected that the Rf deduced from the partition curve analysis will be equivalent to the water recovered from the feed to the underflow stream. In a well-constructed and executed experiment, the Rf estimated from curve fitting and the Rf(water) calculated from the water split should indicate good agreement, as evidenced in Figure 14.3-50.

For completeness, not all experimental partition curves behave like those for a homogenous ore (i.e., a low-grade ore with a gangue matrix of approximately constant specific gravity). For example, it is not uncommon to see the so called "fish-hook" behavior at the fine end of a partition curve, where the p_i values actually dip significantly below the expected Rf(water) value, before coming back to this level at the

Figure 14.3-51 Effect of cone angle on hydrocyclone performance

ultrafine sizes. While beyond the scope of this work, there are ways to model this if necessary, but the physical explanations are not so straightforward. Similarly, there can be inflections at the coarser end of the curve, so called "humps" or even "dips," and these are usually related to the separate classification action of liberated heavy and light mineral particles. In this latter case, one must separate these fractions experimentally (or mathematically) and model the curves separately.

From an operational point of view, maximum efficiency is achieved when γ is maximized (values of ~2.5 or larger are considered "good") and *Rf* is minimized (values of 0.3 or less are considered "good"). In closed-circuit grinding, *Rf* is a clear indication of the amount of fine material needlessly sent back to the mill. In practice, there is always a compromise between efficiency and operational objectives. In general both γ and *Rf* will improve with a lowering of the solids volumetric concentration in the feed. *Rf* can be also reduced using flat-bottom or inclined hydrocyclones, both of which maximize the underflow solids content.

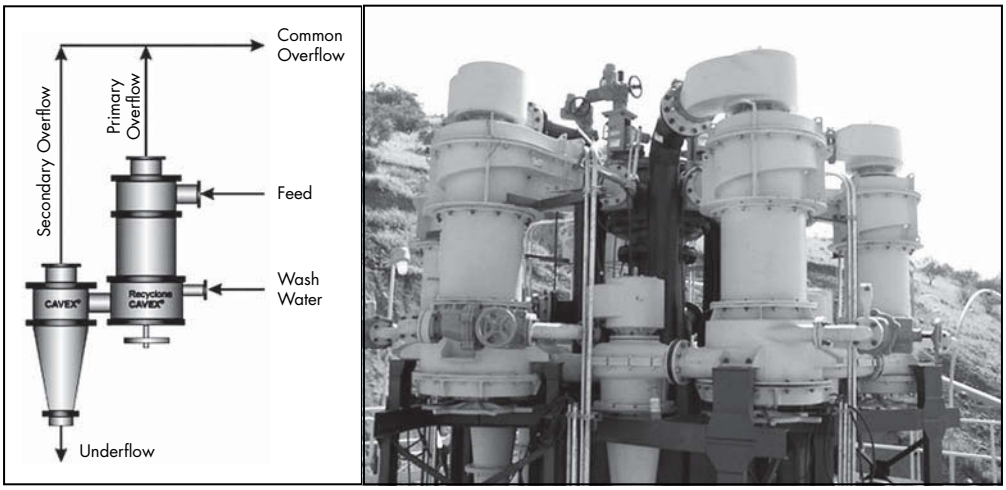
A final word of caution on partition curves is that there are numerous simple two-parameter functional forms used to characterize the corrected partition curve. They all have in common the parameters $d50c$ and γ. However, while the $d50c$ values will usually compare well, the same is not true for the γ values. It is important that one be aware of the underlying functional form in drawing any comparisons between plant results and those quoted by others. To very quickly illustrate, another commonly used model is given in Equation 14.3-18.

$$p_i = Rf + (1 - Rf)\frac{\left[\exp\left(\gamma\frac{d_i}{d50_c}\right) - 1\right]}{\left[\exp\left(\gamma\frac{d_i}{d50_c}\right) + \exp(\gamma) - 2\right]} \quad (14.3\text{-}20)$$

When Equation 14.3-18 is fit to the data in Figure 14.3-47, the parameter values are $d50_c$ = 340 µm, Rf = 0.44, and γ = 2.13. For a given data set, γ values from the model in Equation 14.3-20 are always higher than those from the model given by Equation 14.3-19.

A number of other efficiency measures, such as imperfection and probable error, are sometimes used with hydrocyclones. Many of these are based on the partition curve. In addition, some people use the efficiencies defined earlier for screening (Equations 14.3-3 and 14.3-4). To illustrate, the partition curve in Figure 14.3-50 is seen to be rather inefficient, both in terms of γ and especially in terms of *Rf*. (This is a high-density feed with older model hydrocyclones.) The corresponding figures are E_u = 62.2% (fines removal from oversize) and R_u = 41.2% (fines removal from feed to overflow). Not surprisingly, these poor performance figures, especially R_u, have been the main drivers to explore fine-screening solutions and more efficient hydrocyclone designs.

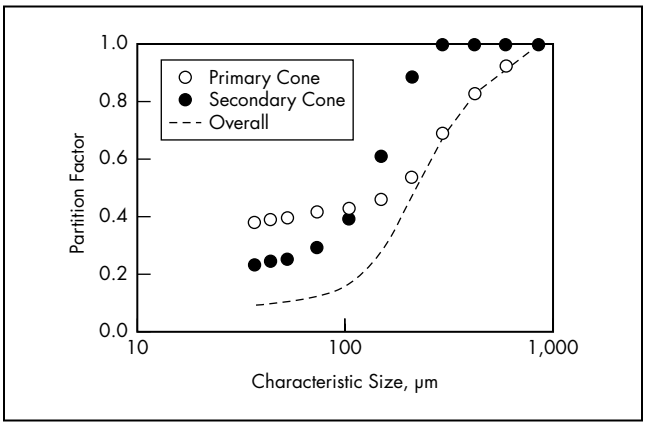
Recent Developments



Design enhancement on existing hydrocyclones. Recently, both FLSmidth Krebs (gMAX) and Weir Minerals (Cavex) have introduced new, more efficient hydrocyclone designs. In both cases it appears that design improvements were made in the feed inlet to minimize turbulence when the new feed enters the body of the hydrocyclone, which impacts capacity, wear, and efficiency. Moreover, both OEMs made changes to the hydrocyclone body design as well. FLSmidth Krebs (Krebs Engineers 2000) exploited the potential for efficiency improvements associated with increasing residence time in the critical conical section of the hydrocyclone, as shown in Figure 14.3-51. An extensive redesign campaign yielded optimal combinations of cylinder and cone length, as well as cone design for each standard gMAX hydrocyclone diameter.

Mohanty et al. (2002) reported that a conventional hydrocyclone separating a fine coal feed (~45 µm cut target) yielded an efficiency of R_u = 37%, while the gMAX improved this to 68%. Adding the FLSmidth Krebs Cyclowash attachment (a means of injecting water into the lower cone section of a hydrocyclone to remove fines) gave a further increase to 70%. (Further technical details may be found on the supplier's Web site.)

New hydrocyclone systems. In addition to the work underway to improve traditional hydrocyclone designs, new designs are also under study by equipment manufacturers and researchers alike, although in general these are application-specific products. Two good examples of this are the three-product hydrocyclone (University of Cape Town) and the ReCyclone (Weir Minerals).



Briefly, the three-product hydroyclone (e.g., Mainza et al. 2004) is intended for use in applications where there are components of distinctly different densities. In conventional hydrocyclones, the heavier minerals concentrate near the hydrocyclone wall, which creates a heavy medium that selectively sends the larger, lighter particles toward the inside of the hydrocyclone, where they can be sent to the overflow. In the case of the platinum ores in South Africa, the lighter silica gangue contains the platinum group metals, while the heavier chromite is barren. Larger silica particles that report to the overflow represent potential recovery losses in the flotation process. The three-product hydrocyclone uses concentric vortex finders to produce two overflow products, and the inner vortex finder collects the fine particles, which are sent directly to flotation. The outer vortex finder collects a coarser middlings overflow, rich in coarse silica, which is then screened to ensure that the coarser material gets to the mill for further grinding, while the finer heavy material joins the flotation feed. Development work continues with this system, which would appear to have other applications in the mineral processing industry.

The ReCyclone (D. Switzer, E. Castro, and J. Lopez, personal communications) uses two-stage classification as a means to reduce *Rf* and increase γ. This concept has been studied and promoted by many academics and a few operators. It

Figure 14.3-53 Partition curves for a ReCyclone

does find application in some coal and iron-ore flow sheets, but generally the extra footprint and the capital and operating expenses associated with such an approach has diminished interest among plant designers. One area where this has been extensively applied is in tailings dam construction, where it is critically important to move as much of the fines as possible from the sand product used to construct the dam. In these cases, two batteries of hydrocyclones (larger primaries followed by smaller secondaries) are common, to ensure that sand percolation rates are sufficiently high to avoid stability problems in the dam. The ReCylone performs these steps in a single unit.

Figure 14.3-52 is an illustration of the ReCylone unit and Figure 14.3-53 presents partition curves for the primary and secondary units and for the overall curve. Note the adjustment system on the primary underflow, which acts conceptually like a variable apex. The effects on *Rf* and, hence, fine particle content in the underflow are clear. All of the case studies reported by D. Switzer, E. Castro, and J. Lopez (personal communications) are on tailings. However, one can easily envisage other applications.

Instrumentation. Although little has been published thus far, the major hydrocyclone suppliers and some third parties are actively looking at technology value additions that would help to improve performance and minimize maintenance costs. For example, hydrocyclones are known to vibrate when they transition from normal underflow spray to a roping regime, and vibration and/or acoustics (e.g., Wedeles 2007) could be applied to diagnose this event or other events such as apex plugging (e.g., tramp grinding balls in the hydrocyclone feed). Another example is the elusive measurement of the relative wear of hydrocyclone liners, an area also under study by pump manufacturers. The interested reader should contact the suppliers directly on this topic.

Computational fluid dynamics (CFD). As was seen earlier in the discussion on screens, most major suppliers are rapidly embracing sophisticated simulation tools as a way to create and screen virtual machines for the purposes of design and optimization. Although this does not preclude the necessary step of field testing prototypes, it does help in the selection of the most appropriate candidate designs, reducing research and development costs and technical risk, and shortening the time to market.

CFD is the simulation technique of choice for fluid systems such as the hydrocyclone. However, at this stage it is impossible to simulate real slurries, and the standard approach is to simulate the fluid and then to use these results with some "tracer particles" (within CFD or in the DEM environment) to gain insight on classification efficiency. This one-way coupling (the fluid influences the particles, but the converse is not true), albeit with dilute suspensions, provides quantitative predictions based on first principles.

Suffice it to say, CFD played a major role in the development of both the Cavex and gMAX hydrocyclone designs described earlier. For the interested reader, the paper by Delgadillo and Rajamani (2007) provides a current vision of the benefits of CFD in advancing the hydrocyclone state of the art.

Media

Briefly, hydrocyclones are usually constructed of urethane or steel. Steel hydrocyclones are lined with wear-resistant materials such as rubber, ceramics, or urethane, and they can sometimes employ special metallic-based compounds. Again, the OEM is in a very good position to provide expert application advice on media choices.

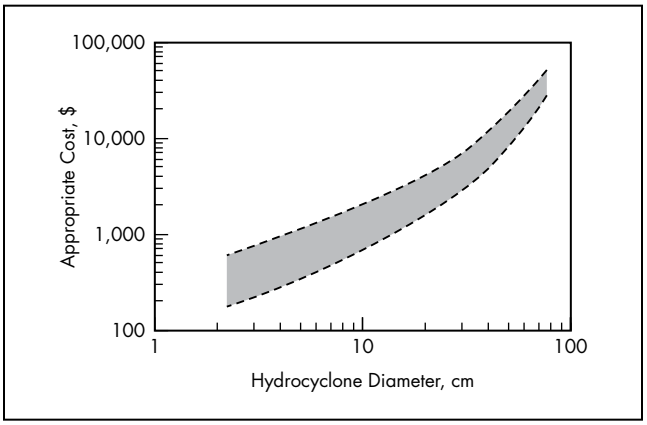

Figure 14.3-54 Typical hydrocyclone pricing

Standard Hydrocyclone Sizing and Relative Pricing

Each hydrocyclone manufacturer has a specific standard product size range, as shown in Figure 14.3-47. Generalizing across several of these suppliers, the usual sizes are approximately 10, 15, 25, 40, 50, 65, and 85 cm (3.9, 5.9, 9.8, 15.7, 19.7, 25.6, and 33.5 in.).

From an investment point of view, the total installation cost depends on the number of hydrocyclones, the materials of construction and lining, the type of radial header, the level of automation (manual versus automatic valves), and so forth. Figure 14.3-54 simply indicates the approximate cost of a single hydrocyclone and demonstrates the usual spread depending on whether lesser or more expensive materials are employed.

CHAPTER 14.4

Gravity Concentration and Heavy Medium Separation

Nimal Subasinghe

Gravity concentration is one of the oldest processes of separating minerals and is aimed at separating heavy minerals from lighter gangue. Gravity concentrators have wide applications in the heavy minerals industry for the recovery of heavy minerals, such as ilmenite, rutile, leucoxene, and zircon, from the lighter gangue. They are used to separate metal sulfides from ores where the sulfides are coarse grained. They have been used to exploit placer gold deposits over many centuries, and as an adjunct in modern mills to recover coarse gold early in the process. When the feed material is comprised of particles with a wider size distribution, gravity concentrators do not produce a clean concentrate and have been used mainly for preconcentration or as a rougher stage. Gravity concentrators are simple devices that are inexpensive to operate and cause comparatively much less environmental pollution than using harmful chemical reagents for the same purpose. Gravity separation may be achieved in either of two ways: relative gravity separation and absolute gravity separation.

In relative gravity separation, all particles settle in the same direction within the device, and large differences in specific gravity (density) between the minerals are needed for effective separation. As settling velocity of particles depends not only on density but also on size, it is important to prepare narrowly sized feeds to these devices. However, as particles of finer sizes settle under gravity at much slower rates, the effectiveness of these devices decreases considerably below about 50 μm. The heavy and light minerals that settle at different rates are made to report to different exit streams by applying a transverse force. There are many devices of this nature, such as jigs, spiral concentrators, Wilfley tables (shaking tables), air tables, Gemini tables, pinched sluices, riffled sluices, Reichert cones, and so on. To improve the efficiency of separation of finer material, centrifugal concentrating devices have been introduced within the past two decades, including Knelson concentrators, Falcon concentrators, Kelsey jigs, and water-only cyclones. These devices use centrifugal acceleration to enhance the movement of finer particles and have been extensively used in the gold processing plants to recover fine gold.

In absolute gravity separation, a fluid or a nonsettling slurry comprised of fine solid particles with a specific gravity (SG) intermediate to those of the two minerals to be separated is used as the medium of separation. Particles of higher and lower specific gravities than the medium move in opposite directions. This technique requires only a small difference in specific gravities of the minerals for effective separation. Heavy or dense medium separation methods are absolute separation methods. Devices of this sort include dense medium vessels and dense medium cyclones.

The amenability to gravity concentration is indicated by the concentration criterion, C, defined (Taggart 1951) as

$$C = \left(\frac{\rho_h - \rho_f}{\rho_\ell - \rho_f} \right) \tag{14.4-1}$$

which has been deduced from Newton's law of settling, where ρ_h, ρ_ℓ, and ρ_f are the densities of heavy mineral, light gangue, and water, respectively. If C is greater than 2.5, the separation may be achieved with relative ease; separation is not commercially feasible for values below 1.25. Table 14.4-1 shows the effectiveness of gravity separation at various feed sizes.

GRAVITY CONCENTRATORS

Gravity concentrators may be classified according to the way particles are made to move relative to each other so that the denser particles will segregate from the lighter ones under the influence of the gravitational force. A gravity concentrator uses essentially one of three mechanisms to provide movement of particles within it: jigging, shaking, and flowing film devices.

Table 14.4-1 Values of concentration criterion required for effective separation

Value of Concentration Criterion, C	Significance for Separation
>2.50	Separation effective down to ~75 μm
2.50–1.75	Separation effective down to ~150 μm
1.75–1.50	Separation possible to 2 mm, but difficult
1.50–1.25	Separation possible to 6 mm, but difficult
<1.25	Relative separations impractical. Absolute separation may be possible down to C of 0.2.

Source: Aplan 1985.

Nimal Subasinghe, Assoc. Professor of Minerals Engrg., Curtin University (Western Australian School of Mines), Kalgoorlie, Western Australia

These gravity separation devices rely on a fluid medium, such as water, to transport the material through the device and also bring about a separation based on settling characteristics of heavy and light particles. The process requires the feed material to be uniformly sized and fed as a slurry. If the feed has a wide size distribution, the smaller heavy mineral particles will report to the same exit as larger light particles because their settling velocities are similar. As the particle size decreases, the differences in gravitational forces acting on heavy and light particles, which bring about differences in their movement, also diminish. Recent advances in the design of gravity separation devices have addressed this problem by introducing "multi-G" devices that impart higher accelerations on smaller particles through centrifugal forces than those due to gravity. These devices are known as centrifugal concentrators. Thus, each gravity concentrator has an optimal feed particle size range for effective separation. The magnitude of the applied acceleration is usually quoted in terms of multiples of the gravitational acceleration, *G*. Figure 14.4-1 shows the classification of gravity separation devices. Table 14.4-2 shows the range of feed sizes suitable for various gravity separators.

Jigging Devices

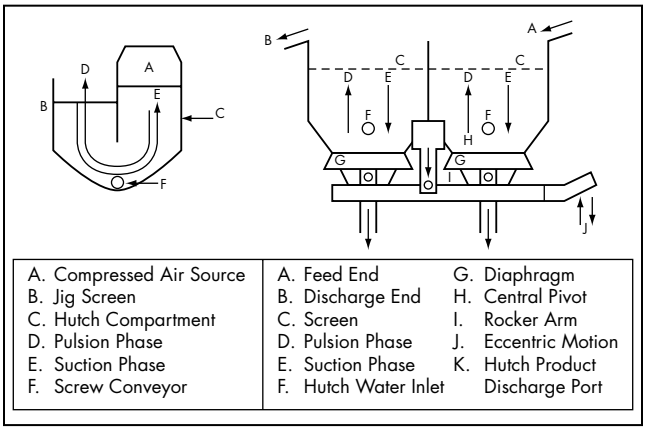
Jigging is one of the oldest methods of gravity concentration. It is commonly used in coal, cassiterite, gold, and iron ore industries. Generally jigs are used for separating coarser material from about 2 to 10 mm in diameter, although efficient separation of particles down to about 75 μm is possible with modified devices. They can handle large tonnages and operate on a continuous basis.

Jigging essentially uses alternating expansion and contraction of a bed of particles. The bed is generally formed over a screen through which the fluid is allowed to flow. Ragging comprised of heavy particles is generally placed over the screen to retain the bed and release the segregated heavies to the hutch during the suction stroke. The bed movement is activated by a pulsating current of fluid, usually water, or by the movement of the screen that holds the bed. The pulsation of the bed may be achieved by means of a plunger or by admitting compressed air at regular short intervals into a limb of a U-shaped tank. Light material is generally discarded through a gate positioned opposite to the feed end.

Gaudin (1939) suggested that three segregation mechanisms may take place within a jig: differential initial acceleration, hindered settling, and consolidation trickling. The extent of prevalence of these mechanisms depends on the properties of the material being processed, such as size and density and the manner in which the force is applied to dilate and contract the bed.

The differential initial acceleration between particles in a pulsating bed is a function of their density and is independent of size. That is, the initial acceleration conveyed to heavy mineral particles by the pulsating current of fluid is larger than that for lighter mineral particles. By applying a higher frequency of pulsation, this effect may be accentuated. This mechanism will segregate heavy minerals beneath the lighter gangue.

Also, during the pulsation stroke, heavy particles within the expanded bed will settle faster than the lighter ones. However, because of the presence of a large number of particles within the bed, hindered settling of particles takes place, the result of particle–particle interactions as opposed to free settling. The differences in hindered settling rates of larger particles are more pronounced than those of smaller particles. Hence, jigs perform better on coarser particles.

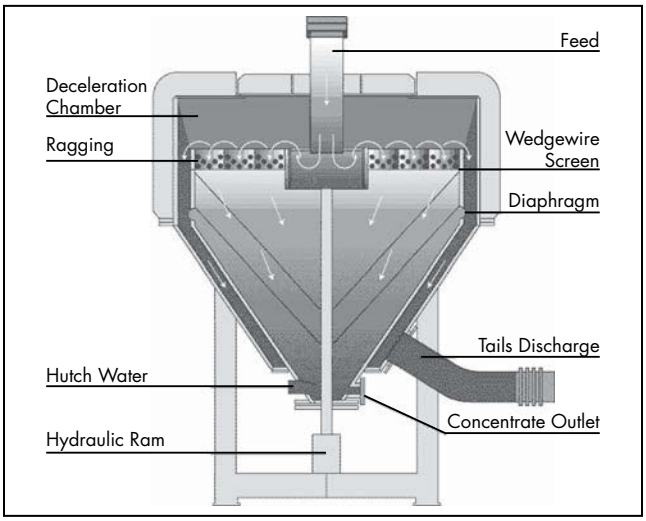


When the dilated bed collapses during the suction stroke, larger particles tend to interlock, leaving voids through which the finer particles may segregate. This process is known as interstitial or consolidation trickling.

Coal Jig

Baum jigs are commonly used for processing coarse coal whereas Batac jigs are used mainly for fine coal. Both these units use compressed air to pulsate the bed. In these units, water is typically pulsed at 60 to 80 pulses per minute and the units handle feed sizes up to 130 mm at capacities of up to 40 t/m^2/h.

Mineral Jig



Jigs that treat placer deposits generally have a diaphragm in the hutch area, which is placed underneath the screen that holds the bed. Typical jigs of this type are Cleveland and Pan-American placer jigs, which have a smaller footprint. Harz and Denver jigs have a wall that separates the hutch area and use an eccentrically driven plunger in one section to pulsate the bed. Schematic diagrams of a few jigs are shown in Figure 14.4-2.

Figure 14.4-3 In-line pressure jig

In-Line Pressure Jig

The in-line pressure jig (IPJ) combines a circular bed with a moveable sieve action. The screen is pulsed vertically by a hydraulically driven shaft. The length and speed of the up-and-down stroke can be varied to suit the application. Screen aperture, ragging dimension, and ragging material can also be altered for the application, which varies the recovery of solids to the concentrate stream. It uses less hutch water, compared to traditional jigs. The engineered ceramic ragging may be selected from a range of specific gravities from 1.6 to 5.0. IPJs have been used across many mineral types including gold, sulfides, tin, coal, and diamonds. Figure 14.4-3 shows a schematic diagram of an IPJ.

IPJs are available in a range of sizes handling 2 to 100 t/h of feed material. The solids recovery to concentrate may be varied from about 5% to about 50% by selecting the appropriate ragging density, ragging size, and screen aperture for a given feed size. Lower yields require tighter ragging sizing. The units are supplied with automatic controllers to control the feed rate, pulse frequency, stroke length, and air bleed rate for optimal performance.

Kelsey Centrifugal Jig

The Kelsey centrifugal jig (KCJ) imparts a centrifugal acceleration on the feed and ragging particles while a jigging action is being applied. It enables the effective separation of particles below about 500 μm down to fine sizes, and has found applications in tin, tantalum, gold, nickel, tungsten, chromite, base metals, iron ore, and mineral sands industries.

The centrifugal acceleration is conveyed by a spinning rotor, the speed of which may be varied and controlled. Inside the rotor, a screen of cylindrical shape is spun coaxially with the rotor. The ragging material is spread evenly on the inside of the screen because of the centrifugal acceleration. The feed enters through a fixed central pipe, then accelerates toward and continually rises up the ragging bed. Pressurized water is introduced into a series of hutches behind the screen, which is pulsed through the ragging to fluidize the bed. The pulsing of the bed is achieved via pulse arms connected to pulse pads, which push against flexible diaphragms at the back of each hutch, thereby pushing the water in the hutch through the screen and ragging bed.

KCJs can handle capacities up to 50 t/h solids and typically use about 30 to 50 m^3/h of hutch water. The rotor spins at speeds up to 200 rpm, generating accelerations of 40 *G*. The pulse rate is between 1,800 and 2,200 pulses per minute at a stroke length of 2 to 3 mm. A schematic diagram is shown in Figure 14.4-4.

The size of ragging used depends on the size distribution of the valuable mineral particles in the feed and should be chosen to avoid excessive blinding of the internal screen. Other operating variables include pulsation frequency, hutch water addition rate, ragging type, ragging SG, depth of bed, and so on. These units also have a number of design features, such as automatic screen cleaners and vibration detection. Programmable logic controller–based interlocks and sacrificial shear pins are provided to avoid major damage in the event of a malfunction.

Air Jig

Air jigs have been used in both coal and gold industries. In these devices, a low-pressure, high-volume air source is used to fluidize the particulate bed while a high-pressure, low-volume air source is used to impose the pulsation stroke for stratification. Recently, the air jig has found wider application in the coal industry as this method does not use process water, with the advantage of eliminating the need to dewater fines or manage slurry confinement. Particulate emissions have been minimized by the inclusion of fabric dust collectors. The new units use a punch plate instead of a fine wire mesh cloth to support a deeper particle bed. However, their application has limitations due to particle size, particle shape, moisture, and near-gravity content (Alderman 2002).

Flowing Film Separators

Flowing film separators have been used for centuries to accumulate heavy minerals such as gold and tin. These devices are cheap to make and operate. In flowing film concentrators, the feed slurry is made to flow over an inclined surface, and segregation of the heavy minerals beneath the lighter minerals takes place during the passage. At low flow rates, the thickness of the film is small and the particles generally settle out and roll over the surface. Heavier particles tend to accumulate in the lower regions closer to the surface and travel at lower velocities while the lighter materials travel closer to the surface and

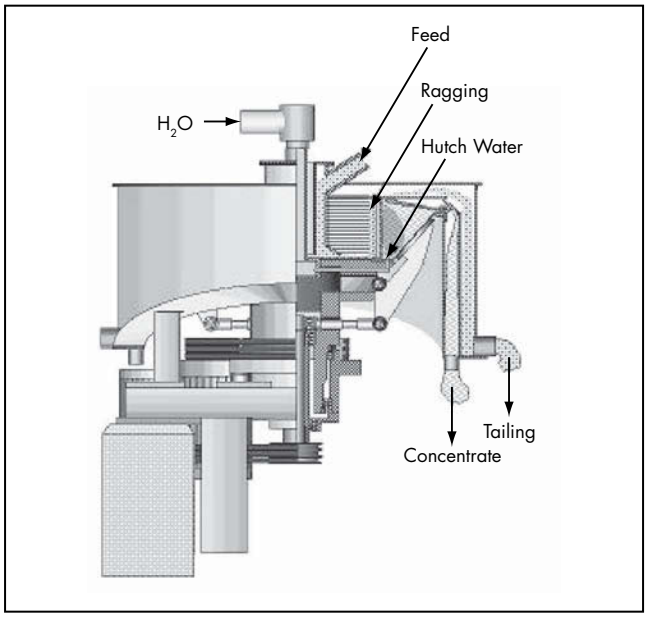
faster. At high flow rates the particles will be suspended in the flow due to turbulent suspension, resulting in a density gradient across the depth of the flow. The particles also experience shearing because of Bagnold forces that give rise to a dispersive pressure on the particles. Commonly used flowing film separators are pinched sluices, Reichert cones, riffled sluices, and spiral concentrators.

Pinched Sluice

A pinched sluice is a device comprised of an inclined plane bottom surface and tapering sides. The feed slurry is fed at the higher end and is made to flow down the inclined surface. The segregated heavy minerals flowing closer to the bottom of the surface are removed through slots placed across the bottom of the channel at the discharge end while the lighter minerals flow over the slot and report to tailings. The depth of flow increases toward the lower end because of the lowering of the area of cross section. These sluices are used by small-scale operators treating alluvial gold deposits and in tin and heavy minerals industries. Figure 14.4-5 shows a schematic diagram of a pinched sluice.

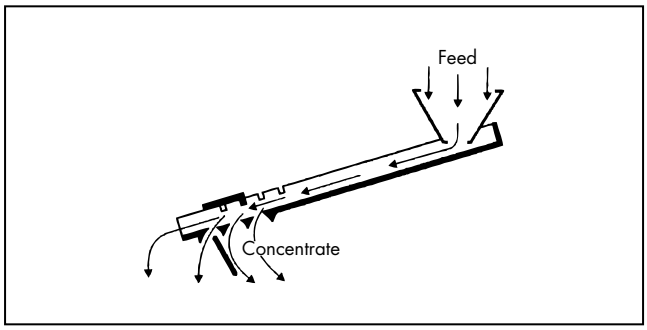
These units are operated at inclinations of between 15° and 20° to the horizontal. Subasinghe and Kelly (1984) demonstrated that at higher inclinations the recovery of coarser particles decreases because of the presence of Bagnold forces acting on the particles. At lower slopes, coarse and dense particles settle out on the deck resulting in poor segregation of heavies in the bed.

Reichert Cone



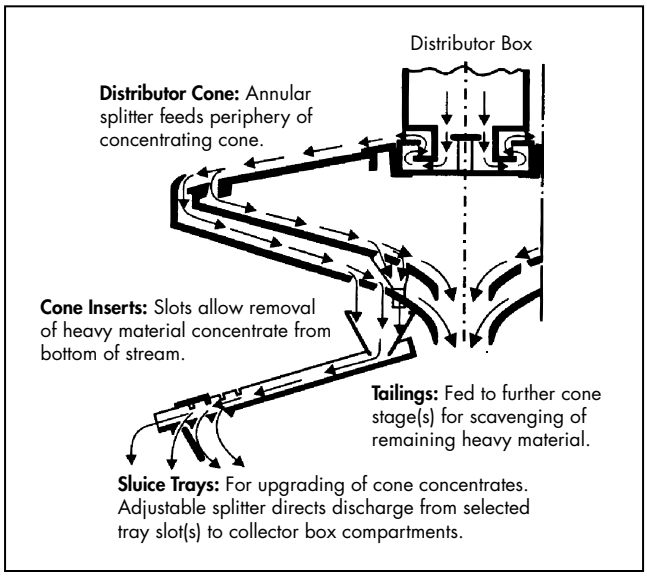
Reichert cones operate in a similar way to that of pinched sluices. The cone is designed as a series of pinched sluices joined in a circular pattern with their sides removed. An inverted cone is placed above the concentrating cone to distribute the feed slurry evenly. Heavy and light materials are removed through annular slots placed near the center column. Several cone pairs may be stacked on top of each other to increase the quality of the separation. Cones are operated continuously. Figure 14.4-6 shows a schematic diagram of a Reichert cone.

Riffled Sluice



Riffled sluices are commonly used by artisan miners to recover gold. The segregated gold or heavy minerals are recovered behind the riffles placed across the sluice. The feed flow rate, height, and spacing of the riffles determine the size of the recovered particles. If the feed contains fine gold, then a lower flow rate and smaller riffles are used. Sometimes instead of the riffles, corduroy cloth or coir mats are used to trap the fine gold particles. Sluices have been used to process fine cassiterite ores.

Spiral Concentrator



Spiral concentrators have found wide applications in the beach sand industry. In a spiral concentrator, the feed slurry is made to flow down a helical conduit of semicircular cross section. The slurry experiences a centrifugal force and has a tendency to move particles toward the outer rim. Because of the shape of the trough's cross section, these particles then travel inward, closer to the bottom of the trough. The heavy particles settle out of suspension and flow down the spiral closer to the trough's inner edge. There they are subjected to a smaller centrifugal acceleration and take up a trajectory closer to the

Figure 14.4-6 Reichert cone

axis of the spiral. The lighter particles move closer to the free surface and are carried toward the outer rim as a result of the centrifugal acceleration. When the slurry reaches the bottom of the spiral, separation of the heavies has occurred, and the heavies may be collected through the inner ports while the lighter material is collected from the outer port. To save floor space, two or more spirals may be incorporated into one unit known as a twin, triple, or quad start, thereby increasing the throughput rate.

The shape of the trough varies with the type of mineral being separated. Coal spirals generally have a flatter profile than mineral spirals. The pulp density may vary between 20% and 40% solids. The feed sizes range from about 2 mm to about 75 μm. The capacity of a single-start spiral may be up to 7.0 t/h, depending on the material being processed. The cut specific gravity depends on the pulp density, feed rate, and size distribution of the feed. In the beach sand industry, spirals are commonly used as a preconcentration stage. Figure 14.4-7 shows a schematic diagram of a concentrating spiral.

Shaking Devices

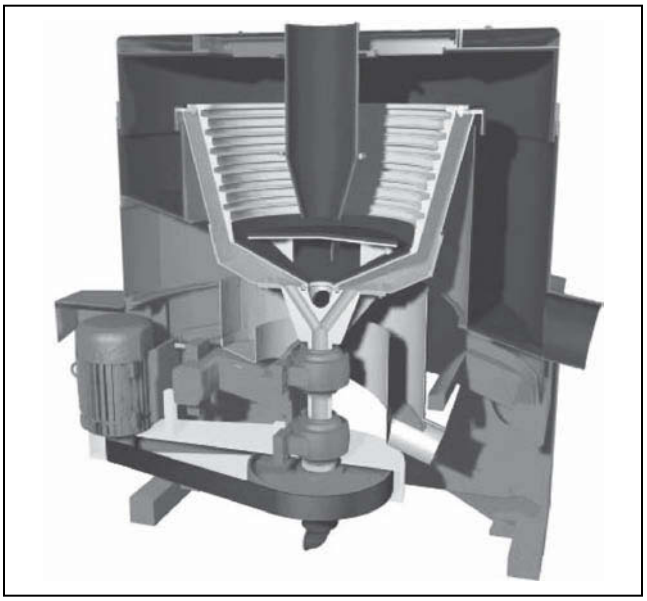
The most common shaking device is the concentrating table or the Wilfley table. Concentrating tables are very efficient gravity separators generally used in cleaning concentrates obtained from other devices. Concentrating tables or shaking tables are comprised of a rectangular flat table inclined horizontally by about 15° to 20°. Riffles are placed along the length of the table and the table is made to vibrate in the longitudinal direction in a reciprocating manner, with a slow forward stroke and a rapid return. The feed slurry enters through a port at the top corner and is distributed over the flat surface because of the vibratory motion. Wash water is introduced along the top edge of the table surface, washing the particles down the slope. Heavy mineral particles get trapped between the riffles and travel across the table in a longitudinal direction. The lighter minerals flow over the riffles and are carried down the slope and report to the tailings stream, nearer to the feed end of the table. The heavy mineral concentrate is collected at the opposite end of the table with middling particles collected in between. The feed to tables may vary from about 1 mm down to about 50 μm. The feed pulp density is between 25% and 35% solids. Figure 14.4-8 shows a schematic diagram of a Wilfley table.

Source: Aplan 1985.

Figure 14.4-8 Wilfley table and distribution of table products

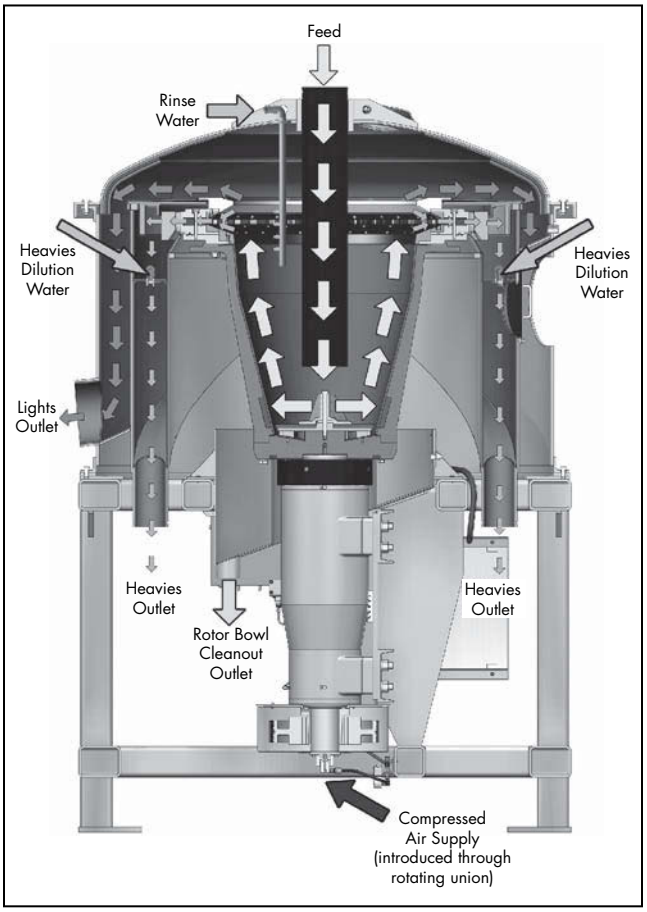
Many designs and riffle geometries exist, depending on the type of material being processed. Tables have been in use for processing of minerals such as coal, barites, beach sands, chromite, garnet, iron, manganese, tantalum, tin, tungsten, and zircon. Generally the variables that may be manipulated to increase the efficiency of separation are deck slope, wash water flow rate, and the frequency and amplitude of the vibratory motion. With larger particles, longer strokes and lower shaking frequencies are used. The separation is judged mainly by visual inspection, and modifications to operating variables may be made accordingly. These are low-capacity devices with about 2 and 0.5 t/h/m^2 for 1.5-mm and 100-μm particles, respectively. As they take up much floor space, multiple decks may be stacked up one above the other to save space.

Gemini tables have found wide application in the gold industry as a device for cleaning concentrates of centrifugal devices such as Knelson and Falcon concentrators. For finer feeds, Bartles–Mozley tables are generally used, in which the shaking mechanism is replaced by a smoother oscillator movement to avoid mixing of the bed due to turbulence. Air tables have also been used in the mineral industry to recover fine particles in which the bed is fluidized using air.



As an aside, air tables were originally developed for use in arid regions but have also been used in the separation of flat, fibrous materials of lower bulk densities such as asbestos and vermiculite. However, these devices demand that the feed be very narrowly sized for their efficient operation. As they also have only limited capacities, their use is limited only to special applications.

Centrifugal or Enhanced Gravity Concentrators



The movement of fine particles that settle under gravitational force within a fluid medium is slow. Even if there is a significant density difference between heavy and light minerals, the separations achieved are inadequate. However, by allowing the particles to traverse a circulatory motion at high speed, a centrifugal acceleration may be transmitted to them that may be several hundred times that of gravity. Devices that use this technique are called centrifugal concentrators. Two devices that have found wide applications in recovering fine gold and other minerals are the Knelson and Falcon concentrators.

Knelson Concentrator

Knelson concentrators, as shown in Figure 14.4-9, are comprised of a slightly conical-shaped rotating bowl with a series of grooves on the outer wall to capture the segregated heavy mineral particles. The feed material enters through a central feed inlet as a slurry. The slurry descends onto the base plate at the bottom of the rotating bowl and is thrown outward because of centrifugal acceleration. As a result,

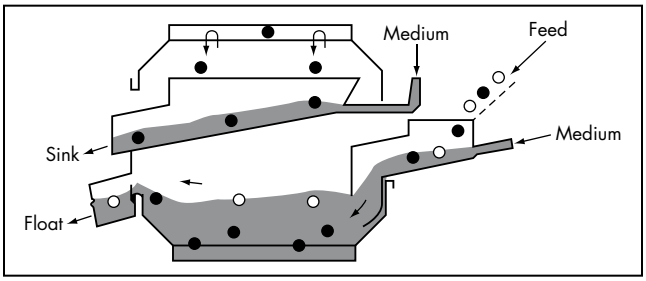
Courtesy of Knelson Gravity Solutions.
Figure 14.4-9 Knelson concentrator

Courtesy of Falcon Concentrators Inc.
Figure 14.4-10 Falcon continuous concentrator

some of the particles get trapped within the grooves of the bowl forming a bed while the excess get carried upward into the tailings stream by the rising current of water. Injection of water through fluidization ports located in the grooves of the bowl prevents compaction of the concentrate bed. This creates a fluidized bed that acts as a concentrating chamber for heavy mineral particles, under an enhanced separating force. Upon conclusion of the concentration cycle, concentrates are collected manually in batch units or flushed from the bowl into a concentrate launder through a multiport hub in continuous units.

As heavy particles experience a higher centrifugal acceleration, they tend to move through the fluidized bed to displace the light materials and produce a heavy mineral concentrate within the grooves of the bowl. The lighter particles are displaced into the tailings stream by the fluidizing water. Fluidizing water flow rate, bowl rotational speed, and particle characteristics of the feed, such as the size and size distribution, determine the optimal conditions for separation and the cycle time.

Falcon Concentrator



Falcon concentrators rely on a rotating bowl to generate high centrifugal accelerations similar to Knelson concentrators. The feed slurry rises upward over a slightly inclined smooth wall. Stratification of higher-density particles occurs toward the bowl wall, and lower-density particles move toward the center of the bowl. Different models vary in the way they collect and produce the concentrate.

In the semibatch unit, the upgraded product that has been forced against the bowl wall is made to move into a vertical, fluidized collection zone in the upper portion of the bowl. The collection zone consists of a number of rings that have pressurized water injected from the back, effectively elutriating and cleaning the concentrate that sits in these collection rings until a rinse cycle begins. These machines are known as semibatch devices because they continually accept feed during the run cycle but only produce concentrate during periodic rinse cycles. Run times range from 30 minutes to several hours depending on the application, while the rinse times are generally less than a minute. The throughput rates range from 1 to 400 t/h. The centrifugal accelerations range from 50 to 200 *G*. These units are mainly used in precious metal recovery plants.

In continuous devices, at the top of the bowl is a ring of specially designed concentrate flow hoppers, followed by pneumatically controlled variable orifice valves. These valves allow for a constant stream of concentrate to be produced. The continuous concentrator is able to vary mass pull to concentrate by adjusting valve orifice size through changes in air pressure. Because of their high mass pull rates of 5% to 40%, these units are used in the recovery and upgrade of tin, tantalum, tungsten, chrome, cobalt, iron, fine oxidized coal, and uranium ores. The ultrafine units are designed to concentrate material below 50 μm at less than 20% solids and may be typically used in deslime cyclone overflow streams. Figure 14.4-10 shows a schematic diagram of a Falcon continuous concentrator.

HEAVY MEDIUM SEPARATION

Heavy medium separation (HMS) is a very effective gravity separation technique in which a nonsettling heavy medium is used in place of a fluid. The heavy medium is generally

Source: Aplan 1985.
Figure 14.4-11 Heavy medium separator

comprised of a nonsettling suspension of fine heavy particles, the density of which is much higher than that of water. Thus, the concentration criterion described in Equation 14.4-1 increases considerably in this case, which indicates a more efficient separation. Also, since the medium density is between those of the heavy and light minerals to be separated, it gives rise to an absolute separation where the two products are separated into a sinks product and a floats product. This technique requires a much lower density difference between the minerals to be separated, compared to the relative separation techniques described previously.

With HMS it is possible to (a) produce a finished concentrate and a final waste product in one operation, (b) reject a waste product at a coarser size, thereby saving grinding costs, (c) achieve separation at a low operating cost with low maintenance costs, (d) make relatively sharp separations, (e) operate continuously, (f) tolerate feed with wide size distributions, and (g) produce a consistent product for further processing. The main industrial applications of HMS with coarse material feeds are in coal and iron ore industries. HMS has also been used in base metal industries such as copper, lead, and zinc. The most commonly used medium in coal separation is magnetite. Although silica, barite, and galena had been used in the past as the medium solid for ore separations, in recent times ferrosilicon (FeSi) has been used extensively. With finer feed materials, the viscosity of the slurry increases, and the separation efficiency decreases as a result. This situation has been rectified by the use of centrifugal separators such as heavy medium cyclones (HMCs). The water-only cyclones work similarly to an HMC that uses a loess medium instead of an external medium. See Figure 14.4-11 for a schematic diagram of a heavy medium separator.

Heavy Medium Solids

The solids used to make up the heavy medium depend on the type of material to be separated. The heavy medium suspension should be nonsettling, which requires the solid particles to be sufficiently small. For coal, the most commonly used are magnetite and barite, as the medium density should be less than the ash density. For ore separations, more dense solid materials such as ferrosilicon and galena have been used (Aplan 2003). Ferrosilicon contains about 15% Si. Ground ferrosilicon is used for separations at SGs up to 3.2; for higher SGs up to 3.8, atomized FeSi may be used. The main requirement in selecting a medium for a given operation is its ability to be separated from the products. Generally the products are washed and screened to remove the medium. Wet magnetic separators are also used extensively to recover magnetite and ferrosilicon. The medium recovered from the product streams needs to be thickened to the required consistency prior to recycling it back to the separating vessel.

Feed Preparation

It is important to prepare the feed prior to HMS, usually by wet screening. The main purpose is to size the ore into fractions that may be treated in various separating units. More importantly, screening is used to remove the slimes that would otherwise increase the viscosity of the medium, giving rise to inefficiencies.

Medium Recovery

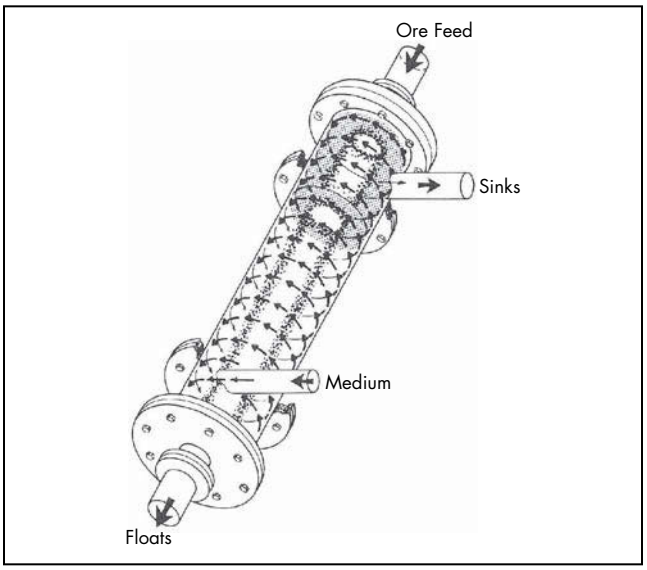
Medium is generally removed from the products in drain and wash screens. Sieve bends are the preferred screen type for medium recovery. Prior to reusing, the medium needs to be cleaned using wet magnetic separators. Magnetic separators are fed at about 30% to 35% solids, and the rate is determined by the type of separator and magnetic susceptibility of the medium.

Heavy Medium Separators

HMS equipment must ensure the feed particles have sufficient time to report to the relevant discharge streams. They generally differ in the way the float and sink products are discharged. The float products will often discharge over a weir with or without the need for paddles or scrapers. The Wemco drum discharges the heavy mineral using lifters while rotating. The Drewboy washer uses paddles to elevate the heavies, while the Norwalt bath uses a bucket elevator. The Dutch State Mines bath uses a drag conveyor with a paddle to deliver the heavies and lights to different discharge ports.

The separations of finer sizes are carried out effectively in units that use centrifugal acceleration to aid in the separation and discharge of particles. HMCs and Dyna Whirlpool separators (DWPs) are the widely used equipment of this type.

Heavy Medium Cyclones



The HMCs are essentially a modified version of hydrocyclones used with a heavy medium as the separating fluid instead of water. In an HMC, the heavy mineral migrates to the outside wall and is discharged through the vortex finder. The shape of the HMC, however, differs from that of a classifying cyclone in that the height of the cyclone is comparatively shorter. HMCs treating coal operate at inlet pressures with a minimum head of about nine times the diameter of the cyclone. The diameters of these HMCs range from about 0.5 m to 1.4 m and have capacities up to 500 t/h. The relative density of the overflow stream should be between 3% and 12% lower than that of the feed stream.

Dyna Whirlpool Separator

The DWP also imparts a centrifugal acceleration to the feed particles. A DWP is essentially a sloping cylinder with cover plates and central openings to which the raw feed is fed centrally at the top end. There are also tangential orifices at either end. The medium enters tangentially at the lower end and migrates toward the top end, leaving the cylinder tangentially along with the heavy mineral. The lights gravitate to the bottom end and leave through a central discharge port. Generally, centrifugal devices such as the HMC and DWP experience higher media losses than static-type devices. A schematic diagram of a Dyna Whirlpool separator is shown in Figure 14.4-12.

PERFORMANCE EVALUATION OF GRAVITY SEPARATORS

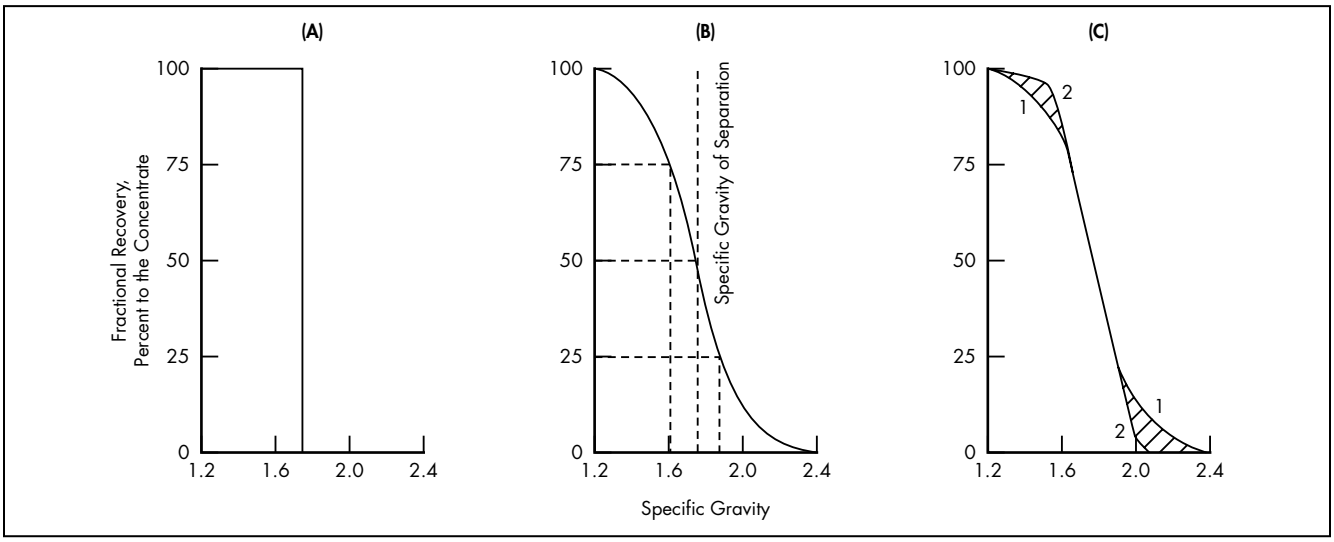
Gravity separators aim to separate minerals at a desired separation density. However, because of the presence of middling particles, which have densities between those of heavy and light minerals, a sharp separation is not possible. Also, since these devices rely on differences between settling rates of the two minerals, fine feed material inherently gives rise to inefficiencies. The efficiency of a gravity concentrator is determined by two factors: material characteristics and machine characteristics. The degree of liberation of the feed material that affects the separation efficiency is represented by separability curves, whereas machine characteristics are evaluated in terms of performance curves (Kelly and Spottiswood 1982). The performance curve of an operating machine is represented by a plot of the fractional mass of particles reporting to the concentrate stream against the extent of the property being exploited for the separation. For gravity concentration, traditionally density (or SG) of the particles has been taken as the property being exploited. Such a plot is commonly known as the performance curve, partition curve, or the Tromp curve, which may be construed as a probability plot that indicates the probability of a particle of given SG reporting to the concentrate stream. A typical performance curve is shown in Figure 14.4-13.

Source: Aplan 1985.

Figure 14.4-12 Dyna Whirlpool separator

A flatter curve represents a poor separation, whereas a steeper slope represents a sharp separation. The specific gravity of particles that have equal chances of reporting to either exit is known as the cut specific gravity (SG_{50}) or separation density. For static heavy medium separators the separation density is close to the medium density whereas for centrifugal separators, it is slightly higher.

To compare different operations with different separation SGs, several efficiency measures have been proposed. Measures of efficiency based on performance curves generally used for gravity concentrators are probable error (Ecart probable, E_p), imperfection (I), and the sharpness index (SI). These are defined as follows:



$$E_p = \tfrac{1}{2}\,(SG_{75} - SG_{25})$$

$$I = E_p/(SG_{50} - 1)$$

$$\text{and } SI = \frac{SG_{75}}{SG_{25}} \qquad (14.4\text{-}2)$$

where SG_{25}, SG_{50}, and SG_{75} are the specific gravities at which 25%, 50%, and 75% of the material would report to the concentrate stream, respectively. The percentage of misplaced material measured as an area between curves has also been used as a measure of efficiency.

E_p represents the inverse of the slope in the middle part of the curve but does not take into account the shape of the two ends of the performance curve that represent most of the misplaced material. Generally, the cut specific gravity of

>25	Formidable	Exceptionally efficient process, expert operation	Heavy media separation, close control

Source: Aplan 2003.

separations involving fine particles is higher. Thus, imperfection that takes into account this variation may be used to compare various equipment that process different-sized feeds. Table 14.4-3 shows typical E_p values for coal cleaning devices.

SELECTION OF GRAVITY SEPARATION EQUIPMENT

The selection of gravity separation equipment is based on the response of the ore to sink-and-float tests using heavy liquids. The commonly used heavy liquids are methylene iodide, tetrabromoethane, methylene bromide, and lithium sodium—tungstates whose densities are 3.3, 2.96, 2.48, and 2.85, respectively. For higher-density separations, Clerici solution is used. Generally an organic solvent may be used to dilute the reagents to a required specific gravity. Caution should be exercised in handling these reagents as most of them are toxic.

The data from these tests are presented as washability curves that essentially indicate the grade and recovery of the concentrate that can be achieved at various separation densities. The selection of gravity equipment is based on the amount of material present in the ore that is near the separation density. The amount of ore within ±0.1 SG units of the separation density is known as the tolerance value, which is a reflection of the degree of difficulty of separation. Table 14.4-4 shows the recommended equipment at various tolerance values.

The selection also depends on the feed size of the ore as each equipment type can handle material only within a specified size range.

For the selection of centrifugal separators for fine gold recovery, a gravity recoverable gold test has been proposed (Laplante et al. 2000). This test is a material characterization test that indicates the amenability of the ore to centrifugal gravity concentration. For the purpose of determining optimal operating conditions of a Knelson concentrator, a model based on a mechanistic approach has been proposed (Subasinghe 2007).

CHAPTER 14.5

Fundamental Principles of Froth Flotation

S. Komar Kawatra

INTRODUCTION

Froth flotation is a highly versatile method for physically separating particles based on differences in the water-repellency characteristics of the surfaces of various rock and mineral species contained in aqueous slurry. The air bubbles generated within a separation vessel collect hydrophobic particles and ascend to the surface with the particles attached to be removed, while the particles that remain completely wetted stay in the liquid phase. Froth flotation can be adapted to a broad range of mineral separations, as it is possible to use chemical treatments to selectively alter mineral surface characteristics so that they have the necessary hydrophobicity for the separation to occur. Many diverse applications, both mineral and nonmineral, are currently in use. Examples of mineral applications include separating sulfide minerals from silica gangue (and selectively from other sulfide minerals), separating potassium chloride (sylvite) from sodium chloride (halite), separating coal from ash-forming minerals, removing silicate minerals from iron ores, and separating phosphate minerals from silicates. An example of a nonmineral application is the de-inking of recycled newsprint. Flotation is particularly useful for processing fine-grained ores that are not amenable to conventional gravity concentration because of their low density differentials that render gravity separation unacceptably ineffective.

The flotation system includes many interrelated components, and changes in one area will produce compensating effects in other areas, as shown in Figure 14.5-1 (Klimpel 1995). Therefore, it is important to take all of these factors into account when developing specific froth flotation applications. Changes in the settings of one factor (such as feed rate) will automatically cause changes in other parts of the system (such as flotation rate, particle size recovery, airflow rate, and pulp density). As a result, it is difficult to study the effects of any single factor in isolation, and compensation effects within the system can sometimes result in an unexpected and undesirable outcome (Klimpel 1995). This makes it difficult to develop predictive models for froth flotation; although work is being done to develop models that utilize readily measurable parameters such as solids recovery and tailings solid content (Rao et al. 1995). Such models incorporate fundamental physical and chemical reactions as well as empirical data that relate to the mineral components, and they are usually validated by various levels of test work (i.e., bench-scale, pilot-plant, and commercial plant trials).

PERFORMANCE CALCULATIONS

A universal method for expressing the effectiveness of a separation does not exist, but there are several useful methods for examining froth flotation processes.

Parameters

The following parameters are used to measure performance.

(a) *Ratio of concentration:* The ratio of concentration is the weight of the feed relative to the weight of the concentrate, which is expressed as follows:

$$\text{ratio of concentration} = F/C$$

where

F = total weight of the feed
C = total weight of the concentrate

One limitation with this calculation is that it uses the weights of the feed and the concentrate. Although these data can be obtained from laboratory experiments, in the plant it is likely that the ore is not weighed and only assays are available. However, it is possible to express the ratio of concentration in terms of ore assays. This can be done starting with the definition of the ratio of concentration (F/C) and using the following mass balance equations:

$$F = C + T$$

$$Ff = Cc + Tt$$

where

F, C, and T = percent weights of the feed, concentrate, and tailings, respectively
f, c, and t = assays of the feed, concentrate, and tailings, respectively

S. Komar Kawatra, Professor of Chemical Engineering, Michigan Technological University, Houghton, Michigan, USA

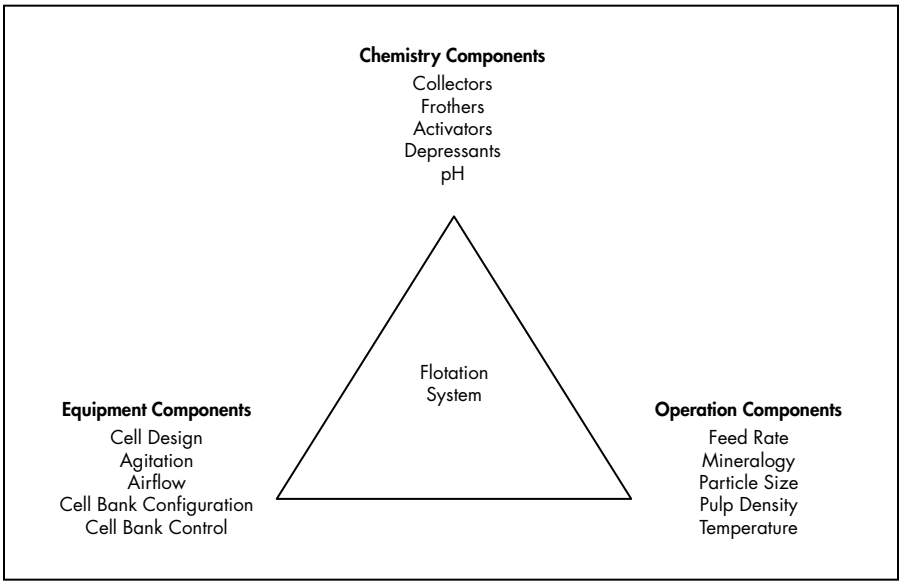

Figure 14.5-1 Interrelated components of a flotation system

So that F/C can be determined, one needs to eliminate T from these equations. Multiplying $F = C + T$ by t gives $Ft = Ct + Tt$, and subtracting this equation from $Ff = Cc + Tt$ eliminates T and gives $F(f - t) = C(c - t)$. Rearranging then gives

$$F/C = (c - t)/(f - t)$$

(b) *Percent metal recovery:* The percent metal recovery is the percentage of the metal in the original feed that is recovered in the concentrate. This can be calculated using weights and assays, for example, $(Cc)/(Ff) \times 100$, or because $C/F = (f - t)/(c - t)$, the percent metal recovery can be calculated from the assays alone using $100(c/f)(f - t)/(c - t)$.

(c) *Percent metal loss:* The percent metal loss is the opposite of the percent metal recovery and represents the material lost to the tailings. It can be calculated simply by subtracting the percent metal recovery from 100%.

(d) *Percent weight recovery:* The percent weight recovery is essentially the inverse of the ratio of concentration and equals $100C/F = 100(f - t)/(c - t)$.

(e) *Enrichment ratio:* The enrichment ratio is calculated directly from the assays as c/f. The weights are not involved in the calculation.

Example Calculations

A copper ore initially contains 2.09% Cu. After carrying out a froth flotation separation, the products are as shown in Figure 14.5-2. Using these data, parameters (a) through (e) are calculated as follows.

(a) *Ratio of concentration:* From Figure 14.5-2, the ratio of concentration can be calculated as $F/C = 100/10 = 10$. If only assays are available, the ratio of concentration equals $(20 - 0.1)/(2.09 - 0.1) = 10$. Therefore, for each 10 t (metric tons) of feed, the plant would produce 1 t of concentrate.

(b) *Percent metal recovery:* Using the example data from Figure 14.5-2, the percent Cu recovery calculated from the weights and assays is as follows:

$$\text{percent Cu recovery} = [(10 \times 20)/(2.09 \times 100)] \times 100 = 95.7\%$$

The calculation using assays alone is as follows:

$$\text{percent Cu recovery} = 100(20/2.09)(2.09 - 0.1)/(20 - 0.1) = 95.7\%$$

This means that 95.7% of the copper present in the ore was recovered in the concentrate, while the rest was lost in the tailings.

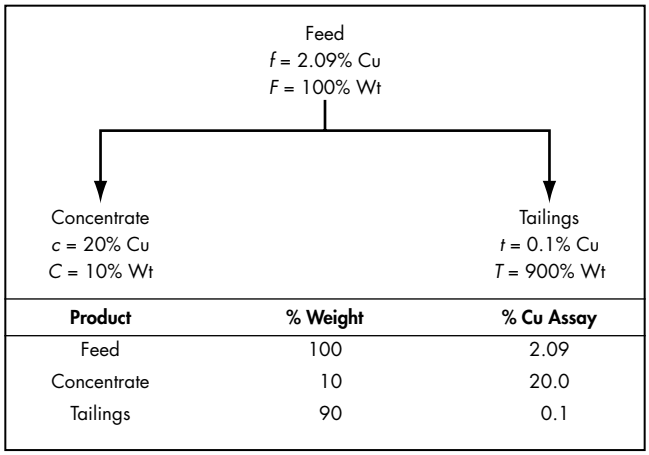
(c) *Percent metal loss:* The percent Cu loss can be calculated by subtracting the percent Cu recovery from 100% as follows:

$$\text{percent Cu loss} = 100 - 95.7 = 4.3\%$$

This means that 4.3% of the copper present in the ore was lost in the tailings.

(d) *Percent weight recovery or percent yield:* The percent weight recovery is equal to the percent weight of the concentrate in Figure 14.5-2. It can also be calculated as follows from the assay values given in the figure:

$$\text{percent weight recovery} = 100 \times (2.09 - 0.1)(20 - 0.1) = 10\%$$



(e) *Enrichment ratio:* The enrichment ratio is calculated by dividing the concentrate assay in Figure 14.5-2 by the feed assay as follows:

$$\text{enrichment ratio} = 20.0/2.09 = 9.57$$

This reveals that the concentrate has 9.57 times the copper concentration of the feed.

Grade–Recovery Curves

Although these calculated values are useful for comparing flotation performance for different conditions, it is most useful to consider both the grade and the recovery simultaneously using a "grade–recovery curve." This is a graph of the recovery of the valuable metal versus the product grade at that recovery, and it is particularly useful for comparing separations where both the grade and the recovery are varying. A set of grade–recovery curves is shown in Figure 14.5-3. If 100% of the

Product	% Weight	% Cu Assay
Feed	100	2.09
Concentrate	10	20.0
Tailings	90	0.1

Figure 14.5-2 Grade–recovery performance of a hypothetical copper ore flotation process

feed is recovered to the product, then the product will obviously have the same composition as the feed, and so the curve starts at the feed composition with 100% recovery. Similarly, if the purest mineral grain that contains the metal of interest is removed, this will be the maximum grade that can be produced by a physical separation, and so the zero percent recovery end of the curve terminates at an assay that is less than or equal to the assay of the purest grains available in the ore. In the curves shown in Figure 14.5-3, the points that are higher and to the right show better performance than the points that are lower and to the left.

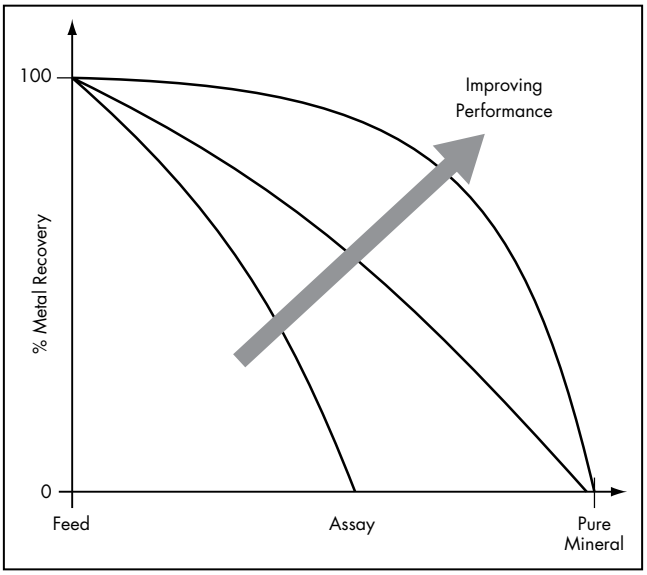


Figure 14.5-3 Typical forms of the grade–recovery curves for froth flotation

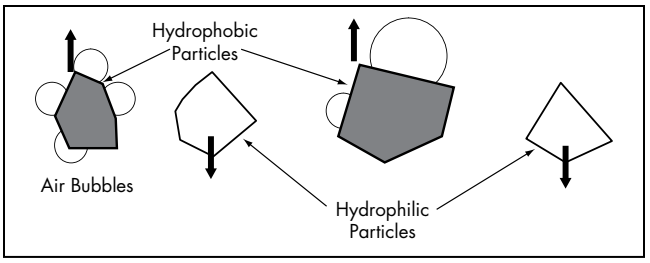

Figure 14.5-4 Selective attachment of air bubbles to hydrophobic particles

HYDROPHOBICITY/HYDROPHILICITY

The basis of froth flotation is the difference in wettabilities of different minerals. Particles range from those that are readily wettable by water (hydrophilic) to those that are water-repellent (hydrophobic). If a mixture of hydrophobic and hydrophilic particles are suspended in water and air is bubbled through the suspension, then the hydrophobic particles will tend to attach to the air bubbles and float to the surface, as shown in Figure 14.5-4. The froth layer that forms on the surface will then be heavily loaded with the hydrophobic mineral, and it can be removed as a separated product. The hydrophilic particles will have limited or no tendency to attach to air bubbles, and so they will remain in suspension and be transported away in the slurry (Whelan and Brown 1956).

Particles can be naturally hydrophobic, or hydrophobicity can be induced by chemical treatments. Naturally hydrophobic materials include hydrocarbons and nonpolar solids such as elemental sulfur. Coal is a good example of a material that is normally naturally hydrophobic, because it is mostly composed of hydrocarbons. Chemical treatments to render a surface hydrophobic are essentially methods for selectively coating a particle surface with a monolayer of nonpolar oil.

The attachment of the bubbles to the surface is determined by the interfacial energies between the solid, liquid, and gas phases. This is determined by Young–Dupré equation as follows:

$$\gamma_{lv}\cos\theta = (\gamma_{sv} - \gamma_{sl})$$

where

γ_{lv} = surface energy of the liquid–vapor interface
γ_{sv} = surface energy of the solid–vapor interface
γ_{sl} = surface energy of the solid–liquid interface
θ = "contact angle"

The contact angle (θ) is the angle formed at the junction between vapor, solid, and liquid phases, as shown in Figure 14.5-5. If the contact angle is very small, then the bubble does not attach to the surface, whereas a very large contact angle results in very strong bubble attachment. A contact angle near 90° is sufficient for effective froth flotation in most cases.

PARTICLE–BUBBLE CONTACT

When particles are rendered hydrophobic, contact with gas bubbles must occur so that attachment to the surface can take place. Contact between particles and bubbles can be accomplished in a flotation cell such as the agitated cell shown in Figure 14.5-6.

In the agitated cell, the rotor draws slurry through the stator and expels it to the sides, creating a suction that draws air down the shaft of the stator. The air is then dispersed as bubbles through the slurry and comes in contact with particles in the slurry that is circulated through the stator.

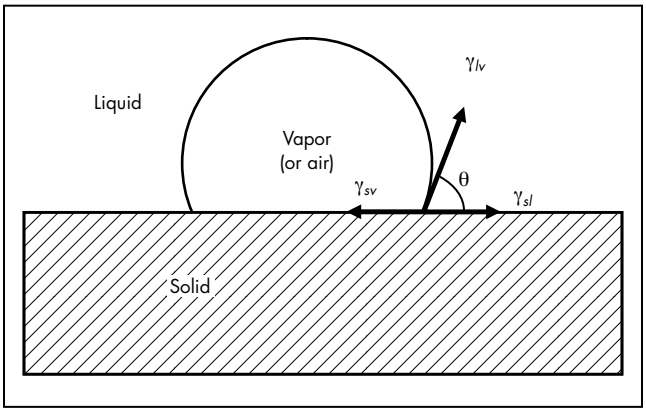

Figure 14.5-5 Contact angle between air bubble and solid surface immersed in liquid

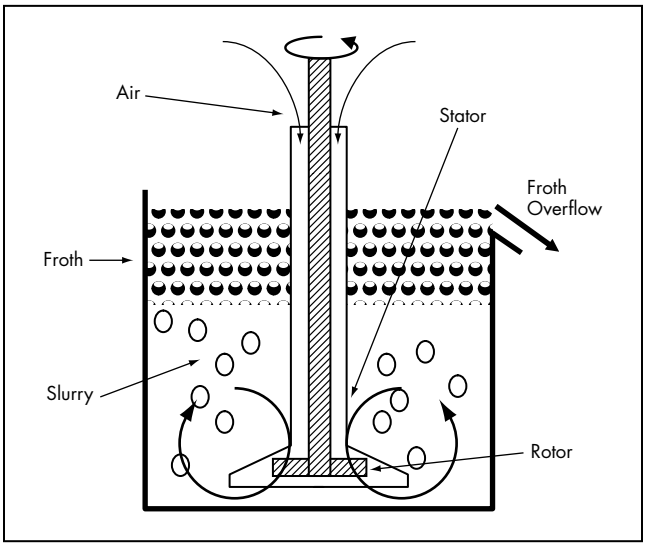

Figure 14.5-6 Simplified flotation cell

Particle–bubble collision is affected by the relative sizes of the particles. If the bubbles are large relative to the particles, then fluid flowing around the bubbles can sweep the particles past without them coming in contact. Therefore, it is best if the bubble diameter is comparable to the particle diameter to ensure good particle–bubble contact.

COLLECTION IN THE FROTH LAYER

When a particle and bubble have come in contact, the bubble must be large enough for its buoyancy to lift the particle to the surface. This is obviously easier if there are low-density particles (as is the case for coal) than if there are high-density particles (such as lead sulfide). The particle and bubble must remain attached while they move up into the froth layer at the top of the cell. The froth layer must persist long enough to either flow over the discharge lip of the cell by gravity or be removed by mechanical froth scrapers. If the froth is insufficiently stable, the bubbles will break and drop the hydrophobic particles back into the slurry prematurely. However, the froth should not be so stable as to become persistent foam, as foam is difficult to convey and pump through the plant.

The surface area of the bubbles in the froth is also important. Because particles are carried into the froth by attachment to bubble surfaces, increasing amounts of bubble surface area allows a more rapid flotation rate of particles. At the same time, increased surface area also carries more water into the froth as the film between the bubbles. Because fine particles that are not attached to air bubbles will be unselectively carried into the froth along with the water (entrainment), excessive amounts of water in the froth can result in significant contamination of the product with gangue minerals.

REAGENTS

The properties of raw mineral mixtures suspended in normal plant circulating water are rarely suitable for froth flotation. Chemicals are needed both to control the relative hydrophobicities of the particles and to maintain the proper froth characteristics. Therefore, many different reagents are involved in the froth flotation process, with the selection of reagents depending on the specific mineral mixtures being treated (Klimpel 1980; Thompson 2002).

Collectors

Collectors are used to selectively adsorb onto the surfaces of particles. They form a monolayer on the particle surface that essentially makes a thin film of nonpolar hydrophobic hydrocarbons. The collectors greatly increase the contact angle so that bubbles will adhere to the surface. Selection of the correct collector is critical for an effective separation by froth flotation. Collectors can be generally classed depending on their ionic charge; they can be nonionic, anionic, or cationic, as shown in Figure 14.5-7 (Glembotskii et al. 1963). Nonionic collectors are simple hydrocarbon oils, whereas the anionic and cationic collectors consist of a polar part that selectively attaches to the mineral surfaces and a nonpolar part that projects out into the solution, rendering the surface hydrophobic. Collectors can either chemically bond to the mineral surface (chemisorption) or they can be held on the surface by physical forces (physical adsorption).

Chemisorption

In chemisorption, ions or molecules from solution undergo a chemical reaction with the surface, becoming irreversibly bonded. This permanently changes the nature of the surface. Chemisorption of collectors is highly selective, as the chemical bonds are specific to particular atoms.

Physisorption

In physisorption, ions or molecules from solution become reversibly associated with the surface, attaching due to electrostatic attraction or van der Waals bonding. The physisorbed substances can be desorbed from the surface if conditions such as the pH or the composition of the solution changes. Physisorption is much less selective than chemisorption, as collectors will adsorb on any surface that has the correct electrical charge or degree of natural hydrophobicity.

Nonionic Collectors

Hydrocarbon oils, and similar compounds, have an affinity for surfaces that are already partially hydrophobic. They selectively adsorb on these surfaces and increase their hydrophobicity. The most commonly floated naturally hydrophobic material is coal. The addition of collectors such as no. 2 fuel oil and kerosene significantly enhances the hydrophobicity of the coal particles without affecting the surfaces of the associated ash-forming minerals. This improves the recovery of

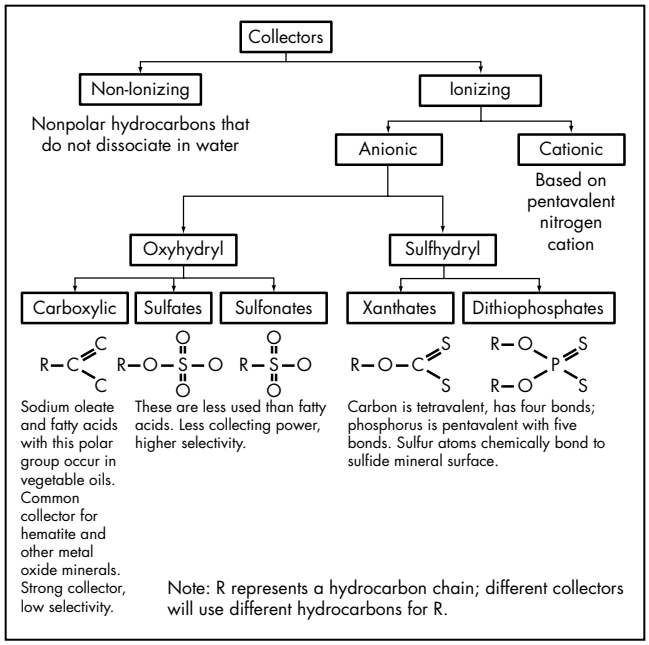

Figure 14.5-7 Basic collector types

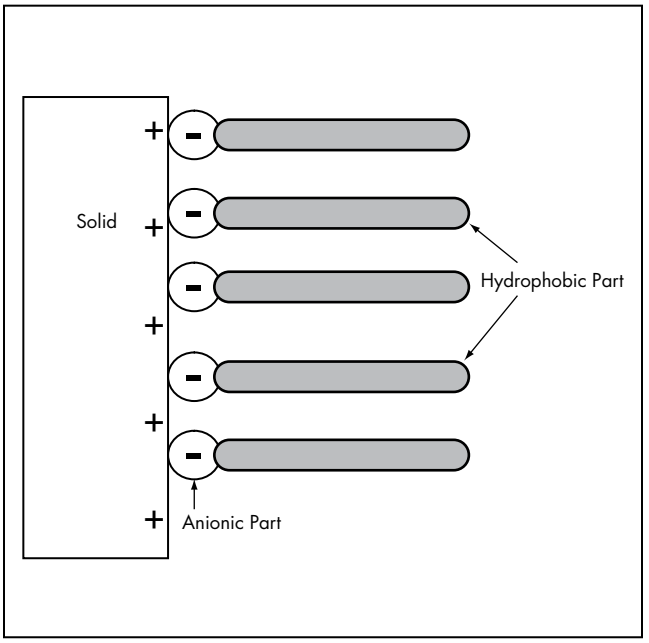

Figure 14.5-8 Adsorption of anionic collector onto a solid surface

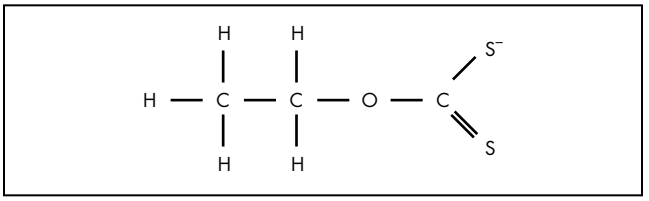

Figure 14.5-9 Structure of a typical xanthate collector (ethyl xanthate)

the coal and increases the selectivity between coal particles and mineral matter. Fuel oil and kerosene have the following advantages over specialized collectors for froth flotation:

- They have a low enough viscosity to disperse in the slurry and spread over the coal particles easily.
- They are very low cost compared to other compounds that can be used as coal collectors.

In addition to coal, it is also possible to float naturally hydrophobic minerals such as molybdenite, elemental sulfur, and talc with nonionic collectors. Nonionic collectors can also be used as "extenders" for other collectors. If another, more expensive collector makes a surface partially hydrophobic, adding a nonpolar oil will often increase the hydrophobicity further at low cost.

Anionic Collectors

Anionic collectors are usually weak acids or acid salts that ionize in water, producing a collector that has a negatively charged end that will attach to the mineral surfaces and a hydrocarbon chain that extends out into the liquid, as shown in Figure 14.5-8. The anionic portion is responsible for the attachment of the collector molecule to the surface, while the hydrophobic part alters the surface hydrophobicity.

Anionic collectors for sulfide minerals. The most common collectors for sulfide minerals are the sulfhydryl collectors, such as the various xanthates and dithiophosphates.

Xanthates are most widely studied and commonly used, and they have structures similar to what is shown in Figure 14.5-9. Xanthates are highly selective collectors for sulfide minerals, as they chemically react with the sulfide surfaces and do not have any affinity for the common nonsulfide gangue minerals (Crozier 1992). The $OCSS^-$ group attaches irreversibly to the sulfide mineral surface. Using xanthates with longer hydrocarbon chains tends to increase the degree of hydrophobicity when they adsorb on the surface.

There are a wide variety of other sulfhydryl collectors (Thompson 2002; Bulatovic 2007), which have somewhat different adsorption behaviors so they can be used for some separations that are difficult using xanthates. These include the following:

- *Dithiophosphates* have greater selectivity against pyrite than do xanthates, and some of these can collect liberated grains of gold. They are also useful in lead sulfide, zinc sulfide, and silver sulfide flotation.
- *Thionocarbamates* selectively float copper sulfides from pyrite at alkaline pH, and they work well for copper sulfides that tend to grind into the slime fraction, such as chalcocite.
- *Dithiophosphinates* are even more selective against pyrite than dithiophosphates, and they are particularly useful for complex polymetallic ores. Although they are selective, they are not particularly strong collectors (produce low levels of hydrophobicity), and so they are often used in combination with other collectors.
- *Trithiocarbonate* has a very high selectivity against pyrite in copper ore flotation.
- *Mercaptobenzothiazole* has improved the recovery of tarnished or semi-oxidized copper and zinc sulfides. It is often used in combination with xanthates.

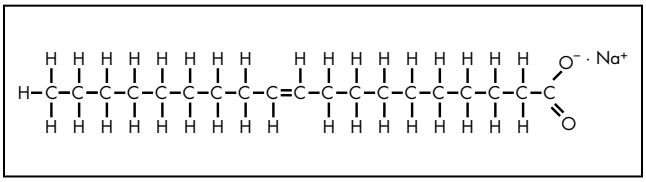

Figure 14.5-10 Structure of oleic acid, a very commonly used anionic collector

- *Mercaptans* can be used in copper flotation, but they are not very popular because of their strong, unpleasant odor.
- *Xanthogen formates* float both copper sulfides and metallic copper, and they have been used to recover both cement copper and precipitated copper sulfide from acid pulps.
- *Monothiophosphates* have strong collecting power for sulfide minerals at pH values as low as 2.0, and they can be used in combination with dithiophosphates at more alkaline pH.

Anionic collectors for oxide minerals. The collectors available for the flotation of oxide minerals (oxyhydryl collectors) are not as selective as the collectors used for sulfide mineral flotation because they attach to the surface by electrostatic attraction rather than by chemically bonding to the surface. As a result, there is some collector adsorption onto the minerals that are not intended to float.

The most widely used oxyhydryl collectors are the carboxylates, with a typical example being the fatty acid sodium oleate, the sodium salt of oleic acid, which has the structure shown in Figure 14.5-10. Numerous other fatty acids can also be used as collectors; these differ from oleic acid mainly in their chain length and their degree of saturation. The anionic group responsible for attaching all of these reagents to the mineral surface is the carboxyl group, which dissociates in water to develop a negative charge. The negatively charged group is then attracted to positively charged mineral surfaces.

Because particles that are immersed in water develop a net charge due to exchanging ions with the liquid, it is often possible to manipulate the chemistry of the solution so that one mineral has a strong positive charge while other minerals have a charge that is either only weakly positive or is negative. In these conditions, the anionic collector will preferentially adsorb on the surface with the strongest positive charge and render them hydrophobic.

Other oxyhydryl collectors include the following (Bulatovic 2007):

- **Alkyl sulfates:** Alkyl sulfates are derived from sulfuric acid and are essentially a sulfate ion with a hydrocarbon group attached to one of the oxygens ($R\text{-}O\text{-}SO_3^-$). They are not much studied as flotation reagents, and because of this their industrial application is limited. Alkyl sulfates are used for flotation of sulfate minerals such as barite ($BaSO_4$), celestite ($SrSO_4$), gypsum ($CaSO_4 \cdot 2H_2O$), and anhydrite ($CaSO_4$).
- **Sulfonates:** These collectors are similar to alkyl sulfates, except that the hydrocarbon group replaces one of the oxygens from the sulfate ion and attaches directly to the sulfur ($R\text{-}SO_3^-$). They are generally manufactured in a poorly controlled way by treating petroleum fractions with sulfuric acid and separating the sulfonates from the acid sludge produced. They are poorly chemically characterized, and they are not much studied as flotation reagents, although they have been available from Cytec Industries.
- **Hydroxamates:** Belonging to the group of "chelating collectors," hydroxamates have structures such as those shown in Figure 14.5-11. These are intended to attach to ions on mineral surfaces at multiple points, with the objective of being more selective than other oxyhydryl collectors. They have been investigated as collectors for malachite, bastnaesite, titanates, and pyrochlore.
- **Sulfosuccinamates:** Derived from carboxylic and succinic acids, the sulfosuccinamates can be considered to be a hybrid of the fatty acid collectors and the sulfonate collectors, with active groups such as shown in Figure 14.5-12. The presence of multiple carboxyl groups and additional sulfonate groups gives them greater collecting power, at some cost to the selectivity. They are used for flotation of cassiterite and monazite.
- **Phosphonic acid:** A typical structure of styrene phosphonic acid is given in Figure 14.5-13, which serves as a basis for a range of collectors that have recently been developed for the flotation of cassiterite, ilmenite, rutile, and pyrochlore.
- **Phosphoric acid esters:** This family of collectors consists of a phosphate core with one or more attached hydrocarbon groups, as shown in Figure 14.5-14. Collectors of this group have been developed for the flotation of apatite, scheelite, ilmenite, rutile, perovskite, zircon, cassiterite, and pyrochlore.

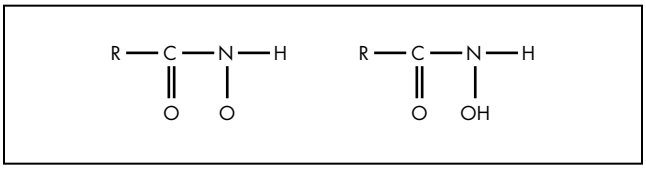

Figure 14.5-11 Typical hydroxamate structures

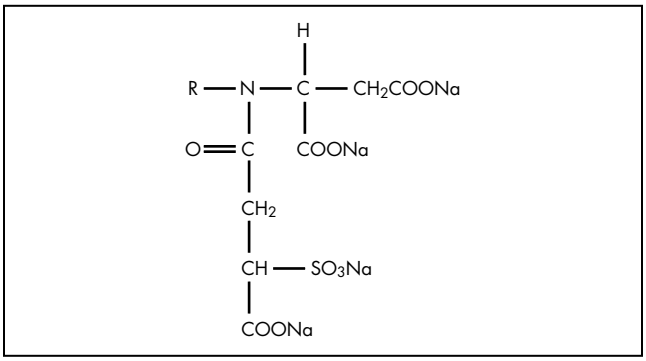

Figure 14.5-12 Active group of sulfosuccinamate

Cationic Collectors

Cationic collectors use a positively charged amine group (Figure 14.5-15) to attach to mineral surfaces. Because the amine group has a positive charge, it can attach to negatively charged mineral surfaces. Cationic collectors therefore have essentially the opposite effect from anionic collectors, which

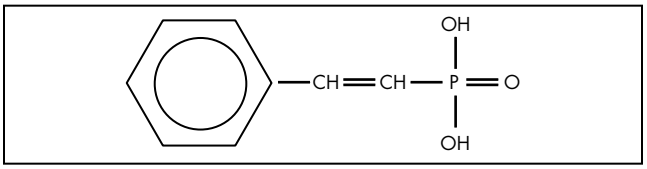

Figure 14.5-13 Styrene phosphonic acid structure

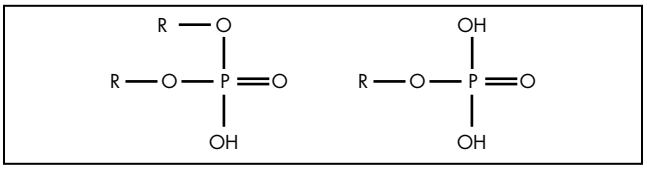

Figure 14.5-14 Structure of dialkylphosphoric acid and alkylphosphoric acid

attach to positively charged surfaces. Cationic collectors are mainly used for the flotation of silicates and certain rare-metal oxides and for the separation of potassium chloride (sylvite) from sodium chloride (halite).

Frothers

Frothers are compounds that act to stabilize air bubbles so that they will remain well dispersed in the slurry and will form a stable froth layer that can be removed before the bubbles burst. The most commonly used frothers are alcohols, particularly methyl isobutyl carbinol (MIBC), or 4-methyl-2-pentanol (a branched-chain aliphatic alcohol), or any of a number of water-soluble polymers based on propylene oxide, such as polypropylene glycols. The polypropylene glycols in particular are very versatile, and they can be tailored to give a wide range of froth properties. Many other frothers are available, such as cresols and pine oils, but most of these are considered obsolete and are not as widely used as they once were. Some work has also been done using saltwater (particularly seawater) as the frothing agent, and the process has been used industrially in Russia (Klassen and Mokrousov 1963; Tyurnikova and Naumov 1981).

Function of Frothers

Klimpel (1995) found that the use of different frothers produced changes in the flotation rate and recovery values in coal flotation and reached the following conclusions:

- When frother dosage was held constant while collector dosage was increased, it was found that the flotation rate increased to a maximum and then decreased. This was observed for all frother types and all particle size fractions. The difference between the frother families studied was that the collector dosage that produced the most rapid flotation rate was different.
- The finest (–88 μm) and coarsest (+500 μm) particles tended to float more slowly than the intermediate-size particles for all of the frother types.
- Changes in flotation rates were due to changes in the coal particle size and to changes in the frother/collector dosage. Although the contribution of particle size was generally more significant, the reagent dosage effect provides a useful means for adjusting the flotation rate in the plant.
- With aliphatic alcohol frothers, the flotation rate maximum was much more pronounced than for the propylene oxide (PO) and combined propylene oxide/alcohol (PO-alcohol adduct) frothers.
- Increasing the frother dosage to increase recovery always leads to less selective flotation, regardless of frother type.
- The PO and PO-alcohol adduct frothers are more powerful recovery agents than alcohol frothers, and they should therefore be used at lower dosages.
- Overdosing with alcohol frothers leads to a slower flotation rate, because excesses of these frothers will lead to eventual destabilization of the froth. This effect does not occur with the PO and PO-alcohol frothers, and therefore overdosing with these frothers leads to high recovery but poor selectivity.
- PO frothers with molecular weights of 300 to 500 are optimal for coal recovery.
- Alcohol frothers tend to be more effective for fine-particle recovery than for coarse-particle recovery. To recover coarse particles, the alcohol frother and the hydrocarbon collector dosages should both be high. The alcohol will still provide reasonable selectivity at these high dosages.
- The high-molecular-weight PO-based frothers are more effective for coarse-particle flotation than the alcohol or low-molecular-weight PO frothers, but they also have a lower selectivity. For both good coarse-particle recovery and good selectivity, the PO frothers should be used at low dosages, with low collector dosage as well. The PO-alcohol adduct frothers are even more effective for coarse-particle recovery, and they need to be used at even lower dosages.
- The optimal frother for high recovery with good selectivity will often be a blend of members of the various frother classes examined. It is reported that such frother blending will give enough benefit to be worth the effort in approximately half of all coal flotation operations.
- Neither the alcohol nor PO-based frothers will change the shape of the grade–recovery curve. Changes in frother type and dosage simply move the flotation results along the curve. Similarly, changes in hydrocarbon collector dosage also mainly move the performance along the grade–recovery curve.
- For medium- and coarse-coal size fractions (–0.5 mm), the total gangue recovered is linearly related to the total coal recovered. It is only for the finest particles (–50 μm) that the gangue recovery increases nonlinearly with increasing coal recovery.
- When floating coals with a broad particle size range, the majority of the gangue reaching the froth is from the finer particle size fractions.
- As the rate of coal flotation increases, the rate of gangue flotation increases proportionately. This is typical of a froth-entrainment process acting on the gangue.

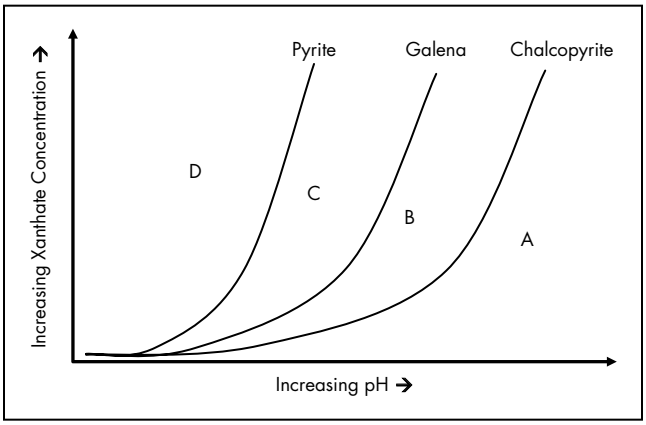

Figure 14.5-16 pH response curves for sulfhydryl collector adsorption on different sulfide minerals

Synthetic and Natural Frothers

The frothers originally used were natural products such as pine oil and cresylic acid. These are rich in surface-active agents that stabilize froth bubbles and are effective frothers. As natural products, they are not pure chemicals, but instead contain components that are effective frother and others that are weak collectors. Although this can have the advantage of reducing the amount of collector that needs to be added separately, it introduces some problems with process control. If the frother is also a collector, then it becomes impossible to alter the frothing characteristics and the collecting characteristics of the flotation operation independently.

Synthetic frothers, such as the alcohol-type and polypropylene glycol-type frothers, have the advantage that their effectiveness as collectors is negligible. It is therefore possible to increase the frother dosage without also changing the quantity of collector in the system. This in turn makes the flotation process much easier to control.

Modifiers

Modifiers are chemicals that influence the way that collectors attach to mineral surfaces. They may either increase the adsorption of collector onto a given mineral (activators), or prevent collector from adsorbing onto a mineral (depressants). Importantly, just because a reagent is a depressant for one mineral/collector combination, it does not necessarily follow that it is a depressant for other combinations. For example, sodium sulfide is a powerful depressant for sulfide minerals being floated with xanthate, but it does not affect flotation when sulfide minerals are floated with the collector hexadecyl trimethyl ammonium bromide.

pH Control

The simplest modifiers are pH-control chemicals. The surface chemistry of most minerals is affected by the pH. For example, minerals in general develop a positive surface charge under acidic conditions and a negative charge under alkaline conditions. Because each mineral changes from negatively charged to positively charged at some particular pH, it is possible to manipulate the attraction of collectors to their surfaces by pH adjustment. Other, more complex effects are due to pH that change the way that particular collectors adsorb on mineral surfaces.

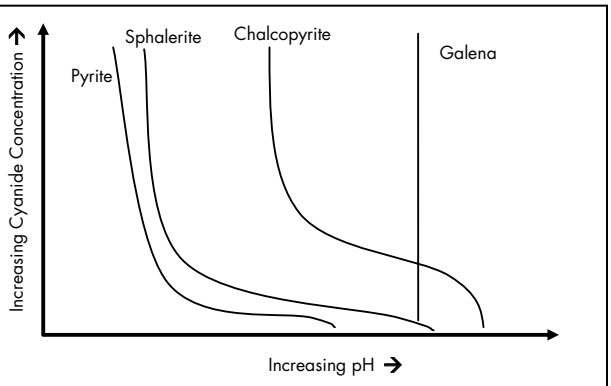
Sulfhydryl collectors such as xanthate ions compete with hydroxide ions (OH^-) to adsorb on mineral surfaces, and so adsorption is a function of pH. This makes it possible for sulfhydryl collectors to be used to progressively separate specific minerals. The pH where the xanthate ion wins the competition with OH^- depends both on the concentration of xanthate in solution and on the specific sulfide mineral present, as shown in Figure 14.5-16.

The curves in Figure 14.5-16 mark the boundaries where the given mineral becomes sufficiently hydrophobic to float. Both xanthates and dithiophosphates exhibit curves of this form, with different pH values and concentrations for each type of collector (Fuerstenau et al. 1985). For example, assume a mixture of pyrite (FeS_2), galena (PbS), and chalcopyrite ($CuFeS_2$). From Figure 14.5-16, if the pH and xanthate concentrations are in Region A, then xanthate will not be adsorbed on any of the minerals, and therefore none of the minerals will be floated. However, if the pH and xanthate concentrations are altered to move into Region B, only chalcopyrite becomes hydrophobic and consequently floats. In Region C, both chalcopyrite and galena will float, and in Region D, all three minerals will float. It is therefore possible to progressively lower the pH to float chalcopyrite first, then galena, and then pyrite, producing concentrates for each mineral and leaving behind any nonfloatable silicate gangue minerals.

Acids. The acids used are generally those that give the greatest control of pH at the lowest cost, with sulfuric acid being the most popular. A key point to bear in mind is that the anion of the acid can potentially have effects of its own that are quite separate from the lowering of the pH. Therefore, acids other than sulfuric acid are useful in some cases.

Alkalis. As with acids, the most popular alkalis are those that are cheapest, with the lowest-cost alkali generally being lime (CaO or $Ca(OH)_2$). However, the calcium ion often interacts with mineral surfaces to change the flotation behavior. In some cases the calcium ions have beneficial effects, while in other cases they change the flotation in undesirable ways. It may therefore be necessary to use sodium-based alkalis, such as sodium hydroxide (NaOH) or sodium carbonate (Na_2CO_3), because the sodium cation generally does not have any significant effect on the particle surface chemistries.

Activators



Activators are specific compounds that make it possible for collectors to adsorb onto surfaces that they could not normally attach to. A classic example of an activator is copper sulfate as an activator for sphalerite (ZnS) flotation with xanthate collectors (Fuerstenau et al. 1985). When untreated, xanthate cannot attach to the sphalerite surface because it forms a zinc-xanthate compound that quickly dissolves, as shown in the following reaction:

$$ZnS(s) + \text{xanthate} \rightarrow S(s) + \text{Zn-xanthate (aq)}$$

The surface of the sphalerite can be activated by reacting it with a metal ion that does not form a soluble xanthate, such as soluble copper from dissolved copper sulfate, as shown in the following reaction:

$$ZnS(s) + CuSO_4(aq) \rightarrow CuS(s) + ZnSO_4(aq)$$

This forms a thin film of copper sulfide on the sphalerite surface, which allows for stable attachment of the xanthate, rendering the sphalerite particle hydrophobic and floatable. Other metals such as silver and lead can also be used to activate zinc,

Note: The flotation of galena (PbS) is unaffected by the presence of cyanide, probably due to lead being less readily complexed by cyanide than are iron, zinc, or copper.

Figure 14.5-17 Effect of cyanide depressant on flotation of minerals as a function of pH

but the copper element is cheaper than silver and is less toxic than lead.

It is also possible to adsorb specific ions onto the surface that can promote attachment of the collector. For example, silica (SiO_2) normally has a strongly negative surface charge at approximately neutral pH, and therefore it has little affinity for anionic collectors such as oleic acid. However, calcium ions specifically adsorb onto silica surfaces, and the negative charge of the calcium ions can actually reverse the surface charge, making it positive. It is then possible for the anionic collectors to electrostatically attach to the calcium-activated silica surface.

Depressants

Depressants have the opposite effect of activators by preventing collectors from adsorbing onto particular mineral surfaces. Their typical use is to increase selectivity by preventing one mineral from floating while allowing another mineral to float unimpeded.

Cyanide. Cyanide (CN^-) is a particularly useful depressant in sulfide mineral flotation, as can be seen in Figure 14.5-17. Its activity is believed to be due to its ability to complex with, and in some cases dissolve, a number of metal ions, preventing them from attaching to the xanthate molecules. In particular, it is a strong depressant for pyrite (FeS_2) and can be used to "deactivate" sphalerite that has been activated by copper ions in solution (Fuerstenau et al. 1985).

Lime. Lime is added as either CaO or $Ca(OH)_2$, and when it dissolves it contributes calcium ions that can adsorb onto mineral surfaces. In combination with its strong alkaline nature, this makes it particularly useful in manipulating sulfide flotation. It is less useful in oxide mineral flotation because it can activate the flotation of silica by anionic collectors, causing it to float along with the other oxide minerals.

Organic depressants. A large number of organic compounds are useful as flotation depressants. These tend to be soluble polymers (such as starch polysaccharide) that selectively become adsorbed and coat mineral surfaces, thereby preventing a collector from attaching. An example of this is in the "reverse flotation" of silica from iron ore, where the silica tailings are floated using a cationic collector at a pH of 8.5 to 11, leaving behind the iron oxide minerals. Starch acts as a depressant for iron oxide in this process, preventing it from being floated by the cationic collector.

Recovery of Gangue Particles in Flotation: Entrainment or Hydrophobicity?

Some gangue material is always carried out of the slurry in the froth. For example, in the flotation of coal, a portion of the ash-forming minerals and pyrite will be carried into the froth along with the coal. It is commonly believed that this gangue mineral can often be prevented from floating if the correct depressant can be discovered. In the case of coal, more than 42 chemicals have been reported by investigators as being capable of depressing pyrite in coal flotation, and yet none of them have ever been useful industrially. This is because, in most cases, the pyrite was not truly hydrophobic (Kawatra and Eisele 1992, 2001).

In a froth flotation machine, there are two ways that a particle can reach the froth layer. It can be carried into the froth by attachment to an air bubble (true flotation), or it can be suspended in the water trapped between the bubbles (entrainment). Although true flotation is selective between hydrophobic and hydrophilic particles, entrainment is nonselective, and therefore entrained particles are just as likely to be gangue minerals as they are to be the valuable mineral. If particles are sufficiently coarse, then they settle rapidly enough that they are not carried into the froth by entrainment. As they become finer, particles settle more slowly and so have more time to become entrapped in the froth, and consequently they have less of a tendency to drain away. Clay particles in particular, which are only a few micrometers in size, are very easily entrained. For particles that are less than a few micrometers in size, their rate of recovery into the froth by entrainment is equal to the rate of recovery of water into the froth. For example, if 20% of the water entering a flotation cell is carried into the froth, then up to 20% of the fine particles entering the cell will probably be entrained. The entrainment of coarser particles will be less than 20% due to their greater ability to drain from the froth.

In addition to the entrained particles, gangue is carried into the froth by being physically locked to the floatable particles. In the case of coal, much of the pyrite consists either of submicrometer pyrite grains that are never liberated from the coal, or pyrite particles with surfaces consisting primarily of coal. These will therefore behave as if they were coal particles. The recovery of entrained particles can only be reduced by lowering the fraction of the water recovered into the froth.

The recovery of locked particles can only be changed significantly by either grinding to a finer size to improve liberation, or by rejecting the locked particles along with the least-floatable liberated particles, which sacrifices recovery of the valuable mineral. Depressant chemicals are not useful in either of these cases, as they are only intended for preventing the hydrophobic bubble attachment and true flotation of particles. Before deciding to use a depressant, it is therefore important to first determine whether the particles to be depressed are actually being recovered by true flotation in the first place or whether there are other causes.

EQUIPMENT

In addition to controlling the chemistry, flotation requires a machine for mixing and dispersing air throughout the mineral slurry while removing the froth product (Nelson et al.

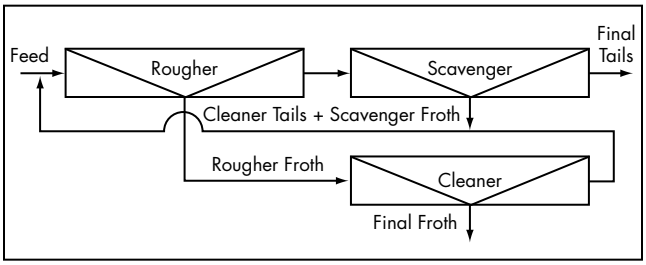


Figure 14.5-18 One configuration for a rougher/cleaner/scavenger flotation circuit

2009). These individual machines are then connected to form a flotation circuit to fully clean the product.

Conventional Cells

Conventional flotation cells consist of a tank with an agitator designed to disperse air into the slurry, as was previously shown schematically in Figure 14.5-6. They differ in the exact location and design of the rotor, the means of air induction, and the size/shape of the tank (Nelson et al. 2009). Considerable design effort has gone into optimizing the hydrodynamics of the system and ensuring that

- The suspended particles do not settle out into dead zones;
- The residence time of slurry throughout the cell is uniform;
- Solid particles are effectively brought in contact with air;
- Air is evenly dispersed throughout the cell;
- The froth layer is collected efficiently without excessive losses of attached particles back into the pulp;
- The pulp level can be accurately controlled;
- Maintenance of the machines is simplified; and
- Power consumption to achieve all of these goals is minimized.

The advances in understanding of flotation cell hydrodynamics has enabled the development of very large machines, with the recent "Supercell" design having volumes as large as 300 to 350 m^3 (FLSmidth Minerals 2009; Nelson et al. 2009).

Flotation cells are relatively simple machines with ample opportunity for particles to be carried into the froth along with the water making up the bubble films (entrainment) or for hydrophobic particles to break free from the froth and be removed along with the hydrophilic particles. Therefore, it is common for conventional flotation cells to be assembled in a multistage circuit, rather than using single flotation cells in isolation. Typically a "rougher" cell bank is used to make an initial, rapid separation of the valuable minerals from the gangue. The valuable mineral concentrate is often then reprocessed in the "cleaner" cells to remove gangue mineral particles that were misplaced into the concentrate. Similarly, "scavenger" cells are used to reprocess the gangue mineral product from the rougher to recover valuable minerals from the tailings. These different cell banks can be arranged in configurations such as the one shown in Figure 14.5-18, although, depending on the nature of the separation, there may be more or fewer stages of cleaners or scavengers added.

The use of a multistage circuit for froth flotation allows a great deal of flexibility, as the recirculation of material between cells can be adjusted to fit the specific needs of the material being processed. One concern is that a large number of flotation cells are typically necessary, which can use a great deal of the available plant floor space.

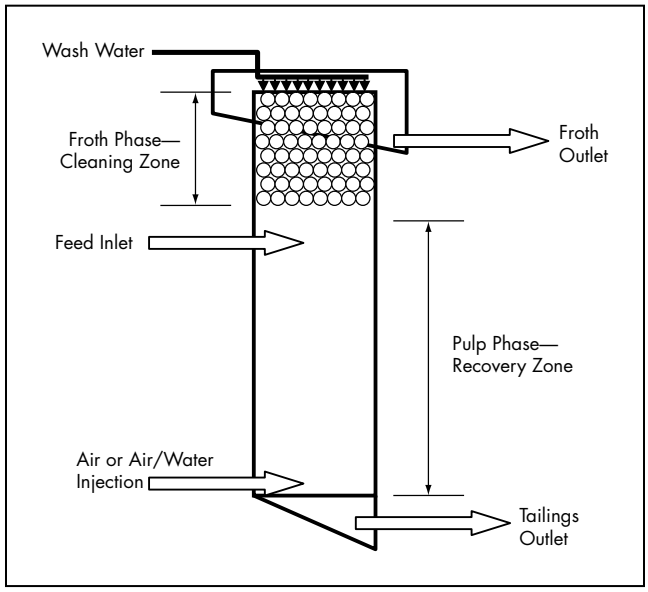

Figure 14.5-19 Flotation column

Flotation Columns

Flotation columns provide a means for improving the effectiveness of froth flotation using a single machine, which can be very useful if floor space is at a premium (Eberts 1986). A column essentially performs as if it were a multistage flotation circuit arranged vertically (Degner and Sabey 1988) with slurry flowing downward while the air bubbles travel upward, producing a countercurrent flow. The first flotation machine design to use a countercurrent flow of slurry and air was developed by Town and Flynn in 1919. It was not until the work of Boutin and Tremblay in the early 1960s that a new generation of countercurrent columns was developed that ultimately became industrially successful (Rubinstein 1995).

A typical flotation column schematic is shown in Figure 14.5-19. The basic principle of column flotation is the use of a countercurrent flow of air bubbles and solid particles. This is achieved by injecting air at the base of the column and feed near the midpoint. The particles then sink through a rising swarm of very small air bubbles.

Countercurrent flow is accentuated in most columns by the addition of wash water at the top of the column, which forces all of the water that entered with the feed downward to report to the tailings outlet. This flow pattern is in direct contrast to that found in conventional cells, where both the air and the solid particles are driven in the same direction. The result is that columns provide improved hydrodynamic conditions for flotation, and thus generally produce a cleaner product while maintaining high recovery and low power consumption. The performance differences between columns and conventional cells may best be described in terms of the following factors: collection zone size, particle–bubble contact efficiency, and fines entrainment (Kawatra and Eisele 1987).

The collection zone is the region where particle–bubble contact occurs, and it differs greatly in size between column and conventional flotation. In conventional cells, contact occurs primarily in the region surrounding the mechanical

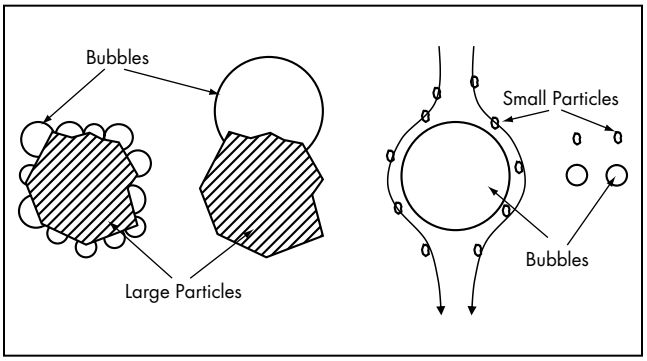

Figure 14.5-20 Effects of relative bubble and particle sizes on froth flotation

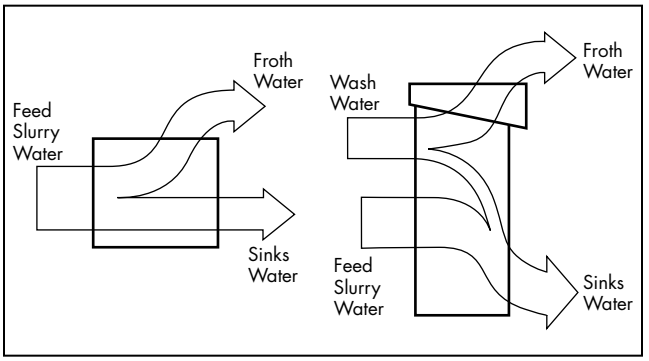

Figure 14.5-21 Effect of wash water on the entrainment of feed into the froth

impeller. The remainder of the cell acts mainly as a storage volume for material that has not yet been through the collection zone. This creates a bottleneck that keeps the flotation rate down. In contrast, flotation columns have a collection zone that fills the entire volume of the machine, so that there are more opportunities for particle–bubble collisions. The reduced level of turbulence needed to achieve a good rate of recovery in columns also reduces the tendency of coarse particles to be torn away from the bubbles that they attach to. Therefore, columns are more effective for floating coarser particles (Kawatra and Eisele 2001).

Columns exhibit higher particle–bubble contact efficiency than conventional machines due to the particles colliding head-on with the bubbles. As a result, the energy intensity needed to promote contact is less and, therefore, power consumption is reduced.

A second beneficial effect in certain types of flotation columns is the reduction of bubble diameter (Yoon and Luttrell 1986). As bubble diameter is reduced, the flotation rate of both the coarser and finer particles is improved. The effects producing the improvement are illustrated in Figure 14.5-20. Coarse particles can attach to more than one bubble if the bubbles are small and the chances of the particle being torn loose and sinking again are therefore reduced. For fine particles, the probability of collision with the bubble is improved if the bubble is small, as then the hydrodynamic forces tending to sweep the particle away from a collision are reduced. The reduction of bubble diameter has the added benefit of increasing the available bubble surface area for the same amount of injected air. Therefore, it is desirable to produce bubbles as fine as possible.

The entrainment of fine waste material in the froth product is a common failing of conventional flotation machines. It results from the phenomena whereby some water is transferred into the froth within the zone surrounding the air bubbles. As a result, fine suspended particles are swept into the froth with this water, even though they are not physically attached to the air bubbles. In most column flotation machines, the entrainment problem is addressed through the use of wash water, as shown in Figure 14.5-21. Where the conventional cell must allow a certain amount of feedwater to enter the froth, the wash water in the column cell displaces this feedwater to the tailings, thus preventing entrained contaminants from reaching the froth. The only drawback to the use of froth washing is that the demand for clean water is increased, which may cause problems in some situations.

In a coal flotation operation, the combined effects of the relatively gentle mixing, the countercurrent flow, and the use of wash water in columns is that, because there is a distance of several meters between the discharge points of the clean coal froth and the gangue tailings, there is a much reduced possibility of coal being misplaced into the tails or of gangue short-circuiting to the froth. The net result is that, depending on the design, a column is typically equivalent to between three and five stages of conventional flotation.

Bubble Generators

The impeller-type mixers that are used in conventional cells are not well suited for use in flotation columns, as they would either need excessively long shafts or rotating seals. In the original flotation column design, bubbles were produced using sintered ceramic air diffusers that produced very fine air bubbles. However, this was found to suffer from plugging problems, particularly in hard water, and for this reason cloth and perforated rubber sheeting alternatives were adopted (Boutin and Wheeler 1967; Dobby et al. 1985). These still tended to require excessive maintenance, and for this reason external bubble generators of various types have been adopted (McKay et al. 1988; Yoon et al. 1990; Davis et al. 1995; Rubinstein 1995). The external bubble generators combine a stream of water with air to produce a mixture of very fine bubbles in water. This mixture is injected into the column. This approach has a number of advantages, including the following:

- The bubble generator is accessible for adjustment and maintenance.
- The column has no porous elements inside that can become clogged or damaged, and so the dispersion of air in the column does not change.
- The bubble generator can be designed to tolerate particulate matter in the water, and so recycle water can be used in the generators.
- External bubble generators can consistently produce very small bubbles in the column.

Axial Mixing Effects

A key issue in flotation column operation is "axial mixing," which is mixing along the vertical axis of the column, as shown in Figure 14.5-22. As the air bubbles rise in the column, they also tend to transfer water to the base of the froth layer. The displaced water then descends again, setting up a strong mixing action. This tendency is greatest if the column is slightly tilted from vertical, as then the bubbles preferentially ascend

on one side while the water descends on the other. This is why it is particularly crucial for flotation columns to be perfectly vertical. The tendency toward axial mixing is also increased if some large bubbles are present, and so performance is optimal if the bubbles are uniformly small in diameter.

Another approach to suppressing axial mixing is the introduction of horizontal baffles made from perforated plates (Kawatra and Eisele 2001). These baffles interrupt the flow of the liquid, as shown in Figure 14.5-22, preventing it from being rapidly carried to the surface or from short-circuiting directly to the tailings. Experiments with horizontal baffles in a flotation column have confirmed that they can greatly improve the operating characteristics of the column without sacrificing capacity, and a sufficiently open baffle design is highly resistant to plugging by coarse particles or debris. Overall, flotation columns generally have superior performance to conventional flotation cells. However, fundamentally, they require automatic control, especially for pulp level control, as they cannot utilize simple tailings overflow weirs, which are commonly used in conventional flotation cells.

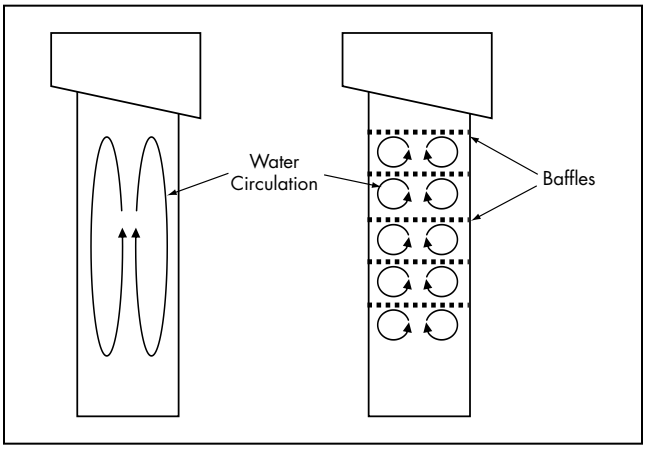

Figure 14.5-22 Comparison of axial mixing in regular columns and horizontally baffled columns

APPLYING LABORATORY RESULTS TO PLANT EQUIPMENT SELECTION

Laboratory Reagent Screening

When the mineralogy of the ore for a new project has been determined, potential reagents for an ore can be based on a review of the relevant literature for similar ores. The sample to be used in laboratory test work should be prepared to minimize the quantity of slimes produced, with a combination of roll crushing and rod milling generally producing a good flotation feed. Because many flotation reagents have a limited shelf life, fresh reagents should be obtained (Thompson 2002).

Flotation experiments to evaluate reagent schemes are generally of two types. Single- and multiple-stage cleaning tests are used to evaluate the relative performance of different reagent types and dosages and show how cleanly the valuable minerals and gangue can be separated. Single-stage "rougher" kinetic flotation tests are used to establish grade–recovery relationships, which are necessary for calculation of residence times and equipment sizes.

Release Analysis

It is often useful to be able to determine the theoretical maximum amount of upgrading that can be achieved by froth flotation, given a specific ore and a particular set of reagents. One approach to this is "release analysis," which is carried out by progressively refloating froth products to collect only the particles that are fully hydrophobic. The procedure is illustrated in Figure 14.5-23.

Release analysis is used for determining the maximum grade of material that can be produced by a froth flotation process. Each stage of flotation removes more of the entrained and poorly floatable particles from the froth, until the final froth product consists only of the most strongly floatable material. It can be considered to be roughly analogous to a heavy-media washability test, except that instead of measuring the separating density that is needed to produce a given grade and recovery, it measures the number of flotation stages needed to achieve a given grade and recovery. It is therefore a valuable method for characterizing the inherent floatability of a particular ore and can be used to produce unbiased comparisons of the relative difficulty of upgrading different ores by froth flotation.

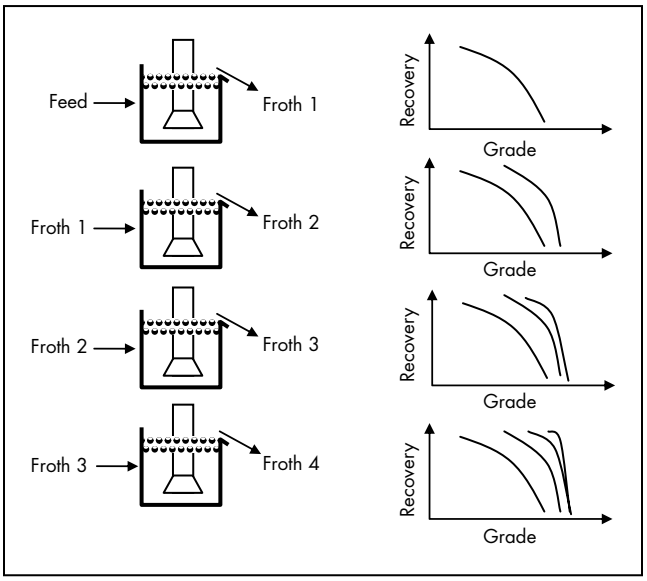

Figure 14.5-23 Release analysis method

Release analysis also provides a means for comparing the performance of conventional flotation with column flotation. The product from release analysis is typically much higher-grade than the product from a single stage of conventional flotation. On the other hand, a correctly operating flotation column will typically provide a product grade that is comparable to the grade of the product from the final stages of release analysis.

Laboratory and Plant Flotation Kinetics

Laboratory kinetic flotation experiments are best carried out in a flotation cell that allows froth to be collected in a reproducible manner over specific time intervals while maintaining a constant level of pulp in the cell. This can be accomplished by use of mechanical froth removal, and a mechanism to continuously provide makeup water to replace the water removed in the froth and prevent the pulp level from dropping and increasing the froth depth in the course of the experiment (Kawatra and Eisele 2001). The time intervals chosen for froth collection will obviously depend on the flotation rate of the mineral, as it is desirable to have at least

five froth increments in order to be able to determine the kinetics properly.

To compare froth flotation experiments in the laboratory with operations in the plant it is necessary to take into account the differences in the way that the two types of cells are operated. This is most easily done by carrying out kinetic experiments to measure the recovery of material to the froth as a function of time.

The following is a simple kinetic equation (Arbiter and Harris 1962):

$$\ln(C_o/C) = kt$$

where

C_o = concentration of the valuable material at the start of the test
C = concentration of valuable mineral in the pulp at time t
k = rate constant

Assuming that all particles of a particular mineral have identical floatabilities, a plot of $\ln(C_o/C)$ versus t will produce a straight line with a slope equal to the rate constant. The higher the value of the rate constant, the higher the collecting power of the reagent used, which provides a means for comparing different reagents in the processing of a particular mineral.

The following equation is a sometimes more useful flotation kinetics model, and it includes a term for both flotation rate and ultimate flotation recovery and takes into account the fact that the particles exhibit a range of hydrophobicities and floatabilities (Klimpel 1995):

$$r = R\{1 - [1 - \exp(-Kt)]/Kt\}$$

where

r = total weight of component recovered at time t
t = time
K = rate constant
R = ultimate theoretical weight recovery at "infinite" time

This model takes into account the fact that the hydrophobic particles vary in size and degree of hydrophobicity, and it is therefore more appropriate than conventional reaction kinetics relationships that are intended to apply to systems of identical molecules. It is particularly useful for correlation of laboratory results with plant results. In conventional laboratory test work, it is common for R to be the most important one in determining the flotation performance, because laboratory tests are often run until all floatable material is recovered. In the plant, it is common for the rate constant, K, to be the most important factor. This is because it is too expensive to provide enough cell volume to recover all material that does not float in a reasonable time. Because of this difference, the results of laboratory studies can be very poor predictors of plant performance. To correct this, it is best to run timed flotation laboratory tests that can produce kinetic data, so that the R and K performances can be determined. Then, based on the residence time of the plant-scale units, it can be determined whether the plant performance is being dominated by kinetics, K, or by the ultimate recovery, R (Klimpel 1995).

Flotation Cell Selection

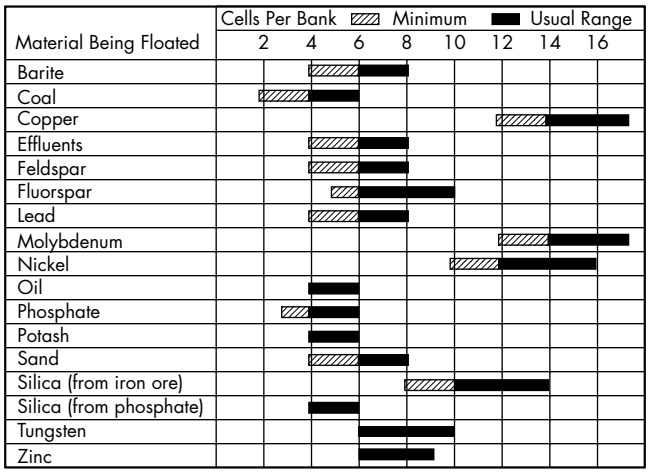
Flotation cells for use in a plant must be selected based on laboratory and pilot-scale data. Laboratory tests are usually carried out as batch experiments and are generally quite straightforward, although it is necessary to keep the following points in mind:

- The pulp must be agitated sufficiently to keep all particles in suspension.
- It is often necessary to condition the reagents with the minerals for a period of time to ensure good coverage with collector.
- In many cases, adding frother in stages along with makeup water may be necessary to keep the pulp level and froth depth constant.
- The capacity of the cell increases as the percent solids increases, and because of this the best process economics are achieved at the highest percent solids practical.

The following is the most important information obtained from this test work:

- **Optimum grind size of the ore:** This depends not only on the liberation characteristics of the ore but also on the floatability. Excessively coarse particles will be too large to be levitated by attached bubbles, and excessively fine particles will float poorly due to not striking the bubble surfaces, oxidation effects, or other problems. The coarsest material that can be floated is normally around 300 μm, whereas the finest particles are around 5 μm.
- **Reagent addition:** Quantity of reagents needed and the appropriate points in the circuit to add each reagent must be determined.
- **Optimum pulp density:** This is necessary for determining the size and number of flotation cells for a given capacity.
- **Flotation time needed to reach desired recovery:** It is important to be aware that a longer time is required for flotation in the plant than in the laboratory, mainly because of the increased time needed for selected particles to ascend through the large equipment. Typical comparative flotation times for different minerals are shown in Table 14.5-1.
- **Variability of the ore:** Because ore properties vary from one location to another in the mine, it is critical to run experiments with ore from several locations.
- **Corrosive and wear properties of the ore:** This information is needed for selecting appropriate materials of construction for the plant equipment.
- **Circuit design:** The type of circuit, the number cells per bank, the number of flotation stages, and the appropriate locations for recirculation of intermediate products must be determined. The number of cells per bank depends on the flotation characteristics of the material being floated. Typical practice can be as little as three or as many as 17 cells per bank, as shown in Figure 14.5-24.

Example Calculation



Problem. As an example of sizing flotation cells, consider the following copper ore:

- Specific gravity of dry ore = 2.7
- Optimum percent solids in laboratory flotation machine = 30%
- Optimum laboratory flotation retention time = 6.5 minutes

Table 14.5-1 Comparison of optimum flotation times in the laboratory and in the plant

Material Floating	Flotation Times in Industrial Rougher Flotation Cells, minutes	Usual Laboratory Flotation Times, minutes
Barite	8–10	4–5
Coal	3–5	2–3
Copper	13–16	6–8
Effluents	6–12	4–5
Fluorspar	8–10	4–5
Feldspar	8–10	3–4
Lead	6–8	3–5
Molybdenum	14–20	6–7
Nickel	10–14	6–7
Oil	4–6	2–3
Phosphate	4–6	2–3
Potash	4–6	2–3
Sand (impurities floated)	7–9	3–4
Silica (from iron ore)	8–10	3–5
Silica (from phosphate)	4–6	2–3
Tungsten	8–12	5–6
Zinc	8–12	5–6

Figure 14.5-24 Normal numbers of cells per bank in froth flotation circuits

Assume that the flotation facility will need to process 14,500 t/d of dry ore.

Solution. Using this information, the following can be calculated:

- From Table 14.5-1, the average laboratory flotation time for copper is 7 minutes, and the average plant flotation time is 14.5 minutes.
- The scale-up factor is 14.5/7 = 2.07, and therefore the time needed for flotation in the plant for this particular ore is (6.5)(2.07) = 13.5 minutes.
- A feed rate of 14,500 t/d of dry ore will require a flow of (14,500/1,440 min/d) = 10.07 t/min, and therefore for a 13.5-min residence time, there will need to be (13.5)(10.07) = 136 t of ore retained in the flotation bank.
- The slurry must be 30% (by mass) solids, and therefore, for 136 t of dry ore, there will be (136/0.3) = 453 t of slurry.
- The ore has a specific gravity of 2.7, and therefore the density of the slurry is calculated from the relationship $(100/\rho_{slurry}) = (X/\rho_{solids}) + ((100 - X)/\rho_{water})$, where X is the percent solids, and ρ_{slurry}, ρ_{solids}, and ρ_{water} are the specific gravities of the slurry, solids, and water, respectively.
- Therefore, $(100/\rho_{slurry}) = (30/2.7) + (70/1.0)$, and solving for ρ_{slurry} gives 1.23.
- The total volume of the 453 t of slurry that the cells must hold will be (453/1.23) = 368 m^3. However, when the pulp is aerated, it will consist of approximately 15% air and 85% slurry by volume, so the actual volume of pulp needed will be 368/(0.85) = 433 m^3.
- Cells of 14.15 m^3 (500 ft^3) are a standard size, and therefore the number required if these are used will be 433/14.15 = 30.6 cells (approximately 31 cells).
- Referring to Figure 14.5-24 for copper, between 12 and 17 cells per bank will be required, with 14 to 17 cells being optimum. Two banks of 16 cells would give 32 total cells, which would provide the 31 cells needed with some extra capacity. The cells would then be arranged in the individual banks in accordance with the manufacturer's recommendations.

Design Software

The design of flotation systems is simplified by the use of appropriate design software. Circuit-simulation packages can take data from laboratory test work and can predict the likely performance of a given design of a full-scale circuit. This allows the evaluation of many different arrangements before beginning pilot-scale studies (Collins et al. 2009). This type of software is under active development, so it is necessary to check the current literature to determine what is available at any given time. Such software packages are typically quite expensive and require training to use to their full potential, and they are most effectively used by specialist firms rather than by individual mining companies.

CHAPTER 14.6

Magnetic and Electrostatic Separation

Partha V. Iyer

The two methods of physical separation—magnetic and electrostatic separation—have developed from very early recognition of the forces that they utilize. Initially only low-field-strength permanent magnets and contact electrification were available, and hence the technologies were of limited value. However, as available magnetic field strengths increased, applications widened. Similarly, the introduction of safe high-voltage supplies opened up new electrostatic separation possibilities. Electrostatic separation is now something of a misnomer, as the most effective use of high-voltage electricity for separation involves small current flows.

Magnetic and electrostatic separation techniques have probably always been bracketed together because historically they were used for dry separation of liberated sand-sized mineral particles. They were mainly applied in the final stages of separation and/or upgrade of beach sand and alluvial tin concentrates (Gaudin 1939; Oberteuffer 1974; Knoll 1997; Svboda 1987; Venkatraman et al. 2003; Wills and Napier-Munn 2006).

Dry magnetic and electrostatic separation are most efficient on closely sized material. In the case of electrostatic separation, brief high-intensity drying can be applied to remove surface moisture and thus enhance differences in surface conductivity. In some cases, the magnetic or electrostatic properties of minerals can be modified by surface treatment at sustained high temperatures.

Wet magnetic separation has found major application in the treatment of fines at iron-ore operations. One of its attractions is its ability to handle a much wider and finer size range than dry systems. It is also applied in the cleaning of heavy media suspensions such as ferrosilicon.

Useful peripheral applications include removal of tramp iron from run-of-mine or coarse-crushed material (magnetic) and removal of dust from roaster and smelter off-gases (electrostatic). One particular attraction of both methods of separation is that they normally create few if any environmental problems and may in fact solve some.

Knowledge of magnetic and electrostatic forces dates back at least to the Greek philosopher Thales of Miletus, who lived about 600 BC. Thales knew some of the magnetic properties of the mineral lodestone, and he was also aware that when amber was rubbed with animal fur, the electrostatic charge produced on the amber (or fur) would attract light, nonconducting particles. The first record of magnetic separation of minerals appears to be a patent issued in 1792 to an English experimenter, William Fullarton, that described the concentration of iron ore. About a century later, in 1886, F.R. Carpenter obtained a U.S. patent for electrostatic concentration of ore.

The application of magnetic separators has extended well beyond either removing tramp iron or concentrating materials that are obviously affected by low-rate (and unsophisticated) magnetic fields. The latest developments in material science and magnet technology have allowed high-intensity and high-gradient industrial magnetic separators with field strengths as high as 6 T (60,000 G [gauss]) to be developed. Development of permanent rare-earth magnets and superconducting magnets has opened new markets for magnetic separators.

The electrostatic separator is still the most reliable and economic unit operation for processing beach-sand deposits rich in minerals such as ilmenite, rutile, leucoxene, zircon, and garnet. Increased environmental awareness has promoted the demand for unit operations that process secondary materials. A classic example is the successful use of electrostatic separators to remove plastics from metals. Triboelectrostatic separators, which can successfully separate two nonconductors, are being used in minerals and plastics separation.

REVIEW OF MAGNETIC THEORY

All materials can be classified as follows, based on their magnetic properties:

- *Paramagnetic* minerals are attracted along the lines of magnetic force to points of greater field intensity.
- *Diamagnetic* minerals are repelled along the lines of magnetic force to a point of lesser field intensity.
- *Ferromagnetic* minerals, a special category of paramagnetic materials, have a very high susceptibility to magnetic forces and retain some magnetism (remnant magnetism) after removal from the magnetic field.

Partha V. Iyer, Consultant, Reading, Pennsylvania, USA

Magnetic susceptibilities and electrostatic responses of minerals are provided in Table 14.6-1. In this section, the fundamentals of magnetic separation are introduced without detailed explanations of the physics involved.

Magnetic Force or Flux Density

In an electromagnet, an electric charge in motion sets up a magnetic field in the space surrounding it, and a magnetic field exerts a force on an electric charge moving through it. In fact, all magnetic phenomena arise from forces acting between electric charges in motion. Therefore, flux density B at point P, resulting from current element I of length dl, is as specified by Ampere's law:

$$dB = KI\left[\frac{dl(\sin\theta)}{r^2}\right] \tag{14.6-1}$$

where

B = magnetic flux density, weber/square meter (Wb/m^2)
K = constant of proportionality
I = current element, amperes (A)
l = length of current element, m
θ = angle between current element and radius vector to point P
r = distance to P, m

Magnetic flux density B, or force per pole, is defined as the number of magnetic flux lines per unit area normal to the lines. The unit for magnetic flux is the weber (Wb). The unit for term B is webers per square meter, called a tesla (T). The largest values of magnetic induction that can be produced in the laboratory are about 50 to 60 T (500,000 to 600,000 G).

Industrial high-intensity superconducting separators can reach fields of about 5 T (50,000 G). High-intensity induced-roll dry separators reach values as high as 2 T (20,000 G). Low-intensity wet drum separators for concentration of iron ore have drum-surface field strengths on the order of 0.1 T (1,000 G). However, the magnetic force acting on particles depends not only on the magnetic field B, but also on its gradient dB/dz, where z is the direction of the changing field.

Magnetization

A ferromagnetic material can be magnetized simply by being brought close to a permanent magnet or by passing current through a wire winding around the material. The magnetic state of a body can be defined by (1) stating the magnetization of all points within the body, (2) defining the strength of the magnetic poles, or (3) defining the magnitude of equivalent surface currents.

Coulomb's law for magnets is similar to that for electric charges; that is,

$$F = \frac{1}{4\pi\mu_o} * \frac{m_1 m_2}{r^2} \tag{14.6-2}$$

where

F = force, newtons (N)
μ_0 = permeability of a vacuum ($4\pi \times 10^{-7}$ H/m [henry/meter])
m_1 and m_2 = pole strength, A/m
r = distance, m

Magnetization (or, more completely, the intensity of magnetization M) is the total magnetic moment of dipoles per unit volume, in units of amperes per meter or pole strength m per unit area A.

$$M = \frac{m}{A} \tag{14.6-3}$$

Magnetic Field

The strength H of the magnetic field has the same units as does M (amperes/meter) and can be thought of as the cause of magnetization. It is defined as

$$H = \frac{B}{\mu} \tag{14.6-4}$$

where μ is absolute permeability.

In free space, a magnetic field produces a magnetic force given by $B = \mu_0 H$. However, in most applications the space is filled with some magnetic substance that causes an induced magnetization, $\mu_0 M$. Therefore, the total magnetic flux density B is the vector sum of the flux caused by the magnetic field H and the flux resulting from the magnetization M of the material. For ferromagnetic materials, however, the contribution of M usually dominates B:

$$B = \mu_0(H + M) \tag{14.6-5}$$

Permeability and Susceptibility

Magnetic flux density B, strength H of the magnetic field, and magnetization M can be used to compare the magnetic response of various materials. The ratio M/H is a dimensionless quantity called the *volume susceptibility* or simply *magnetic susceptibility*, χ. Similarly, the ratio B/H is called the *absolute permeability*, μ. The *relative permeability* μ_r is defined as

$$\mu_r = \frac{\mu}{\mu_o} \tag{14.6-6}$$

where

μ_r = relatively permeability
μ = absolute permeability
μ_0 = permeability in a vacuum ($4\pi \times 10^{-7}$ H/m)

The relative permeability of diamagnetic materials is slightly less than 1, that of paramagnetic materials is slightly greater than 1, and that of ferromagnetic materials is very high (e.g., for iron with 0.2% impurities, μ_r = ~5,000).

Summary

Paramagnetic minerals have magnetic permeabilities that are higher than the surrounding medium, usually air or water, and they concentrate the lines of force of an external magnetic field. The higher the magnetic susceptibility, the higher the field intensity in the particle and the greater the attraction up the field gradient toward increasing field strength.

Diamagnetic minerals have magnetic permeabilities that are lower than the surrounding medium, usually air or water, and they repel the lines of force of an external magnetic field. These characteristics cause the expulsion of diamagnetic

Table 14.6-1 Minerals and their magnetic and electrostatic responses

Mineral	Composition	Specific Gravity	Magnetic Response			Electrostatic Response		
			Ferromagnetic	Paramagnetic	Nonmagnetic	Conductive		Nonconductive
Actinolite	$Ca_2(Mg,Fe)_5(Si_4O_{11})_2(OH)_2$	3.0–3.2		x				x
Albite	$Na(AlSi_3O_8)$	2.6			x			x
Almandine	$Fe_3Al_2(SiO_4)_3$	4.3		x				x
Amphibole	$(Fe,Mg,Ca)_xSiO_3$	2.9–3.5		x				x
Anatase	TiO_2	3.9			x	x		
Andalusite	Al_2SiO_5	3.2			x			x
Andradite	$3CaO{\cdot}Fe_2O_3{\cdot}SiO_2$	3.8		x		(2)	←	x
Anhydrite	$CaSO_4$	3.0			x			x

Figure 14.6-2 Magnetic drum separators operating as lifting magnets

minerals down the gradient of the field toward decreasing field strength. This negative diamagnetic effect is usually orders of magnitude smaller than the positive paramagnetic attraction. Thus, a magnetic circuit can be designed to produce higher field intensity or higher field gradient, or both, to achieve effective separation (Falconer 1992).

CONVENTIONAL MAGNETS

Magnets are used in the mineral industry to remove tramp iron that might damage equipment and to separate minerals according to their magnetic susceptibility.

Low-Intensity Magnetic Separators

Low-intensity magnetic separators have flux densities up to 0.2 T (2,000 G). These separators are used mainly to remove ferromagnetic materials (such as iron bolts, bars, cables, and tools), to protect downstream unit operations (such as conveyor belts), or to scalp ferromagnetic materials to improve the performance of permanent or electromagnetic separators used to separate weakly magnetic materials. Low-intensity separators can treat wet slurry or dry solids.

Protective Magnets

The device most widely used to protect downstream operations from tramp iron is a magnetic pulley installed in the head of a conveyor (Figure 14.6-1). These devices remove tramp metals from dry solids. They contain either a permanent magnet or an electromagnet. Many types of magnets can be used—for example, plate magnets, cross-belt magnets, cobbing magnets, grate magnets, magnetic humps, and magnetic filters. An arrangement of magnetic drum separators is shown in Figure 14.6-2.

Wet Magnetic Separators

Low-intensity wet magnetic separators have been the workhorse of the iron-ore industry for several decades. Iron ore that is rich in magnetite has traditionally been enriched by these magnets. The coal industry uses these magnets to recover magnetite or ferrosilicon in a media-recovery circuit.

Several types of separator work on the same principle but have different design features. The common types are counter-rotation drum separators and concurrent-rotation drum separators (Figure 14.6-3).

High-Intensity Magnetic Separators

Separating paramagnetic or weakly magnetic particles requires a higher flux density. This higher density is achieved by means of electromagnetic circuitry that can generate a magnetic force of up to 2 T (20,000 G). For example, in a silica sand processing plant, these separators remove weakly magnetic iron-bearing particles.

Induced-Roll Magnetic Separator

Induced-roll dry magnetic separators are widely used to remove trace impurities of paramagnetic substances from feedstock such as quartz, feldspar, and calcite. The machine contains laminated rolls of alternating magnetic and nonmagnetic discs. A magnetic flux on the order of 2 T (20,000 G) is generated, and very high gradients are obtained where the flux converges on the sharp edges of the magnetic laminations.

A thin stream of granular material is fed to the top of the first roll (Figure 14.6-4). The magnetic particles are attracted to the roll and deflected out of their natural trajectory. Selectivity

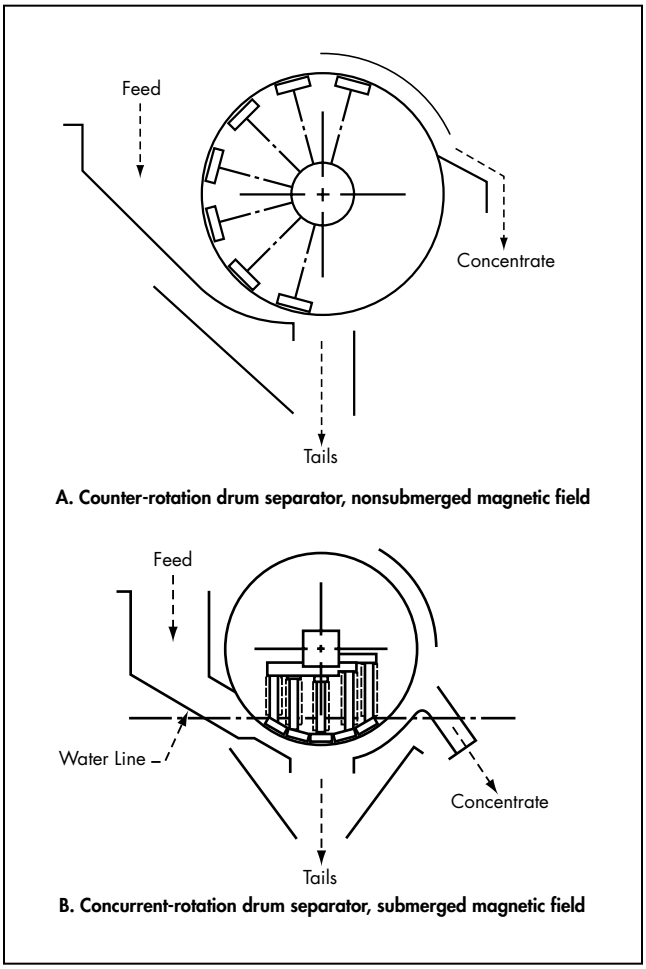

Figure 14.6-3 Wet magnetic separators

is obtained by varying roll speed and magnetic flux. A rather closely sized material must be treated if high selectivity is required. An industrial induced-roll magnetic separator consists of several rolls and can treat up to 10 tph (Figure 14.6-5).

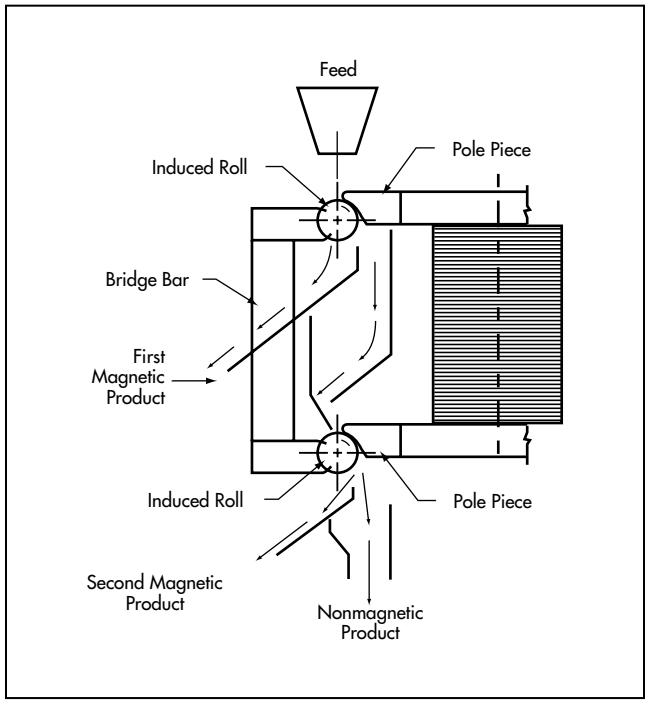
Lift-Type Magnetic Separator

Lift-type magnetic separators are used on granular and powdered material that is dry and free-flowing. This type of separator produces a clean magnetic product because the magnetic particles are lifted out of the stream against the force of gravity, which minimizes entrapped particles (Figure 14.6-6). The selectivity of the lift-type separator is superior to that of induced-roll separators. Their main limitation is lower capacity. The cross-belt separator, a type of lift magnetic separator, has been used to some extent in processing ilmenite, garnet, and monazite in beach sands.

Jones Separator

The Jones separator is a wet high-intensity separator built on a strong mainframe made of structural steel (Figure 14.6-7). Magnet yokes are welded to this frame, and electromagnetic coils are enclosed in air-cooled cases. Actual separation takes place in plate boxes that are on the periphery of the one or two rotors attached to the central shaft.

Feed, which is a thoroughly mixed slurry, flows through the separator by means of fitted pipes and launders, and then



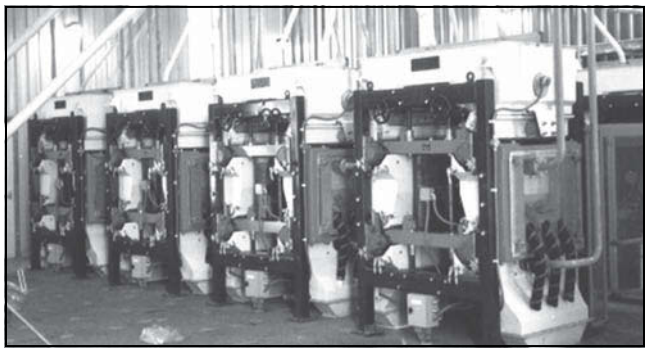


Figure 14.6-4 Induced-roll dry magnetic separator

Courtesy of Outotec USA, Inc.

Figure 14.6-5 Induced-roll dry magnetic separators treating silica sand

into the plate boxes. The plate boxes are grooved to concentrate the magnetic field at the tips of the ridges. Feeding is continuous as a result of the rotation of plate boxes and rotors, with feed points at the leading edges of the magnetic fields. Each rotor has two symmetrically placed feed points. The feebly magnetic particles are held by the plates, while the remaining nonmagnetic slurry passes straight through the plate boxes and is collected in a launder. Before leaving the field, entrained nonmagnetic particles are washed by low-pressure water and collected as a so-called "middlings product." When the plate boxes reach a point midway between the magnetic poles where the magnetic field is essentially zero, the magnetic particles are washed out under high-pressure scour water sprays of up to 5 bars of pressure.

Field intensities of >2 T (20,000 G) can be produced in these machines. They are widely used to recover iron minerals from low-grade hematite ore. Other common applications include removing magnetic impurities from cassiterite

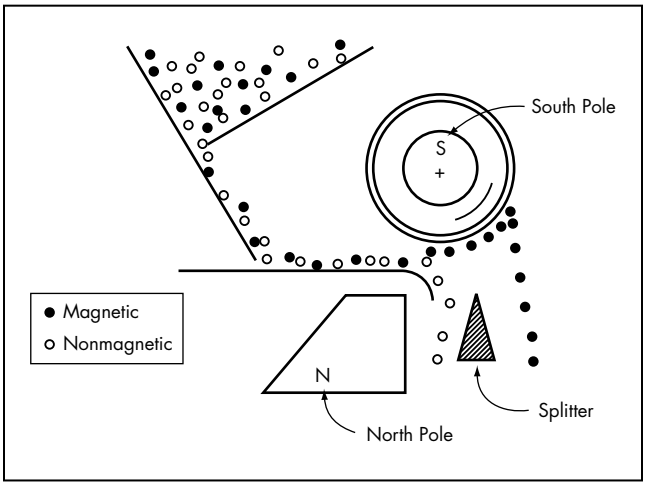

Figure 14.6-6 Lift-type magnetic separator

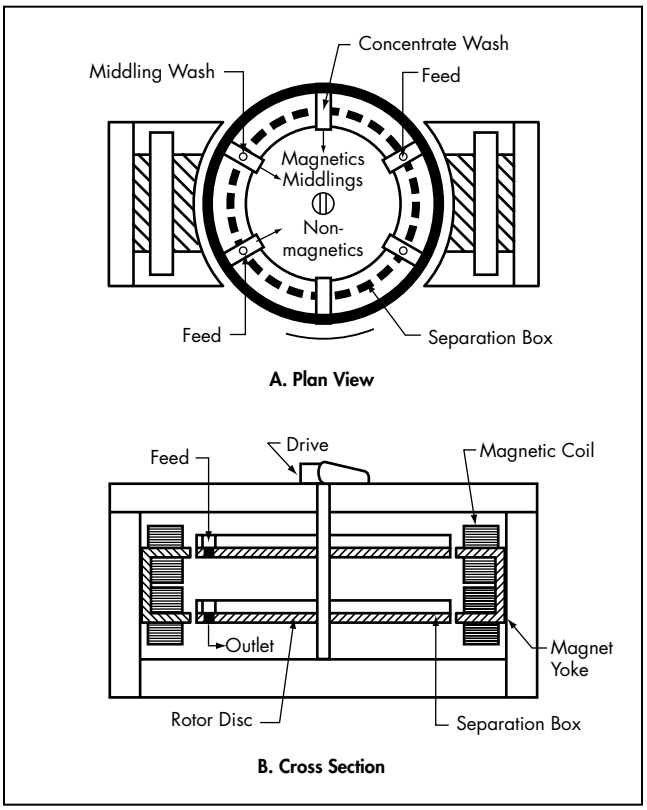

Figure 14.6-7 Jones separator

concentrate, removing fine magnetics from asbestos, and purifying talc.

Frantz Isodynamic Separator

The Frantz Isodynamic separator, introduced in the early 1930s, is the most efficient magnetic separator for separating minerals with field-independent magnetic susceptibilities. The isodynamic field, generated by a bipolar magnet with special pole-tip profiles, provides constancy of the product of the field and the field gradient. However, mineral separation in an isodynamic magnetic field is limited to minerals that have a constant susceptibility at the laboratory scale. Only this category of mineral then experiences a constant force throughout the isodynamic area.

PERMANENT MAGNETS

Most weakly magnetic minerals, such as garnet, ilmenite, and magnetic impurities in silica sand, can be effectively separated with a magnetic separator that has a flux density of >0.6 T (6,000 G). For nearly a century, induced-roll magnetic separators were the only economically viable unit operation in these applications. However, in spite of their considerable success, induced-roll separators have certain limitations in their selectivity and application. The development of permanent-magnet technology during the last three decades has reestablished the importance of magnetic separation and has increased the efficiency of fine-particle separations that were not successful with induced-roll magnets.

Principle and Design

In the last three decades, magnetic separation technology has undergone a revolution. Research in material science and ceramic technology has culminated in the development of new permanent rare-earth magnets and superconducting alloys. Successful adaptation of these magnetic materials, combined with knowledge of magnet geometry, has led to the design and development of a number of new magnetic separators that have opened niche markets that were previously considered beyond the realm of magnetic separation. These new separators are capable of

- Effectively removing magnetic impurities or reducing their concentration (even to parts-per-million levels);
- Producing high-grade mineral separates;
- Operating on virtually no energy, which makes them economical; and
- Generating higher magnetic flux levels, of up 2.1 T (21,000 G).

Dry Permanent Magnetic Separator

Recent improvements in magnet composition and design have led to the development of permanent magnetic separators. These improved rare-earth permanent magnets—for example, neodymium iron boron (NdFeB) and samarium cobalt (SmCo) magnets—have a magnetic attractive force that is an order of magnitude greater than that of conventional permanent magnetic circuits. The two main types of dry permanent magnetic separators that have found wide industrial applications are the rare-earth drum (RED) and the rare-earth roll (RER). They are widely used to separate weakly magnetic materials (such as garnet, ilmenite, and chromite) and to separate magnetic impurities present in low concentrations in silica sand (Dingwu et al. 1997; Dobbins et al. 2009; Wasmuth and Mertins 1997).

Rare-Earth Drum Separator

In a RED separator, NdFeB magnets are uniquely arranged to provide an intense (≤0.9 T or 9,000 G) and "deep" magnetic field perpendicular to the drum surface (Figure 14.6-8). Particles on the drum surface experience uniform flux density that minimizes misplacement of pinned particles to the middlings. Weakly magnetic particles pinned to the drum are carried to the region of no magnetic intensity and released as magnetics. The centrifugal force of the rotating drum throws those particles not influenced by the magnetic field into the nonmagnetic hopper.

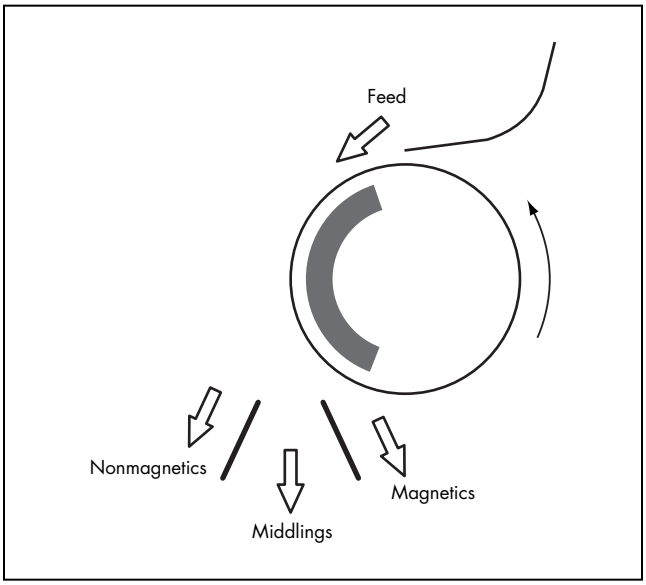

Figure 14.6-8 Operating principle of a rare-earth drum separator

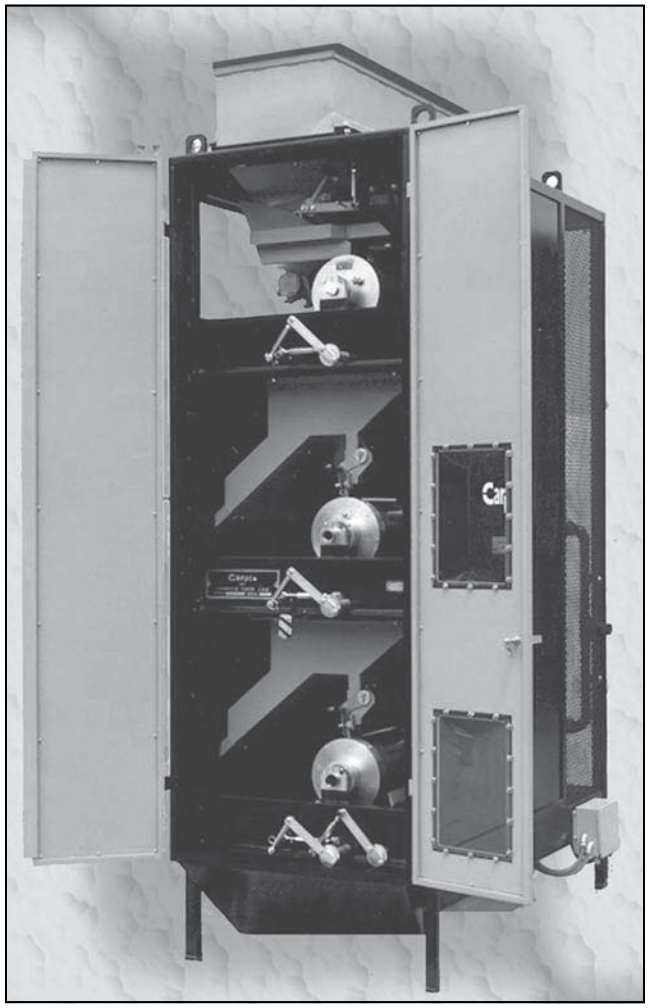
An industrial-scale RED separator usually has three drums (Figure 14.6-9). The top drum is generally a low-intensity (≤0.2 T or 2,000 G) scalper magnet that removes ferromagnetic particles; the nonmagnetic fraction is subsequently treated on the REDs. The main purpose of the scalper is to protect the bottom two REDs as well as to increase their capacity. Some separators have a built-in internal air-cooling system to protect the magnets from overheating when feed is preheated, as in plants that process beach and silica sand.



Rare-Earth Roll Separator

An RER separator operates by means of a thin belt (usually 0.076–0.51 mm) that travels at very high velocity. The unique aspect of this separator is the way in which it is configured as a head pulley. Feed passes through the magnetic field, and magnetic (or weakly magnetic) particles are attached to the roll and separated from the nonmagnetic stream (Figure 14.6-10).

Although drum separators can effectively handle coarse particles (12.5 to 0.075 mm), roll separators are very effective in treating fine particles (<1 mm). The capacity of deeper-field drum separators is generally higher than that of roll separators at 7–9 t/h/m (400–500 lb/h/in.) for drum separators but 1.8–5.4 t/h/m (100–300 lb/h/in.) for roll separators. The major advantage of the drum separator is its low maintenance cost, because it does not have a belt that must be replaced frequently. However, both separators have their own niche markets. Drum separators can treat coarser particles (such as garnet, ilmenite, and iron ore) at a higher throughput. Roll separators can produce high-grade, high-purity glass sand products when feed is not preheated.

Considerable research has been conducted to increase the throughput of REDs and RERs without compromising product quality. Most of these improvements have come from improved magnetic-circuit design, increased drum diameter, higher-quality nonmagnetic stainless steel, better manufacturing processes, and more compact layout design.

Case study I: Performance evaluation of RED and induced-roll magnetic separators. A series of tests compared

Courtesy of Outotec USA, Inc.

Figure 14.6-9 Industrial-scale rare-earth drum separator

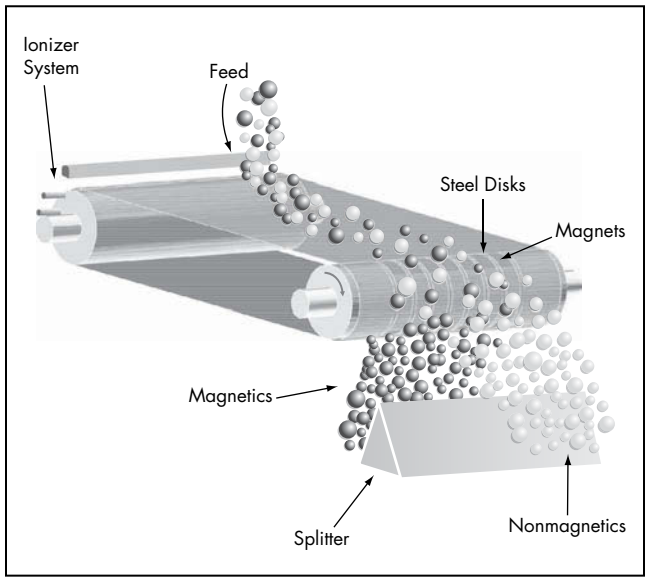


Figure 14.6-10 Operating principle of a rare-earth roll separator

the performance of a RED separator and an induced-roll magnetic separator to process a titanium-rich magnetic feed. The feed contained 76% TiO_2 and 1% Al_2O_3; it was obtained from a beach-sand processing plant. The goal was to produce high-grade nonmagnetic TiO_2 product (Table 14.6-2). Compared to the induced-roll magnetic separator, the RED separator gave product containing nearly twice the TiO_2, 45% rather than 24%, at a comparable product grade (TiO_2 grade of >90% and Al_2O_3 content of ~1%).

Case study II: Performance evaluation of RED and RER separators. A detailed study of the effect of feed rate on RED and RER separators used a garnet-rich heavy mineral sample (Figure 14.6-11). The RED separator was only minimally sensitive to feed rate. Garnet recovery decreased very marginally with increasing feed rate; it was 96.5% at a 2.6-tph feed rate and 95.1% at a 7.8-tph feed rate. In contrast, the RER separator seemed to be very sensitive to feed rate. Garnet recovery was 94.6% at a 2.6-tph feed rate, but fell to 81.3% at a 7.8-tph feed rate.

Eddy Current Separator

In the case of RED and RER magnetic separators, the outer drum or belt rotates; inside the shell, rare-earth magnets are mounted on a stator. In contrast, in an eddy current separator, not only does the nonmetallic outer drum rotate but the inside shell also rotates. The inside shell is a faster-moving rotor containing rare-earth magnets arranged in alternating polarity to induce eddy currents. An induced eddy current sets up a repulsive force in good conductors and thus separates nonferrous electrically conductive metals (such as copper and aluminum) from nonconducting materials.

Wet Permanent Magnetic Separator

A wet permanent magnetic separator (Figure 14.6-12) has permanent-magnet (NdFeB) bars positioned more or less horizontally inside a revolving drum made of stainless steel. This separator provides a field strength of 0.7 T (7,000 G) on the drum surface. The pulp tank is made of stainless steel with a concurrent or semi-countercurrent flow tank design and an adjustable discharge gap at the magnetics discharge end. The separator is equipped with an adjustable valve on the nonmagnetics discharge pipe to help control the flow rate and overflow level. This separator has found industrial applications in processing low-grade (martitic) iron ore.

SUPERCONDUCTING MAGNETS

High magnetic fields (up to 2 T or 20,000 G) are generated by passing current through a resistive coil or by permanent magnets. Development of newer computer models, through the use of finite-element-analysis techniques, has helped to achieve higher magnetic force. However, there is a logical maximum magnetic field for both the resistive coil and permanent magnet. Resistive coils are limited by the intrinsic resistance applied by the windings; the field strength of existing permanent magnets can be increased only marginally by modifying the magnet geometry. In the future, new magnetic materials may help to overcome this limitation.

Principle and Design

Currently, superconducting magnets are the only economically and technically viable way to achieve field strengths as high as 5 T (50,000 G). Most of the industrial superconducting magnetic separators designed and installed in the 1990s and 2000s include expensive cryogenic systems that use liquid helium. This cooling system is essential to help maintain the temperature of the matrix, made of superconducting niobium/titanium alloy, below ~4 K, in order to achieve field strengths as high as 5 T.

Three types of cryogenic system are commonly used:

1. **Closed-cycle liquefier system.** In a closed-cycle liquefier system, the superconductor resides in a bath of liquid helium, and boil-off gas is recirculated through a helium liquefier. Although system installation is quite complex, system performance has been good and reliable, provided that there are no long-term interruptions in the supply of electrical power and cooling water.
2. **Low-loss system.** In a low-loss system, the superconductor windings reside in a reservoir of liquid helium. A very

Table 14.6-2 TiO_2 recovery and composition of nonmagnetic product*

Type of Separator	TiO_2 Recovery, %	Product Grade TiO_2, %	Product Grade Al_2O_3, %
Induced-roll magnet separator	24.2	92	0.96
RED-7000 gauss separator	44.7	92	1.03

*Treated by an induced-roll magnetic separator (feed contained 76% TiO_2 and 1% Al_2O_3; two passes; nonmagnetic retreat) and a RED-7000 gauss drum separator.

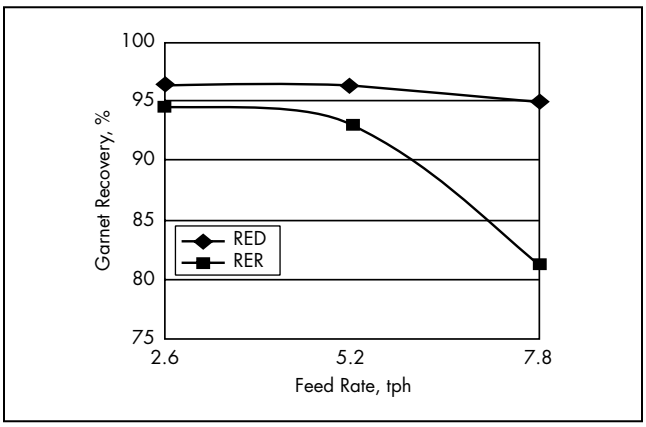

Figure 14.6-11 Performance of RED and RER separators

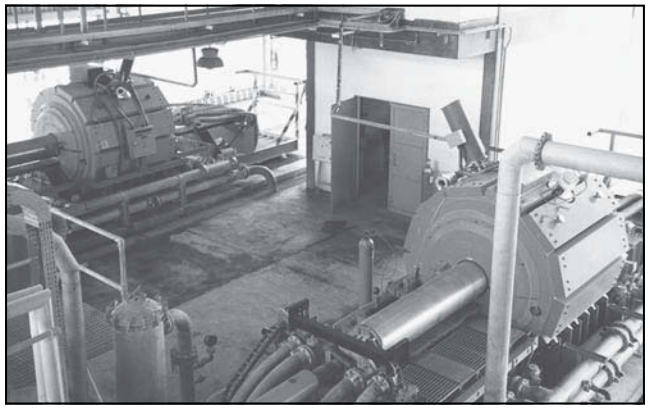
Courtesy of Outotec USA, Inc.

Figure 14.6-13 Operating principle of a reciprocating canister superconducting magnetic separator

efficient insulation system enables the magnet to operate for long periods, typically a year or more, between liquid-helium refills. The salient feature of this system is its relative immunity to short-term electrical failures. This feature allows this technology to be used where equipment is operated under difficult conditions.

3. **Indirect-cooling system.** The advent of heat engines based on the Gifford–McMahon cycle, which generate temperatures of ≤4 K, has made it possible to cool superconducting windings without the need for liquid helium. This technique offers great potential for small-scale systems in which the economics of helium supply or the cost of a liquefier cannot be justified. However, a constant power supply is essential for reliable operation.



In recent years, however, developments in cryogen-free cooling technology as well as advances in materials science have spurred design of more robust superconducting magnetic separators that do not require expensive helium refills.

In summary, superconducting magnets have two main advantages:

1. Low power consumption resulting from zero resistance of the magnet winding
2. Generation of high magnetic fields

Superconducting Wet High-Gradient Magnetic Separator

In a superconducting wet high-gradient magnetic separator (HGMS), magnetic particles are captured on a stainless-steel–wool matrix contained within the bore of a high-intensity magnet (Carpco SMS Ltd. 1993; D'Assumpção et al. 1995). The high intensity is generated using a superconducting coil. Because these coils have essentially zero resistance, little electrical power is required to energize the magnet. Furthermore, after the magnet is energized, the coil ends can be shorted, leaving the magnet in a fully energized state without any additional power supply. This practice is called operating the magnets in persistent mode.

Courtesy of Outotec USA, Inc.

Figure 14.6-14 Industrial-scale reciprocating canister superconducting magnetic separator

Unloading trapped magnetic particles from the matrix is an essential step that determines the separation efficiency and capacity of the unit operation. Demagnetization is achieved either by deenergizing the magnet (a state commonly referred to as switch-mode) or by moving the matrix canister (referred to as a reciprocating canister HGMS). In reciprocating technology, captured magnetic particles are flushed using a ram to remove the trapping zone from the magnetic field regions. The ram operates on a magnetically balanced canister that houses a multisection separation region with unique and separate trapping zones (Figure 14.6-13).

Units that combine reciprocating canister technology and a low-loss cryogenic system have been used in kaolin processing throughout the world. Figure 14.6-14 shows a typical large-scale reciprocating canister HGMS.

Superconducting Dry Open-Gradient Magnetic Separator

In a conventional dry open-gradient magnetic separator (OGMS), the magnet structure is arranged to provide a region in open space with a highly divergent field. Thus, the magnet geometry supplies both the magnetic field and the field gradient. Paramagnetic material passing through this region experiences a force directly proportional to the field intensity and the magnitude of the field gradient. Compared with a conventional OGMS, a superconducting OGMS offers not only a higher magnetic force but also a deeper magnetic field, which translates to larger separation volumes.

ELECTROSTATIC SEPARATION

Almost all minerals show some degree of conductivity. The electrostatic separation process uses the difference in electrical conductivity or surface charge of the mineral species of interest. It has generally been confined to recovering valuable heavy minerals from beach-sand deposits. However, growing interest in plastic and metal recycling has opened up new applications in secondary material recovery (Knoll and Taylor 1985; Prabhu 1999).

When particles come under the influence of an electrical field, depending on their conductivity, they accumulate a charge that depends directly on the maximum achievable charge density and on the surface area of the particle. The

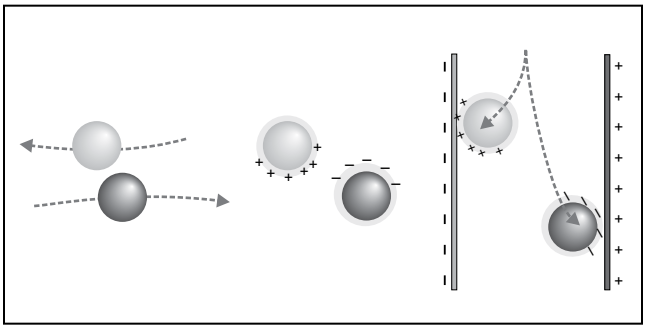


Figure 14.6-15 Work functions after particle–particle charging

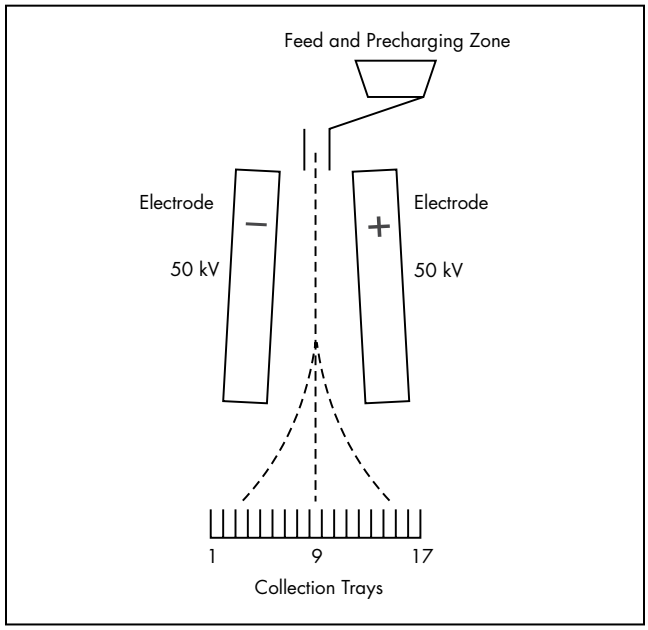
charged particles can be separated by differential attraction or repulsion. Therefore, the important first step in electrostatic separation is to impart an electrostatic charge to the particles. The three main types of charging mechanism are contact electrification or triboelectrification, conductive induction, and ion bombardment. After the particles are charged, separation can be achieved by equipment with various electrode configurations.

Triboelectrification

Triboelectrification is a type of electrostatic separation in which two nonconductive mineral species acquire opposite charges by contact with each other (Alfano et al. 1988). The oppositely charged particles can then be separated under the influence of an electric field. This process uses the difference in the electronic surface structure of the particles involved. A good example is the strong negative surface charge that silica acquires when it touches carbonates and phosphates.



The surface phenomenon that comes into play is the *work function*, defined as the energy required to remove electrons from any surface (Figure 14.6-15). After particle–particle charging, the positively charged particle has a lower work function than does the negatively charged particle.

Over the years, several different types of triboelectrostatic separator have been designed and tested. A few tube-type and plate-type triboelectrostatic separators are now in commercial use processing minerals such as wollastonite, silica sand, and calcium carbonate. Unfortunately, in most applications, these separators suffer from low throughput and poor separation efficiency. The main challenge has been the inability to help particles acquire and retain charge for a desired period of time during the separation process.

Conductive Induction

When uncharged particles, whether conductors or nonconductors, contact a charged surface, the particles assume polarity and the potential of the surface. Electrically conductive minerals do so rapidly. However, in the case of nonconductors, the side that faces away from the charged surface is slower to acquire the same polarity as the surface. Hence, if both conductor and nonconductor particles are just separated from contact with a charged plate (Figure 14.6-16), the conductor particles are repelled by the charged plate, and the nonconductor particles remain unaffected by the charged plate—they are neither attracted nor repelled.

The most common industrial separators working on this principle are plate- and screen-type separators. Feed falls under gravity onto an inclined, grounded plate and into an

Courtesy of Integrated Mineral Technology, Ltd.

Figure 14.6-16 Operating principle of a plate-type electrostatic separator

electrostatic field induced by a high-voltage electrode. These electrodes are generally oval. Conductor particles acquire an induced charge from the grounded plate and move toward the oppositely charged electrode; that is, the particles experience a "lifting effect." Nonconductor particles are generally not affected by this field. Because the lifting effect depends on surface charge as well as particle mass, fine conductors are effectively separated from coarse nonconductors.

Ion Bombardment

When conductor and nonconductor particles placed on a grounded conducting surface are bombarded with ions of atmospheric gases generated by an electrical corona discharge from a high-voltage electrode, both conductor and nonconductor particles acquire a charge. When ion bombardment ceases, conductor particles rapidly lose their acquired charge to the grounded surface. Nonconductor particles react differently; the side that faces away from the grounded conducting plate is coated with ions of charge opposite in electrical polarity to that of the grounded conducting plate. Therefore, nonconductor particles remain pinned to the grounded plate because of electrostatic force (Figure 14.6-17).

An industrial high-tension electrostatic separator that uses the pinning effect to process plastics and metal scrap is shown in Figure 14.6-18. This separator consists of a rotating roll made from mild steel that is grounded through its supporting bearing. The electrode assembly consists mainly of two types of electrodes: a beam or corona electrode and a static-type electrode. The beam electrode, usually connected to a DC supply of ≤50 kV negative polarity, charges all particles and pin nonconductors to the roll. Feed is presented uniformly to the rotating roll surface by a velocity feed system. Both conductor and nonconductor particles are sprayed with ions. Conductor particles rapidly lose their charge to the grounded roll surface and are thrown off by centrifugal force. Nonconductor particles are pinned to and then brushed off the rolled surface.

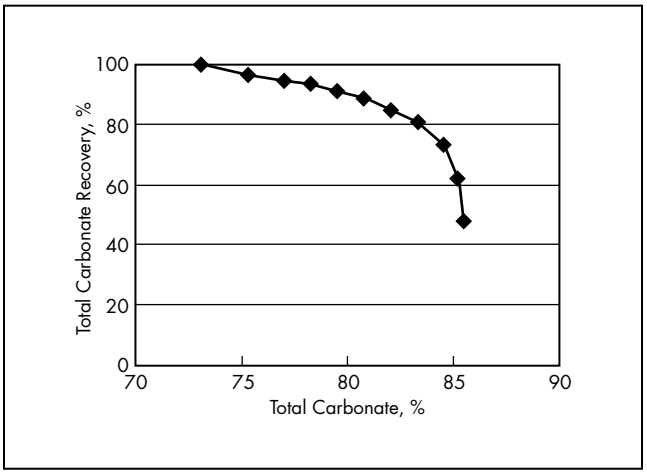


Figure 14.6-17 Operating principle of a roll-type electrostatic separator

Courtesy of Outotec USA, Inc.

Figure 14.6-18 Industrial roll-type electrostatic separator

Both conductor and nonconductor particles are collected in a partitioned product hopper at the bottom of the unit. The operating variables—roll speed, applied voltage, feed rate, splitter position, and electrode combination and position—can be adjusted to achieve effective separation.

After a long hiatus, there has recently been some significant development in designing new and efficient high-tension separators. OreKinetics has taken the lead and developed a new generation of high-tension roll and plate separators that have additional well-insulated static electrodes. This new design has helped improve separation efficiency and reduce the number of reprocessing steps.

CHAPTER 14.7

Dewatering Methods

Donald A. Dahlstrom

INTRODUCTION

Liquid–solid separation is a relatively slow-moving field in terms of technological change. Improvements in this process have been evolutionary rather than revolutionary. Water is used to process the majority (between 80% and 90%) of the minerals and coal mined. (A small and decreasing percentage of coal is crushed and screened dry, and industrial minerals, such as diatomaceous earth, bentonite, cement raw materials and clinker, and base metal ores prior to roasting are often crushed and ground to a fine powder using dry processes.) Beneficiation processes usually use water because it allows for greater efficiency, higher recovery, and lower cost per unit of valuable product. In addition, it eliminates air pollution.

Where capital and operating costs are mentioned in this chapter, they should be regarded as order-of-magnitude only and not definitive.

Costs of Liquid–Solid Separation

In general, when considering the need to separate solids from water, as the particles to be separated decrease in size, the cost increases and the capacity per unit area decreases. When the solids are colloids (generally considered to be –10 μm), costs increase even faster. They are difficult to remove by filtration or centrifugation. Usually, a flocculant is added to the mixture to cause the colloids to form large flocculi or agglomerates. Accordingly, liquid–solid separation is a major cost in mineral processing, probably exceeded only by the cost of comminution, flotation, and endothermic reactions.

For example, the capital cost of a coal preparation plant increases by about 30% to 40% if the –28 mesh coal fraction is processed instead of discarded and the process water is recovered (by liquid–solid separation) for recycle and reuse. Operating costs per ton of –28 mesh coal also increase substantially when compared to coarser coals. These costs are due primarily to the use of flotation and the liquid–solid separation steps involved.

At the same time, liquid–solid separation by mechanical means (i.e., sedimentation, filtration, and centrifugation) is much less costly than thermal drying, primarily because those means consume less energy per unit of water removed.

To illustrate some highly efficient liquid–solid separations, consider the following example. A 30-m-diameter conventional gravitational thickener (at a normal design rate for tailings concentration and water reclamation of 0.1 m^2/t of dry solids per day) will process more than 2,400 t (metric tons) of solids per day. With a feed of 15% (by weight) solids, an underflow concentration of 50% (by weight) solids or higher can usually be achieved if the solids contain 50% to 55% particles that are –200 mesh or coarser. This size means that 4.67 kg of water per kilogram of solids has been eliminated and that more than 82% of the water will report to the thickener overflow for reuse. The thickener drive head will be equipped with only a 3.7- or 5.6-kW motor.

In the processing of magnetite concentrates derived from the beneficiation of taconite, disk filters are used to dewater magnetite concentrates before the balling step. For a 1,800 cm^2/g Blaine concentrate (approximately 85% to 90% –325 mesh), a filtration rate of 1,100 kg of dry solids/h/m^2 is used as a design basis (Wolf et al. 1971). The feed concentration would be maintained at 65% (by weight), and the vacuum level should be at 60 cm of mercury by using a vacuum pump capacity of about 1.8 m^3/m^2 of filtration area. Power consumption will be very high because of the high vacuum and flow rate. Considering also the filter drive, compressed air requirements, filtrate pump, and agitator, a total of 26 kW would be required for 10 m^2 of filtration area. This power requirement is equivalent to 2.5 cal/m^2 of filtration area. However, 100 kg of dry magnetite solids per hour are dewatered to the 9% (by weight) moisture required for hauling. At the same time, 4,600 kg of water are extracted. Thus, only 25 kcal/kg are eliminated.

Thermal drying, on the other hand, requires around 4,900 kcal/kg of water evaporated. Obviously, mechanical methods of dewatering have relatively low energy consumption per unit of liquid removed.

Liquid–solid separation is also critical in water discharge, water reclamation and closed water circuits (Wolf et al. 1971). Water that has been used for processing and beneficiating minerals and coals will contain solids that can range in size from a fraction of a micrometer to 6 mm or more. Some streams will

Donald A. Dahlstrom, Former Professor Emeritus, University of Utah, Salt Lake City, Utah, USA

contain the valuable solids and others the refuse or tailings. In both cases, the solids must be separated out if the water is to be reused. Furthermore, the concentration of suspended solids in recycled water must be low enough so that the water does not contaminate the next product. In the case of iron ore processing, the return water must contain between 100 and 150 mg/L or less to minimize the percentage of silica in the final pellet. Coal requires a suspended solids concentration of less than 1% (by weight).

Water discharge requirements often necessitate even better solids–liquids separation than process requirements. In the United States, state and federal regulations generally require that effluent disposed in lakes, streams, or other public water sources contain no more than 10 to 50 mg/L of suspended solids.

Steps in Liquid–Solid Separation

Separating liquid and solids requires many steps, and these are treated extensively in the literature (e.g., Fuerstenau and Han 2003; Wills and Napier-Munn 2006).

In coal processing, centrifuges and screens are usually used. For minerals beneficiation, ore is usually ground much finer than is practiced for coal processing, often to 80% passing 75 μm or even 80% passing 44 μm (Henderson et al. 1957; Kobler and Dahlstrom 1979). Thus, base metals and iron ore concentrates, which are large-tonnage minerals, will usually be rated according to the percentage of –325 mesh or even –400 mesh solids. Because of their abrasive character, these and other minerals will be dewatered in thickeners and then on filters. Both continuous filters and centrifuges are used with crystalline solids such as potash sulfate. Gravity thickeners are used for both concentrate and tailings (Coe and Clevenger 1916; Roberts 1949; Terchick et al. 1975). Tailings are generally sent to tailings ponds without solids–liquids separation, as their tonnage and volume can be very large. However, more stringent regulation of the construction of tailings ponds ensures that mechanical dewatering methods will be increasingly used in the future (Chironis 1976).

Hydrometallurgical processing always creates abundant colloidal solids during the leach step. Proper liquid–solid separation enables the recovery of the maximum amount of pregnant liquor while minimizing its dilution. Thus, multistage countercurrent sedimentation, countercurrent washing filtration on a single filter, or two- or three-stage filtration with single washes per stage are practiced. Both continuous vacuum filters and pressure filters are involved (Nelson and Dahlstrom 1957; Osborne 1975; Kobler and Dahlstrom 1979).

Current practice at many locations requires "zero discharge," or 100% recycling of water streams. If solids are disposed of in a landfill, the discharged solids must be low enough in moisture (generally 80% solids or more) so that liquids do not leach out by gravity. Thus, in a modern mineral processing plant, efficient liquid–solid separation processes are critical to low-cost processing, and these processes can substantially affect capital and operating costs.

MAJOR INFLUENCES ON LIQUID–SOLID SEPARATION

Many factors external to the liquid–solid separation equipment itself influence its performance and productivity. The most common of these are as follows (Cross 1963; Robins 1964; Scott 1970; Bosley 1974; Silverblatt et al. 1974; Wetzel 1974; Hsia and Reinmiller 1977; Weber 1977; Dahlstrom 1978; Rushton 1978; Sakiadis 1984; Baczek et al. 1997; Lewis 2007), and of which only the first factor will be discussed in detail in this chapter:

- Particle size and shape
- Weight and volume percentage of solids
- Fluid viscosity and temperature
- pH and chemical composition of the feed
- Variation and range in feed quality (i.e., of the first four items)
- Specific gravity of solids and liquid
- Quality requirements of discharge streams from liquid–solid separation steps, particularly as they influence results upstream and downstream

Particle Size and Shape

Size distribution greatly affects liquid–solid separation rates. Stokes' law can be used to illustrate this fact. This law permits the terminal settling velocity (maximum velocity achieved during free fall) to be determined as follows:

$$\nu_t = \frac{(\rho_s - \rho) g D^2}{18\mu}$$

where

ν_t = terminal velocity, m/s
ρ_s = particle density, kg/m^3
ρ = liquid density, kg/m^3
g = gravitational acceleration = 9.806 m/s^2 at sea level at 45° latitude. This value is used for g, the standard gravitational acceleration on this planet, and is usually symbolized by g_c.
D = particle diameter, m
μ = fluid viscosity, kg/m × s

Viscosity is normally measured in centipoise. One poise = 1 g·cm^{-1}·s^{-1}. (All nomenclature is metric [International System of Units], but English units can be used as long as they are used consistently.)

This equation has some limitations. It assumes laminar flow (i.e., a Reynolds number of less than 0.1) and nonhindered settling. In nonhindered settling, a particle is not influenced by the presence of other particles or by the slurry's specific gravity, conditions that require very dilute slurries.

If one assumes a 20-μm particle and an 80-μm particle of the same density and in the same fluid, the terminal velocity is found from the equation to be directly proportional to the square of the diameter. In this case, the 80-μm particle will fall 16 times as fast as the 20-μm particle (see Table 14.7-1).

Unfortunately, mineral slurries contain a variety of particle sizes of different densities and agglomerating behaviors, so the application of the equations is usually difficult. The size distribution of particles in the slurry also has a major effect, so a simple characterization, such as 80% –200 mesh, is not very useful when designing equipment. Percentage of clay-like particles and type of clay are very important variables and can change throughout a mineral deposit. For most heavy metal mineral processing operations, the clay content is usually within manageable limits. For these plants, discharge streams from conventional thickeners are typically 55% to 60% solids, discharge steams from filters are typically 80% to 83% solids (dry enough so it can be stacked with a bulldozer), and discharge streams from high-density thickeners

are typically 68% to 73% solids (a thick paste but of pumpable consistency).

The designs for thickeners and filtration equipment are usually decided in a program of laboratory testing, and a large safety factor is included when designing equipment. In general, even very finely ground mineral slurry will respond to dewatering if the correct equipment is employed. Although equipment suppliers should be contacted early in the design process, it is important that the client take charge of this process (rather than leaving it up to equipment suppliers), because the results can be interpreted in a variety of ways, which might favor some equipment over others.

LIQUID–SOLID SEPARATION EQUIPMENT

Commonly used equipment for liquid–solid separation in the minerals processing industry can be categorized into the following unit operations: screens, cyclones, thickeners and clarifiers, filters, centrifuges, and tailings ponds.

Screens

Screens are often the first liquid–solid equipment encountered by the ore stream as it enters the processing plant. Screens serve the dual purpose of separating the solids into different size fractions and separating solids from liquids. Typical applications for the latter use are "trash screens," which remove nonmineral particles such as wood chips from the mineral slurry. While this is a somewhat mundane application, it can be critically important to the functioning of downstream equipment, so a trash screen is usually present following the grinding stage in most mineral processing plants. This screen is usually an inclined-deck vibrating screen. In the gold-processing industry, many plants employ coarse carbon particles (1,600 μm, 10 mesh) to adsorb dissolved gold from 75-μm ore slurry. The carbon particles are recovered from the slurry on a variety of screen types, typically inclined-deck vibrating screens (commonly called Dutch State Mines screens or DSM screens), which employ parallel bars/wires at right angles to the flow and a steeply dipping nonvibrated deck (Fuerstenau and Han 2003).

In 2005, vibrating screens with very fine screen decks came into limited use to make a very fine separation, typically at 200 μm (65 mesh), of the product fines fraction from slurry, which is recirculated to the grinding mills. Formerly this job was always done using cyclones or spiral classifiers.

Cyclones

Cyclones are typically configured as a straight-sided cylinder connected to a tapered pipe section. The ore slurry stream is introduced tangentially into the cylindrical section, and it rapidly spins to separate the solids from the liquids. Typically, the dimensions are 25 cm in diameter and 100 cm long, but they can be much larger or smaller. Cyclones are commonly used as size separation devices to separate the fine product slurry from the coarse recycle slurry in the grinding section of mineral processing plants. Size separation is not the subject of this chapter, but the cyclones also serve the dual purpose of making a dense underflow (high solids content, coarse material) from a dilute overflow. This effect is utilized by dewatering cyclones, which are used to separate dense solids slurries to form a nearly clear liquid overflow. In this application they substitute for thickeners.

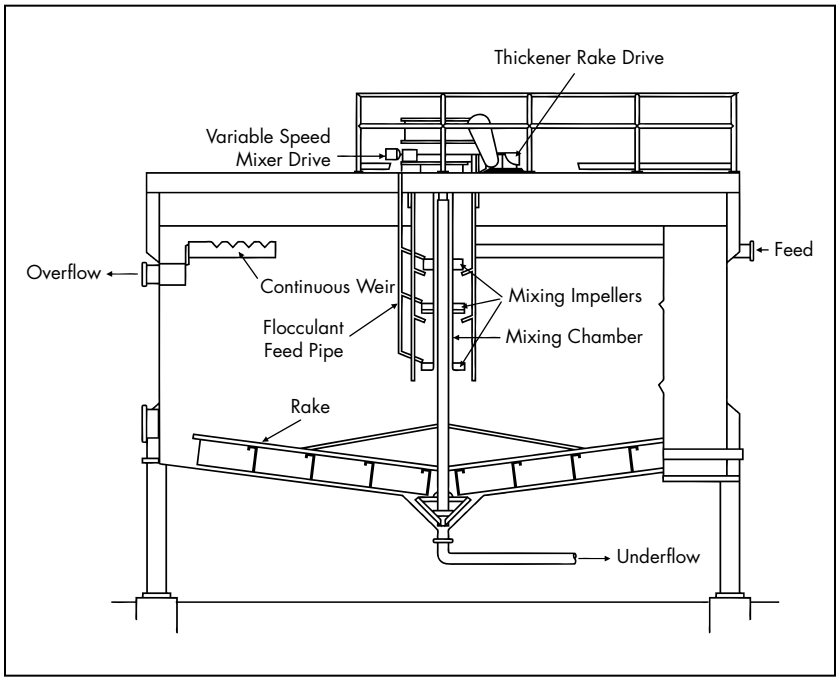

Figure 14.7-1 High-density thickener

Thickeners and Clarifiers

While cyclones employ centrifugal force, which can be many times the force of gravity, thickeners and clarifiers use gravity only to allow settling of mineral particles and separation of a dense slurry, which is pumped from the bottom of the thickener below a clear or nearly clear overflow liquid. Most mineral processing plants employ thickeners at multiple points in the process. Thickeners can range from 3 m to more than 100 m in diameter. Thickeners with diameters in the range of 20 to 50 m are applicable to settle the process stream in medium sized mineral processing plants treating 1,000 to 5,000 t of ore per day.

Where colloidal solids are present (which is usually the case), flocculants will improve operation of thickeners by causing the colloids to form agglomerates or flocculi of much larger size (which still contain probably 95% or more of liquid) that will settle at reasonable rates. In a typical mineral processing plant, flocculants are employed at multiple points, and the total reagent cost is between $1.00 and $5.00/t of mineral processed.

There are three basic types of thickeners: conventional, high-rate, and high-density. They all consist of a large, round, relatively shallow tank with a bottom that slopes toward the center, and they are equipped with a slowly rotating rake mechanism that moves the settled solids toward the central discharge. Overflow liquid is collected in a peripheral launder (trough) and is directed to a pipe outlet. Conventional thickeners can be very large and are sometimes run without the addition of flocculant. Capital cost is relatively high, but operating costs are low. High-rate thickeners can be much smaller in diameter than conventional thickeners for the same duty, and they rely on recycled slurry plus high usage of flocculants. Both conventional and high-rate thickeners discharge solids of the same density, usually 45% to 60% solids.

High-density thickeners have much deeper tanks with steep cone bottoms, and they rely on the auto-compression of the cake to increase density of the discharge solids up to 70% or more (see Figure 14.7-1). At this percent solids, the discharge is a thick paste solids that can be pumped only with special pumps. High-density thickeners are useful where water must be conserved or where a dense paste is needed for other applications such as mine backfill.

Although the overflow of a thickener must usually be of reasonable clarity, the emphasis is primarily on underflow concentration. Clarifiers are thickeners that operate on a dilute solids stream (often the discharge from thickeners) in which the flocculated stream is introduced below a blanket of flocs to capture all the suspended solids into the settled bed at the bottom of the clarifier. Clarifiers may have different internal configurations than the simple circular-rake thickener. For example, clarifiers may be rectangular tanks filled with submerged inclined plates (lamella thickeners), or they may be inclined tubes that reduce the settling distance of the particles to the vertical distance between plates.

The term countercurrent decantation (CCD) thickeners refers to the use of three to ten thickeners operated in a continuous train, in which slurry containing a process solution enters the first thickener and water enters the last thickener. Solids are pumped from the underflow of the first thickener into the next downstream thickener and so forth to the last thickener.

Solution is pumped from the overflow of the final thickener to the next upstream thickener, and it is mixed with the solids as they enter the thickener from the upstream direction. In this manner the solids slurry is continuously mixed and then settled, and the process solution (containing chemicals or dissolved products to be recovered) is gradually displaced by water. A five-stage thickener stream can often recover >95% of the dissolved values from the slurry using a volume of clean

Figure 14.7-3 Rotary drum vacuum filter

water equal to the volume of process solution entering with the slurry. CCD thickeners are the normal final stage in leach plants that chemically leach metals such as gold/silver, copper, nickel, or aluminum for their ores (see Figure 14.7-2).

Filters

Filtration can be divided into three modes: continuous, batch and semicontinuous, and clarifying. Each of these modes can be further subdivided. Ther are many books devoted to filtration and selection of filtration equipment, and the subject is discussed here in a very limited manner.

Vacuum Filters

Continuous vacuum filters can be rotating discs or drums, or traveling belts (Figure 14.7-3). They are usually used for dewatering mineral concentrates or for dewatering large volume, easy-to-filter materials such as the cleaned coal product of a coal washing plant. Traveling belt filters up to 6 m wide and 30 m long are employed for high-volume or slowly-filtering slurries. Large drum filters (with the filtration surface being the exposed outer surface of the drum) have been employed for the separation of solids slurry from process liquids, although this application has largely been replaced by thickeners.

Low-Tonnage Pressure Filters

Pressure filters are commonly employed in mineral processing plants to remove relatively low-tonnage, dilute solids from process streams. Although there are many types of pressure filters, in mineral processing plants these typically take the form of vertical-leaf filters with multiple parallel vertical leaves in a pressurized tank-like housing, or plate and frame filters with multiple plates sandwiched within a compression framework (Figure 14.7-4).

Typical applications are for achieving high clarifying process streams, where the prefiltration solids density is a few

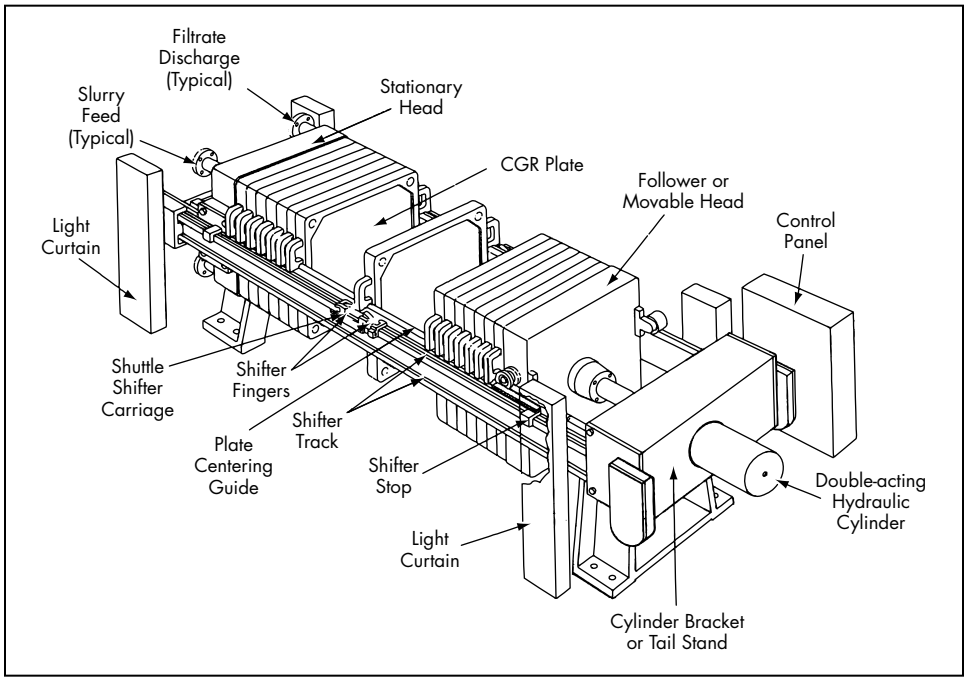

Figure 14.7-4 Plate and frame filter

hundred ppm up to 1%, and for the recovery of precipitated products such as gold and silver after these are precipitated in fine suspended solids form after the addition of zinc dust to a cyanide leach solution.

Clarifying filters typically have multiple parallel leaves consisting of a framework covered with filter cloth, and are usually precoated with diatomite to improve filtration capacity. Plate and frame filters for these low-solids applications are usually opened and closed, and cleaned manually.

High-Tonnage (Continuous) Pressure Filters

Continuous (actually semicontinuous) recessed plate filters are widely used to produce a dry tailings from a dilute slurry in high-tonnage process plants. A typical filter might contain 60 plates, each with a filter surface 1 × 1.5 m on each side of the plate. Such a filter might be able to process 1,000 t/d of slurry in a 12-minute cycle that includes 3 minutes of cake formation and other intervals for washing and blowing. The capital cost of a 1,000 t/d filter is around $2 million, but the final installed cost is around $5 million because the fitler is supported by a complex arrangement of pumps, piping, tanks, air compressors, and discharge conveyors.

Where a conventional tailings pond can be employed (in which the ore slurry is sent to the pond and clear solution is recovered), this is always preferable to tailings filtration, but in many cases topography or environmental considerations make tailings filtration necessary (see Table 14.7-2).

Centrifuges

Centrifuges are used with less-abrasive solids such as fine coal and crystalline solids. They can also beneficiate coal as the concentrate solids are usually appreciably higher in ash content than the feed.

Centrifuges, as their name implies, use a centrifugal force to substantially increase the settling rate of particles. This centrifugal force, created by pumping the feed into a cone-shaped unit, forces the feed to separate into two discharges: a solid-rich fraction and an aqueous fraction. There are no moving parts. However, a choke nozzle on the solids discharge allows adjustment and fine-tuning.

For mineral dewatering, the solid-bowl scroll centrifuge is frequently employed because it continuously discharges solids. The unit consists of a revolving horizontal cone-shaped casing inside which a screw conveyor of similar internal diameter revolves in the same direction but at a slower speed. The feed enters through a central tube of the screw conveyor from where it is subjected to high centrifical forces that cause the solids to settle on the inside of the casing where a screw conveyor "scrapes" and transports them to the discharge port located at the tapered end of the unit. Bowl diameters are usually from 15 to 150 cm. They have a throughput of 0.5 to 50 m^3/h of liquid and 0.25 to 100 t/h of solids with the moisture content of the discharge varying from 5% to 20% (Wills and Napier-Munn 2006).

Tailings Ponds

Tailings ponds are widely employed at mineral processing plants. Mineral slurries are pumped to the ponds, the solids settle and consolidate to form a stable mass, and the clear liquid is recycled to the plant or discharged to the environment. For chemical containment, tailings ponds may be lined with plastic liners and leak detectors, but where the process involves only nonchemical processing (physical methods such as gravity concentration or flotation), the tailings pond may be a simple excavated area with a compacted soil base. The fine solids in the tailings usually serve as an effective seal to prevent most escapes of process water.

Tailings pond management and construction (which is a continuous process as more tailings are created) may be a significant part (5% to 8%) of overall plant operating cost.

Table 14.7-2 Typical equipment factors for continuous vacuum filters (standard designs)

Filter Type	Submergence, %*		Total % Under Vacuum	Maximum % Cake Wash	Maximum % Dewatering Only	% Required for Cake Discharge	Minimum Cake Thickness, mm
	Apparent	Effective					
Filters Forming Cake Against Gravity							
Drum filters							
Scraper	35	30	80	29	50–60	20	6.4
Roll 1	35	30	80	29	50–60	20	0.8
Belt	35	30	75	29	45–55	25	3.2–4.8
Precoat	35	35	100	29	50	0	0
Disk filters	35	28	75	NA†	45–50	25	9.5–12.7
Filters Forming Cake with Gravity							
Horizontal belt as required			100*		As required	0	3.2–4.8
Horizontal table as required			80		As required	20	19.1

*Horizontal belt filter is based only on effective area (area under vacuum).
†NA = not available.

Where zero discharge is practiced, excess solution may be evaporated from the tailings pond using natural solar evaporation or various types of evaporative sprinkler. Evaporators of the "turbo-mist" variety blow a stream of fine droplets high into the air after mixing the solution with compressed air to form the fine droplets. A typical equipment unit of this type might evaporate 2,000 m^3 of water per month while consuming 45 kW. Capital cost is of the order of less than $150,000. Multiple units can be installed. The heat needed for evaporation can come from simple solar heating of the pond surface, but a larger contributor is the latent heat contained in the moving air mass above the tailings pond.

SUMMARY

Liquid–solid separation and the related problem of water balance is one of the major design issues for any mineral processing plant. Regardless of the mineral to be treated or the process employed, mistakes or design uncertainties in this area are one of the most common reasons for slow plant startup or underperformance. This chapter has intended to identify some of the more common design practices, but a very broad body of published literature, supplier brochures, and Internet information exists on the subject of flow-sheet design and liquid–solid separation. After a liquid–solid application is identified, the engineer should invest substantial time in quantifying the design factors and limitations, and in researching the alternatives, before making the selection of specific equipment.

ACKNOWLEDGMENTS

This chapter is based on the "Liquid–Solid Separation" chapter by the same author in *Principles of Mineral Processing*, published by SME.

PART 15

Health and Safety

CHAPTER 15.1

Mine Safety

David Laurence

The modern mine site is a different place than that which existed in 1989. Unlike the majority of mines that operated throughout the world at that time, many mines are no longer residential operations; instead they are staffed by a "fly-in, fly-out" work force. Workers at most mines are likely to be employed by contractors rather than the mining company itself and may not belong to a labor union. Many workers joined the industry during the boom times from 2004 and lack experience. All of these factors add to the challenges faced by mine managers to provide a safe place of work for all those employed on a mine site.

Even casual visitors to a mine are required to comply with the stringent safety requirements and the legislative responsibilities placed on mine management to ensure the health and safety of all people. The measures include

- Security procedures at the gate or entrance to the mining lease,
- Random or compulsory drugs and alcohol testing (many mines now have a zero-alcohol limit; many have no tolerance to any drugs, including analgesics),
- A safety induction program (for a contractor or employee, this can take a week to complete), and
- Continuous supervision by an employee.

One of the most significant issues for mine managers is achieving a safe working environment at their mine. "Zero harm" is the phrase that sums up the mission of many mining companies, contractors, and their employees. It is likely to be driven by one or all of the following points:

- The community no longer accepts that injuries are a necessary part of the mining process.
- If a fatality occurs at a mine site, there may be community angst, which grows to outrage if multiple fatalities occur.
- Politicians may act contrary to the mine's best interest but in their best interest.
- Regulator enforcement has strengthened, implying that
  - Mines can be shut down or
  - Managers and directors can be imprisoned or fined.
- The loss in human and financial terms can be immense.
- Remuneration and career progression are tied to safety performance.

Safety is one of the dimensions of sustainable mining practices, along with the other important dimensions of economy, environment, community, and efficiency (Figure 15.1-1). Three of these dimensions—economy, environment, and community—represent the pillars of sustainable development. In mining it is also important to consider safety and efficiency. Efficiency relates directly to the resource and encompasses optimization, technical excellence, nurturing the resource, and so forth (Laurence 2008).

Safety in the mining industry must encompass the full cycle of exploration, development, construction, operations, rehabilitation, closure, and final walkaway. Of course, associated activities such as mineral processing, smelting, and transport are all part of the industry, and excellence in safety needs to apply there as well.

In discussions of mine safety, the terms *dangerous* and *accidents* are not specific enough to engender clarity. Rather than using the word *dangerous*, the term *hazardous* is more meaningful when describing the working environment of mine sites. Hazards are present in the mining industry, but these can be identified and the resultant risks managed. The use of risk management techniques has been universally adopted in the

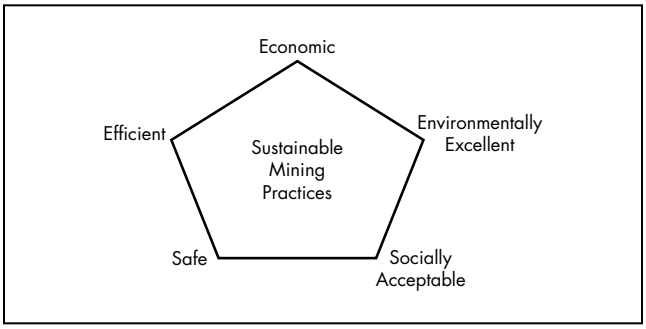

Figure 15.1-1 Sustainable mining practices

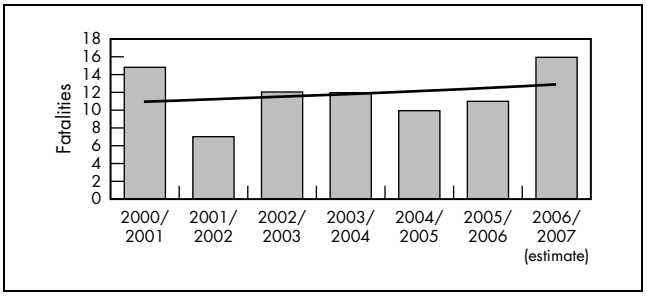

Figure 15.1-3 Mining industry fatalities in Australia, 2000–2007

Australian mining industry, and it has achieved a significant reduction in lost-time injuries and other safety performance measures. In a similar vein, the word *accident* connotes that uncontrollable natural forces may have been involved in an event. The industry prefers to use the term *incident*, with the knowledge that such events are preventable, whereas accidents are not.

Although the content of this chapter focuses on the Australian mining industry, the lessons can be applied anywhere.

DEFINING SAFETY

The Australian Standard 1470:1986, titled *Health and Safety at Work*, defines *safety* as "the provision and control of work environment systems and human behaviour which, together, give relative freedom from those conditions and circumstances which can cause personal damage." The Minerals Council of Australia (MCA), the peak lobby group for the mining industry in that country, defines *safety awareness* as "the state of mind where we are constantly aware of the possibility of injury and act accordingly at all times." On its Web site, MCA describes its vision for safety as "An Australian minerals industry free of fatalities, injuries and diseases." The MCA believes that

- All fatalities, injuries, and diseases are preventable;
- No task is so important that it cannot be done safely;
- All hazards can be identified and their risks managed;
- Everyone has a personal responsibility for the safety and health of themselves and others; and
- Safety and health performance can always be improved (MCA 2009).

Similar values and statements can be found on the Web sites of the major mining companies in Australia and throughout the world.

Exposure to dust, noise, and hazardous substances has long been an occupational hazard for mine workers. Cases of mesothelioma, asbestosis, silicosis, and pneumoconiosis are still appearing in mine workers many years after exposure. Although the health issues are at least as important as the safety issues and, in many cases, are more insidious and can take longer to manifest, the focus of this chapter is on mine safety rather than occupational health issues.

It is also important that workers are not subjected to injury through the use of machines. Mechanization and automation have helped to reduce any adverse interactions between humans and machines. Many mines still use handheld drilling techniques, however, and cases of repetitive strain injury in arms, hands, and fingers continue to occur. Similarly back injuries remain a major component of all workers' compensation claims in the mining industry. Part 15 of this handbook provides detailed information in this problem area.

MEASURING SAFETY IN MINING

Is mining a safe industry? Is *safety* a relative or absolute term? Some would argue that relative to other comparable industries, such as deep sea fishing, logging, and the construction and transport industries, mining is safe. Others would argue that, compared with the nuclear and chemical industries, it is not safe.

Defining how safety is measured is an important first step before attempting to compare mining with other industries. In mining, the two most commonly used measures are lost-time injuries and fatalities. Usually these measures are expressed as frequency rates, e.g., the lost-time injury frequency rate (LTIFR), which indicates the number of lost-time injury events that occur for a given number of hours worked. Figure 15.1-2 shows that on a lost-time injury basis, the Australian mining industry is performing in a continuously improving fashion. The use of this measure alone, however, leaves the industry open to the usual criticisms of reliability of this factor. It is well known that the LTIFR can be manipulated, particularly in this era of flexible work rosters.

One measure that cannot be manipulated is the number of fatalities that occur on mine sites. As shown in Figure 15.1-3, which covers the same period, 2000–2007 (financial years), an increasing number of deaths occurred. Although it can be persuasively argued that the number of employees in the mines increased, the numbers are far from the MCA's vision of "an industry free of fatalities, injuries and diseases." The risk of fatalities is measured by the fatal injury frequency rate (FIFR—the number of fatal injuries per one million hours worked). The Australian national FIFR in 2006–2007 was 0.05 per million hours worked, which was, according to the MCA, higher than the previous year at 0.04. Although an FIFR of 0.05 is below the 10-year average FIFR of 0.07, rates have fluctuated widely from year to year, and a consistent downward trend has not emerged.

According to the MCA, the Australian mining industry is performing relatively well compared with other countries. "The Australian minerals industry average FIFR for the ten-year period 1997–1998 to 2006–2007 was 0.07. Internationally the Australian industry compares favorably to South Africa on this indicator, which recorded an equivalent rate of 0.27 for this period, and the United States of America (USA),

which recorded a rate of around 0.17 for this period" (MCA 2009). Comparisons must be made on equal terms, however, as the indices vary from country to country. For example, in Australia, an LTIFR is defined as the number of lost-time injury events per million hours worked; in North America, it is per 200,000 hours worked.

THE CONCEPT OF RISK

The minerals industry has approximately 10 fatalities per year, based on a 10-year rolling average (MCA 2009). The minerals industry work force is about 120,000 strong, which means that about 1 in 12,000 workers are killed each year.

Is this an acceptable risk? Although no government agency in the world has a prescribed acceptable rate of work-related fatalities, several studies have shown that the community is comfortable with industries that kill less than 1 employee per 100,000 per year, as indicated in Table 15.1-1. This means that fatality risk in the minerals industry is much too high.

It may be useful to begin by examining the mining industry's safety record in comparison with other industries. There is no doubt that many industries have a higher incidence of serious or fatal injuries than mining. It has been estimated, for example, that the construction industry kills one person a week in Australia. The transport sector also results in more deaths than the mining industry in Australia. In a single state, Queensland, 23 truck drivers died in work-related incidents in 2007. Recent safety data is notoriously difficult to obtain, but a 2003 study of fatal crashes involving articulated trucks in Australia indicated that the number of fatalities between 1991 and 2002 (the latest available data), was relatively stable at around 190 per year (Australian Transport Safety Bureau 2003).

In a final comparison and according to recent statistics, in Australia, between 5 and 10 people per year are killed by lightning strikes, approximately the same number as those killed in mines (Bureau of Meteorology 2009).

RISK MANAGEMENT

The mining industry in Australia has embraced the concepts of risk management in virtually every aspect of its business. Risk assessments are usually mandated by legislation and are carried out before a new (major) piece of equipment is introduced or a new mining method, process, or system is implemented. Risk management has been credited with markedly improving safety performance in Australian mines.

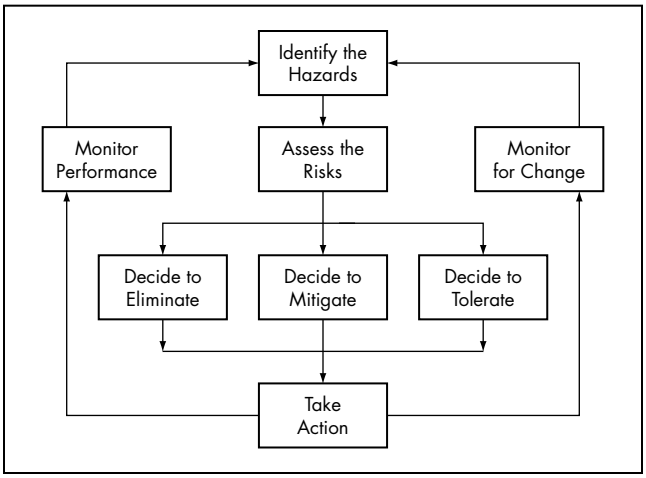

Figure 15.1-4 illustrates the steps usually followed in carrying out a risk assessment. First the hazard is identified. The risk presented by that hazard is then assessed. This can be done in a qualitative or a quantitative manner. Risk is generally assumed to be the product of the likelihood of a loss caused by that hazard occurring and the consequences of it occurring. After the risk is estimated, a decision is made to eliminate, mitigate, or control the risk to an acceptable level. Monitoring is the final step in the process to close the loop.

Hazards are a source of potential harm. In the mining industry, hazards are numerous, and the challenge for the work force, in the first instance, is to be aware of them. One of the reasons that hazards in mining are so great is because of the significant energies involved, be they gravitational, mechanical, chemical, electrical, or other types. The risk analysis allows the individual risks to be plotted on a matrix allowing management to allocate priorities to each.

Table 15.1-1 Estimates of risk

Activity	Risk of an Individual Dying in Any One Year
Smoking 10 cigarettes a day	1 in 200
Deep sea fishing	1 in 260
Influenza	1 in 500
Offshore oil and gas industries	1 in 600
Natural causes, 40 years old	1 in 850
Road accident	1 in 8,000
Road traffic accident	1 in 10,000
Playing soccer	1 in 25,000
Accident at home	1 in 26,000
Accident at work	1 in 43,500
Working in a "safe" industry	1 in 100,000
By fire or explosion at home	1 in 1,000,000
Struck by lightning	1 in 10,000,000

Figure 15.1-4 Basic risk-management process

MINE SAFETY LEGISLATION

In May 1970, the British government appointed a committee, chaired by Lord Robens, former chairman of the U.K. National Coal Board, to inquire into the provisions made for the safety and health of people in their workplace. The Robens Report was the major instigator to changing the philosophy and design of safety legislation in the United Kingdom and globally (Robens 1972). Up until that time, health and safety regulation consisted of a number of Acts of Parliament such as the Mines and Quarries Act (U.K. Office of Public Sector Information 1954), which had numerous sets of regulations covering specific risks or activities. Many of these had originated because of past accidents and disasters. Robens felt that this rule-based legislation was too complex, often inadequate, and had built-in obsolescence due to rapid technological changes.

Robens recommended a single broader and more flexible system of legislation based on more effective self-regulation by employers and workers jointly. Workplace health and safety should be effected by a tripartite approach involving workers, employers, and the regulator. The resultant Health

and Safety at Work Act (U.K. Health and Safety Executive 1974) included the following features:

- The duty of the employer to provide safe and healthy working systems, premises, working environments, and equipment, and to ensure that people work safely through training, instruction, and supervision
- The duty on each employee to observe safety and health provisions and to act with due care
- Elimination of prescriptive detail, replacing it with goal setting or performance achievement
- An emphasis on hazard identification, risk management, and risk assessment
- The use of codes of practice and guidelines to assist industry in compliance

In Australia, the New South Wales (NSW) government incorporated the philosophy of Robens in its Occupational Health and Safety (OHS) Act (NSW Government Legislation 1983), which was updated in 2000 and applies to all industries including the mining industry. This is a performance standard or enabling act. That is, it states the standard of performance to be achieved, leaving it to those bound by the act to select for themselves the methods to be used in achieving that standard. It is thus, philosophically, standing apart from the traditional prescriptive legislation, which prescribed for operators how to achieve standards.

The OHS Act acknowledges that the best results will be achieved by influencing attitudes and creating a framework for better health and safety organization and action by industry itself. Key features of the approach are

- Replacement of a mass of legislation by a single statute of general application;
- Provision by legislation of a comprehensive set of duties relating to the basic and overriding responsibilities of employers, employees, manufacturers, and others, which should be simple, easily assimilated precepts of general application (the "general duty" provisions); and
- The use of approved and voluntary standards and codes of practice in order to provide progressively better conditions.

Thus, under this legislation, both employers and employees have duties of care. An employer must ensure a safe and healthy workplace. An employee must take reasonable care of the health and safety of persons (including themselves) while at work and to cooperate with the employer.

Tasmania has a similar act, the Workplace Health and Safety Act (Australasian Legal Information Institute Tasmanian Consolidated Acts 1995). Part 3 of the act describes the general duties and obligations of both employers and employees. Section 9 provides that an employer must ensure, so far as is reasonably practicable, that the employee is safe from injury and risks to health. Section 16 of the act requires an employee to take reasonable care for the employee's own health and safety and for the health and safety of other persons and to comply with any direction given by an employer with respect to any matter relating to health and safety. Under this legislation, all parties, including the employer (and its employees) and the contractor (and its employees), have a duty to contribute to a safe working environment at the mine.

Other countries have different styles of legislation. A feature of the Canadian regulatory framework is the internal responsibility system or IRS. This is a system in an organization where everyone has direct responsibility for health and safety as an essential part of the job (Ontario Ministry of Labour 2000). The position a person holds in the organization does not reduce the obligation; however, the chief executive officer has overriding responsibility for implementing the system. Each person takes the initiative on health and safety issues and works to solve problems and make improvements.

A company's Joint Health and Safety Committee has a key contributory role in making the IRS work well. The keys to a successful IRS involve fixing responsibility at the worker level. For instance, each person must

- Have a sincere wish to prevent accidents and illnesses,
- Accept that the causes of accidents and illnesses can be eliminated or greatly reduced,
- Appreciate that risks can be continually reduced so that the time between accidents and illnesses gets longer and longer,
- Make health and safety an essential part of the job,
- Have a clear understanding of their responsibilities,
- Be able to explain what proactive measures they have taken to ensure health and safety on the job,
- Have a clear understanding of their abilities and limitations,
- Strive to more than meet the minimum standards,
- Strive to cooperate with others to reduce risk,
- Understand and believe in the IRS process,
- Recognize that reprisals and incrimination are not part of the process (Ontario Ministry of Labour 2000).

The IRS is a system that drives responsibility for health and safety down to the operator level. If mine managers can obtain this level of responsibility from their workers, then there is a chance of ensuring the health and safety of employees, which is a general duty under most mining OHS legislation.

INFORMATION SHARING

One significant advance contributing to improved safety performance over the past 20 years has been a greater openness among mining companies and government regulators to share safety information. Although this openness is threatened in some jurisdictions because of the litigation that follows some incidents, there is a great deal of information available, particularly on the Internet. This is mainly in the form of safety alerts, significant incidents reports, and bulletins. Most of these are generated by regulators and designed to inform mine operators about significant incidents that occurred within their jurisdictions. They are also shared between regulators, however, so that an operator of an underground coal mine in Queensland, Australia, for example, is aware of a fatality at a similar mine in West Virginia in the United States. The fatality reports issued by the U.S. Department of Labor's Mine Safety and Health Administration (MSHA) contain detailed information and are designed to ensure that such tragedies do not reoccur. Reports of this nature can be found at the Web sites for MSHA; the Department of Mines and Energy, Queensland, Australia; and the Department of Primary Industries, New South Wales, Australia.

THE HUMAN FACTOR

One body of evidence suggests that despite the best systems and procedures, accidents and incidents do occur and many of these are caused by risk taking or human error. For example, "Recent history in the mining industry in Queensland has shown that incidents and accidents have occurred as a result

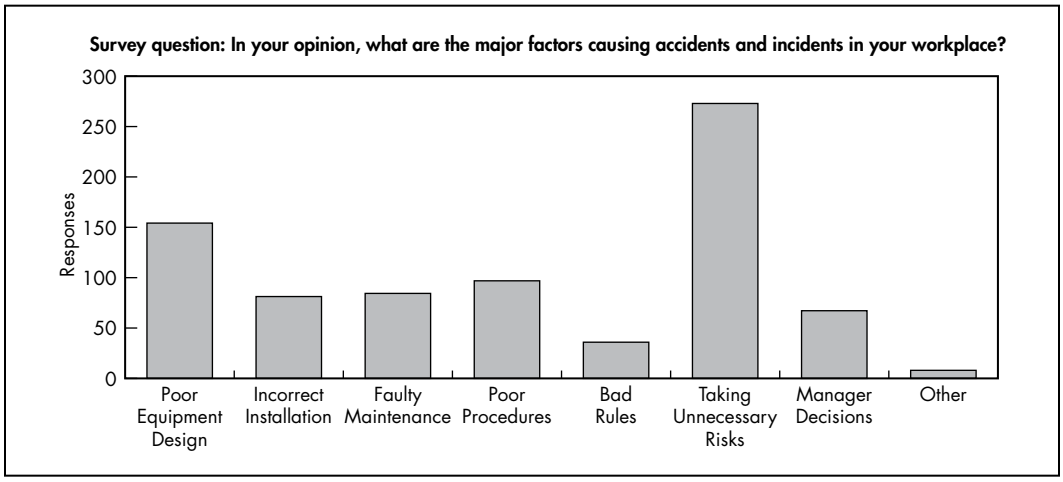

Figure 15.1-5 Miner survey results for causes of accidents and incidents

of unintentional errors or actions that do not recognise the personal risk present. Too often, the serious accidents are a result of conscious risk-taking, such as taking the easy way out, taking a short cut or not thinking about the risks in your workplace before starting work. It is not uncommon to find that the victims knew the potential risk of accidents before the incident" (Queensland Department of Mines and Energy 2002). And "very few people have accidents for which there is no procedure in place and we have a significant degree of accidents as a result of people breaking rules, ignoring rules or simply not knowing about them.…" (Pitzer 2000).

A recent study of risky behaviors of continuous miner operators in underground coal mines found that more than 90% of employees interviewed "expressed misgivings" about safety rules and regulations. There was a clear distinction between operating within the rules and operating normally, with the latter referring to the quickest possible way to complete a task. "The issue is not whether the rules are practical or not, or whether the rules should be simply followed or not. A more serious issue is that possibly the large majority of employees (including deputies/supervisors) operate dangerous machinery every day in underground mines with a basic disposition that safety rules are 'irrelevant, superfluous, non-essential or excessive.' If this is the case, an important resource for limiting the risky behaviour of employees is critically deficient" (Pitzer 2000).

A further study of 39 multiple-fatality coal mine disasters, mainly from the United States, United Kingdom, and Australia, found that serious violations of mining laws were discovered among 33 (Braithwaite and Grabosky 1985). It was found that serious violations either caused the disaster, were components of the causes, or exacerbated the effect of the disaster.

These findings are supported by a 1991 study, commissioned by the NSW Department of Mineral Resources, which found that 83% of fatal accidents from strata movements in underground coal mines in the period 1972–1990 were associated with breaches of rules (Roylett et al. 1991). Human error was simultaneously present with breaches of rules in more than half the fatal accidents analyzed. It was concluded that fatalities would continue to occur unless management found strategies to focus on the development of better support rules, compliance with rules, and improvements in technology to "counter against human error." Subsequent investigations have suggested that, apart from rules breaches, a major contributory cause of these incidents was inadequate mine design, including undersized pillars (J. Galvin, personal communication).

A supplementary study on roof and rib fall incidents commissioned by the NSW Department of Mineral Resources in 1999 updated the findings of the Roylett et al. 1991 study. It found that "to effectively minimise roof fall fatalities the industry must control the behavioural causal factors involved in these fatalities. In particular, miners going out under unsupported roof and not working to the support rules" (Pereira 1999).

Another research project focused on the development of more effective mine safety rules and regulations (Laurence 2002). Responses from almost 500 mine workers were analyzed and some simple guidelines established, in particular regarding rule content. The recommendations were that management and regulators should not continue to produce more and more rules and regulations to cover every aspect of mining. Miners will not read nor comprehend to this level of detail. Detailed prescriptive regulations, detailed safe work procedures, and voluminous safety management plans will not "connect" with a miner. The aim should be to operate within a framework of as few rules as possible, but rules of the highest quality.

Of course, achieving more effective rules and regulations is not the only answer to a safer workplace. Possibly less emphasis should be on content and more about the process, in particular ensuring that a positive safety culture exists and that communication channels are open and working well. This was confirmed in the survey when the expressions "simply bad rules" or "poor rules" were rarely blamed for accidents and incidents, risk taking, or error making. More often the problems of implementation, communication, and learning were the main causal factors.

The mine workers were also asked what they considered to be the major causes of accidents and incidents. Taking unnecessary risks was considered by far to be the most significant response, as shown in Figure 15.1-5.

Human error is defined by Reason (1990) as "the failure of planned actions to achieve their desired ends—without the intervention of some unforeseeable event." Errors can be divided into those where the plan was adequate but actions

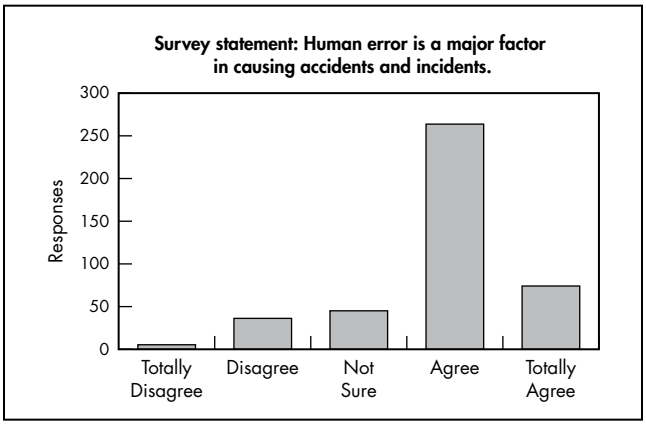

Figure 15.1-6 Miner survey results regarding human error and accidents

failed to go as planned, or those where the actions conformed to plan but the plan was inadequate. The former are known as slips, lapses, and trips, and the latter as mistakes.

There was general agreement among the mining work force that human error is a major cause of accidents and incidents, as illustrated in Figure 15.1-6. The major reason that people make errors is haste, according to the work force, as shown in Figure 15.1-7.

In his analysis of 25 incidents involving fatalities or serious injury, Joy (1999b) found that many were caused by management systems failures. Active human error was also a significant cause. The error was not generally intentional: "most active human error occurs where the person intended to do things correctly." Of the 25 accidents, 46% were violations; 31%, mistakes; 8%, slip/lapses; and 15%, no active human error. In some of these incidents, mine workers

- Were unaware of the rules,
- Were aware of but did not understand the rules,
- Mistakenly applied the rules,
- Ignored the rules,
- Deliberately violated the rules,
- Took a risk,
- Were unable to identify hazardous situations, or
- Were poorly trained or lacked sufficient educational background (Joy 1999b).

Further confirmation of the extent of the contribution of unsafe behaviors to accidents and incidents on mine sites in Australia is shown in Table 15.1-2. The table shows all published incidents over a 4-year period where a human factor can be identified. Such incidents are listed on the Web pages of each government mines' inspectorate in New South Wales, Queensland, and Western Australia. It can be seen that many of these accidents were caused, at least in part, by

- Lack of awareness of procedures or rules,
- Not complying with or ignoring rules,
- Lack of clear instructions,
- Poor communication generally,
- Production taking precedence over safety,
- Overriding or bridging out safety barriers,
- Inadequate training,
- Lack of familiarity with equipment, or
- Fatigue.

EXERCISING DUE DILIGENCE

It is important that mine managers are aware of the need for due diligence should an incident occur at their mine site. In the event of a serious incident, a regulator may wish to see

- A report of the incident;
- Whether it was reported to the authorities as required;
- Whether an accident report was filled out;
- What system of work was being used;
- What equipment was being used;
- The extent of the injured person's qualifications and experience in work of this type;
- Whether the injured person was inducted and trained;
- Who the supervisors and managers were, their qualifications and experience, and what instructions were provided to the injured person;
- Whether a risk assessment was carried out prior to the work;
- Whether a job safety analysis, safe operating procedure, or equivalent was in place; and
- Evidence of a safe system of work.

A SAFE SYSTEM OF WORK

An organization has implemented a "safe system of work" when it has employed and trained competent people, utilized fit-for-purpose equipment, and implemented effective systems and practices, all in a controlled work environment, as illustrated in Figure 15.1-8.

Competent People

To achieve safe production in a mine, competent people must be employed in senior management, in line management, and at the coal face. Evidence of competence includes inductions, training including refresher training, assessments, experience, formal educational qualifications, and so on. In most Australian states, mine managers have to demonstrate in a formal written and oral examination that they are competent to run a mine. They also need a degree or diploma in mining engineering or equivalent. Mine managers in New South Wales and Queensland are now required to hold the G3 certificate, which demonstrates competency in integrating risk management into the mining operation.

Equipment

Clearly the equipment and machinery used on a mine site needs to adequately carry out the task for which it was designed; it needs to be "fit for purpose." In recent times, manufacturers have worked in partnership with mines to continuously improve mining from a safety and ergonomic perspective.

Effective Systems and Practices

In an underground mine, examples of effective systems and practices include a safety management plan, ground control management plan, ventilation surveys, job safety analyses, formal risk assessments, and so on.

A Controlled Work Environment

Because of geological and geotechnical uncertainties, a controlled work environment is difficult to achieve, particularly in an underground mine. This can be overcome to a certain extent by ensuring that geological and geotechnical data is sufficient to enable sound decisions to be made for managing ground support, one of the principal hazards. Ground support measures are usually routine and can thus be considered as

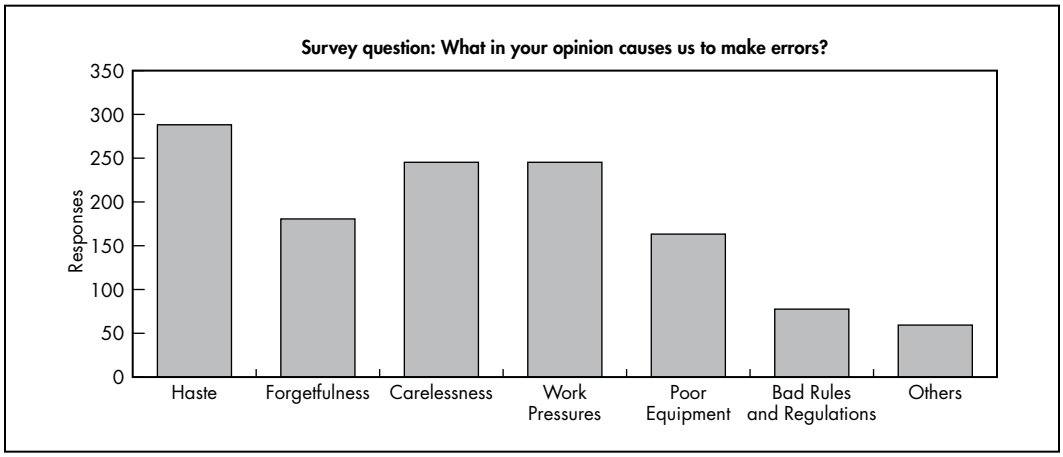

Figure 15.1-7 Miner survey results showing reasons for error

close to a controlled work environment as can be achieved underground.

AVOIDING MINE DISASTERS

In the past, there has been a tendency to focus on low-consequence, high-probability events, also known as "slips, trips, and falls." Doing this may certainly result in a lower injury rate and thus better safety statistics, which of course is one of the common key performance indicators of mine management. Experience shows, however, that if this aspect of safety is the only focus, opportunities may be missed for identifying potentially more damaging events, sometimes resulting in mine disasters.

Increasingly, the community is becoming less tolerant of any injury or human loss caused by mining and associated operations. Society is prepared to accept a certain amount of loss in mining, but community outrage may occur if fatalities are involved.

Reason (1997) argues that all organizational accidents arise from breaching a defense or series of defenses, barriers, or safeguards separating damaging hazards from vulnerable people or assets. Defenses should be present in layers, termed *defenses in depth*, and each defense would protect against the possible breakdown of the one before (Figure 15.1-9). Defenses should

- Provide alarms and warnings when danger is imminent,
- Restore the system to a safe state in an off-normal situation,
- Interpose safety barriers between the hazards and the potential losses,
- Contain and eliminate the hazards should they escape the barrier, and
- Provide the means of escape and rescue should hazard containment fail.

Many organizations harbor what Reason (1997) terms *latent conditions*, which resemble pathogens in the human body—they may be present for many years before they combine with local circumstances and active failures to penetrate the system's many defenses. Examples include poor design, gaps in supervision, manufacturing defects, maintenance failures, inadequate training, and impractical procedures. Latent conditions were present in the *Challenger* space shuttle tragedy, the *Herald of Free Enterprise* sinking, the *Piper Alpha* oil rig fire, and the underground fire at King's Cross Station in London, to name a few.

Using Reason's Swiss cheese example, an accident occurs when there is a connecting set of holes in successive defenses, allowing an accident trajectory to occur, as shown in Figure 15.1-9.

Hopkins (1999) analyzed multiple-fatality events at the Gretley mine in New South Wales and the Moura mine in Queensland, Australia, which resulted from water inrush and a coal dust explosion, respectively. He found the following indications:

- Normalizing of the evidence. In much the same way as the National Aeronautics and Space Administration's management and engineers came to regard O-ring failure in the space shuttle *Challenger* disaster of 1986 as normal due to the frequency of malfunction in earlier launches, Gretley supervisors and managers (and probably the employees as well) normalized the warning signs of water inflow.
- Management reluctance to withdraw workers from danger. Hopkins indicated that at both Moura and Gretley, common sense would dictate that workers not be placed in danger until the hazard had passed or been eliminated.
- A culture of denial. "New evidence appears reliable and informative if it is consistent with one's initial beliefs; contrary evidence tends to be dismissed as unreliable, erroneous or unrepresentative." There were strong production pressures at Moura, which may have resulted in a tendency to dismiss any contrary evidence. Hopkins calls this the culture of denial, "a set of beliefs which enabled management to deny that there was any immediate danger, no matter what the evidence."

Organizational and systemic factors are thus recognized as major contributors to mine disasters. Human factors also played a part in these mining disasters, namely

- Communication failures,
- Failure to recognize warning signs,
- Lack of knowledge about the hazards,
- Lack of training,
- Errors,
- Poor judgment, and
- Risk taking.

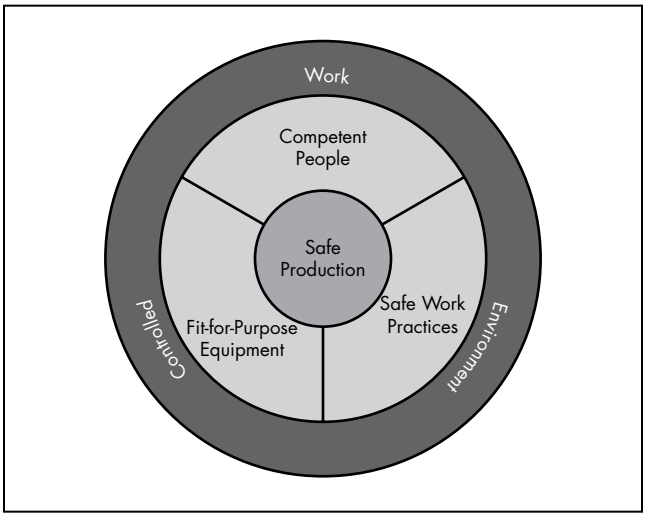

Table 15.1-2 Extracts from significant incident reports 1998 to March 2002, Queensland and New South Wales, Australia

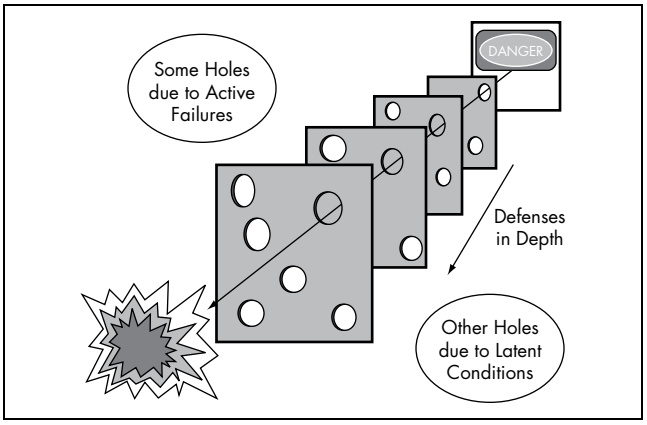
Incident	Behavioral Contribution to Cause of Incident
	Queensland Mines
Highway trucks collide	Local **road rules were not clearly understood and followed.**
Light vehicle drives off high wall	Operators should ensure that they are provided with **clear work instructions**, particularly where they are working in an area of the mine with which they are not familiar.
Catastrophic failure of a dragline boom	Unconfirmed reports indicate that draglines are now being loaded above their rated suspended load, in **a drive for greater productivity**.
Dump truck with unbalanced load becomes unstable	**A standing instruction** that large rocks are not to be loaded but reblasted **was ignored** by the shovel operator.
Driller reports for work in an intoxicated state	The driller's offsider was disciplined and given a mine site reinduction where the **statutory requirement of not reporting for duty in an intoxicated state** was stressed. His workmate was also given the same mine site reinduction.
Methane monitors were bridged out of circuit in two mines while producing coal.	On each occasion the tailgate methane **sensor was bridged out of circuit** during calibration checks and not recommissioned after these routine checks were completed.
Dumping overburden near coal crew operations	A dump truck operator dumped overburden outside of the allotted dump area **without knowledge or consideration of the potential consequences**.
An operator had two fingers pinned and a third severely lacerated when a bolting rig autoretracted.	Operator was attempting to do multiple tasks consecutively and **pinch points were not guarded or identified**.
Collapse of bridged material in pugmill feed bin	The plant operator walked along the edge of the top of the feed bin with **no safety belt/harness attached**.
Rigger struck on head by 500-kg assembly	The crews dismantling the crusher **did not understand** the function of the component parts or **were unaware** of the condition of the component parts.
Dozer runs over light vehicle	The mine site **procedure** for entry into a work area **was not followed**.
Truck falls backward over tipping edge	**Ignorance of safe work practices**; the truck driver was **not familiar with a safe procedure** for tipping over the edge of a stockpile.
Rollover of rear-dump truck	The height and size of the rill was inadequate and **not identified as a risk** by the operators. Lack of handover between shifts led to hazards in the workplace **not being communicated**. The dozer operator on the previous shift **had not worked to the mine's standard** for a dump area by allowing the dump face to become misaligned.
	New South Wales Mines
Two large trucks out of control	Maintenance, testing, and inspection of the braking systems were inadequate. Drivers **had not been given training** in emergency response procedures.
Danger from a misfire	**Communications were not clear** between the day shift and the night shift about the result of the refiring.
Unstable structure crushes workman	For some time before the accident, both the injured person and his supervisor **had worked more than 11 hours** a day.
Quarry worker killed by front-end loader	Management **should have safe work procedures in place** for people who need to approach mobile equipment. Everyone at a mine, including contractors and visitors, **should be trained** in the procedures.
Operator crushed by overturned forklift	**No standard operating procedures** were available. **No formal, refresher, or emergency training** had been given. The vehicle appears to have been **traveling too fast** for the conditions; the driver was **not restrained by a seat belt.**
Electric shock from damaged circuit breaker	The electrical maintenance engineer and the electrical staff generally were **not aware of this hazard**, even though it was reported in previous safety alerts.
Continuous miner drill rig fatally crushes tradesman	Managers should also address **basic hazard recognition and control skills training** as a priority.
Vehicle brake failure while travelling in a decline	If the truck were driven in third gear in the decline, it would have eliminated the need to use the brakes.
The 415-V conductors shorted out, and the power tripped off on short circuit.	The electrical contractor was **not aware** of the site *Electrical Management Handbook*.

Source: Data from Queensland Department of Mines and Energy 1998–2002; NSW Department of Mineral Resources 1998–2002.
Note: The behavioral issue in each incident is emphasized in bold.



Disasters in the mining industry are usually followed by a political and/or bureaucratic response in the form of inquiries, inquests, changes to legislation or restructuring, and re-resourcing of mines departments. Some ideas for reducing these potential disasters include the following:

- Better communication in both directions at mine sites, both top-down and bottom-up, will reduce the opportunity for a high-potential incident.
- Relying solely on sophisticated safety management systems is not enough; it is necessary to ensure that employees understand and are trained in procedures.
- Failure to comply with existing regulations can contribute to the making of disasters, as can out-of-date regulations. On the other hand, strict adherence to rules also causes disasters, as was shown in the *Challenger* explosion.
- There is a need to avoid normalizing abnormal events and to be aware of incremental changes in processes.

Source: Adapted from Nertney 1987 and Joy 1999b.

Figure 15.1-8 Work process model or Nertney wheel of safe work

Source: Reason 1997.

Figure 15.1-9 Reason's Swiss cheese model

- The development of active foresight, or what Reason (1997) describes as constant vigilance, will also help to reduce disasters.

CONCLUSIONS

Advances in mine safety over the past two decades have been significant. Apart from the obvious advances in technology that have made tasks more efficient and less physically intensive, other initiatives include

- Changes to the regulatory framework in the form of goal or performance orientation rather than prescribing how to achieve safety;
- Stronger enforcement and higher penalties for mine operators if an incident occurs;
- Better training and standards for the work force;
- Better systems and practices;
- More rigorous due diligence;
- More awareness of the importance of the human factor;
- Extra emphasis on reducing the risk of a large event occurring, rather than focusing only on the less damaging slips, trips, and falls;
- More sharing of safety information among mining companies and regulators, particularly through governmental Web sites.

CHAPTER 15.2

Health and Medical Issues in Global Mining

Frank H. Fox

INTRODUCTION

Mining normally takes place in remote areas, and as resources become increasingly scarce, new deposits are only found in the more inaccessible and inhospitable parts of the world. These are often in countries with poorly developed infrastructure and are characterized by extremes of terrain and climate, all of which contribute to potential medical and health challenges. Climatic extremes (heat, cold, high and low humidity, altitude, and hyperbaric conditions) increase the possibility of relatively minor medical conditions becoming major impediments to health, safety, and productivity and pose challenges to even the fittest individuals. Remote locations also bring psychological stresses that may manifest in the form of alcohol and substance abuse.

With a global shortage of skills in the mining industry it is likely that the work force will be a mixture of local and expatriate employees. Health problems may range from endemic diseases such as malaria to the psychological stress of isolation and continuous shift systems that can lead to wellness issues as well as alcohol and substance abuse.

Prevention of medical and health problems in mining operations (from exploration to production environments) starts with anticipation and recognition of the potential issues and proceeds with a thorough risk-assessment process inclusive of projected frequency and severity of incidents, development of risk-control measures, and allocation of adequate resources to implement the controls to manage the risk.

GENERAL APPROACH

The key to managing all potential health problems is prior risk assessment at the design stage of operations, before travel and before operations begin. During operations, continuous risk assessment is vital as things change. This is based on anticipation, recognition, evaluation, and control. Additionally, awareness of the differences between health and safety needs must be clear; too often, safety concerns are given priority over health issues. This is a short-term focus that must be corrected.

Global travel is so commonplace that travelers are often complacent about potential health risks. Yet the risks may be significant, even for local travel to mine sites within one's home country. And while mining and its associated processes have become safer over the years, and engineering design and equipment have improved, the extraction of minerals remains an inherently hazardous task. Mining requires close attention to detail to avoid these hazards.

Historically, mining has focused primarily on accident rates as the primary driver for performance measurements and safety awards. Improvements in engineering and processes have resulted in fewer accidents, but similar improvement has not been achieved for illnesses. In fact, some engineering improvements may have inadvertently contributed to an increase in health issues such as obesity, risk of cardiovascular disease, and cumulative trauma as more tasks have been engineered to reduce physical effort.

The following factors should be considered when planning for optimum health of mine workers: location of the site, climate, endemic diseases, local infrastructure (health care, transport, and accommodations), local legislation, the make-up of the work force (local, expatriate), the process (ore, products, and effluent), and shift system (continuous operation, fly-in/fly-out, etc.). If the site is an exploration base, travel to and from the site may pose a health risk and should be considered.

There are three ways in which health can be approached with regard to mining: those issues that affect personal health, those that concern occupational health, and those that relate to health in the community. These overlap in a number of areas but can be usefully approached in these subdivisions. A few of the more well-known conditions will be presented together with an approach for management from the mining engineer's perspective. Mining engineers will gain a basic understanding of the health issues that face them and an approach to dealing with them.

PERSONAL HEALTH

Personal health conditions and behaviors start at home, are taken to the mine site, and continue with residence there. A worker's lifestyle (diet, exercise, sleeping habits, stress level, substance abuse, etc.) has as important an affect on health and safety as conditions at the mine itself. Hazards at

Frank H. Fox, Head of Occupational Health, Anglo American plc, Johannesburg, South Africa

the mine site will include the location and local infrastructure of the mine and the occupational health hazards that may be encountered in the mining environment. In addition, there may be local climatic conditions that pose a risk: excessive humidity or low humidity, high altitude, and exposure to ultraviolet radiation.

Exposure to infectious diseases can occur both on and off the job. The specific diseases vary from country to country and cover the entire spectrum of bacterial, viral, protozoal, fungal, and parasitic infections. Exposure to disease occurs through personal contact, insect vectors, food sources, contact with animals, and water.

Malaria, tuberculosis (TB), and HIV/AIDS (human immunodeficiency virus/acquired immunodeficiency syndrome) are three prevalent diseases that are currently receiving worldwide attention. These diseases are not only important at a personal level but also as social issues in the communities surrounding mines in many developing countries. Ultimately they are an important factor in the productivity of the work force. These will be treated separately, as they illustrate the spectrum of involvement and intervention that may be needed in mining.

Traveling—locally and globally—presents its own unique set of health risks. Before traveling to exotic or unfamiliar locations, it is wise to seek advice from a health practitioner who is knowledgeable about worldwide medical issues, as well as from local medical practitioners who are experienced in dealing with health concerns specific to the area.

Health insurance is an important consideration when traveling and particularly when engaged in exploration work. Local health care facilities may be less than ideal, and suitable emergency evacuation arrangements should be in place before the work is undertaken. Many companies employ paramedical personnel to provide a basic level of primary and emergency care on-site with additional arrangements in place for evacuation in case of emergency. However, the key in all situations is prevention of the emergency in the first place, which means evaluation of fitness before placement, correct prophylaxis for endemic diseases while on-site, and careful attention to public health measures.

Although often taken for granted, some mention must be made of personal hygiene. Work in hot, humid conditions, underground or topside in tropical climates brings with it potential health problems. Fungal infections, insect bites, and bacterial skin infections are a common source of disease and can become serious problems if neglected. These are often prevented through simple measures and attention to personal hygiene.

OCCUPATIONAL HEALTH

Sir Thomas Legge, the United Kingdom's first Medical Inspector of Factories (appointed in 1897), wrote a simple axiom that remains relevant today:

> All workmen should be told something of the danger of the material with which they come into contact and not be left to find it out for themselves—sometimes at the cost of their lives (Robbins and Landrigan 2007).

This principle is enshrined in occupational health and safety law and various International Labour Organization conventions, specifically in Article 9 of Convention 176 (ILO 1995).

A full discussion of occupational health is beyond the scope of this chapter, but there are a few basic points that should be considered. Occupational health is defined as follows:

> Occupational health should aim at the promotion and maintenance of the highest degree of physical, mental and social well-being of workers in all occupations; the prevention among workers of departures from health caused by their working conditions; the protection of workers in their employment from risks resulting from factors adverse to health; the placing and maintenance of the worker in an occupational environment adapted to his physiological and psychological capabilities and; to summarize: the adaptation of work to man and of each man to his job.
>
> The main focus in occupational health is on three different objectives: (i) the maintenance and promotion of workers' health and working capacity; (ii) the improvement of working environment and work to become conducive to safety and health and (iii) development of work organizations and working cultures in a direction which supports health and safety at work and in doing so also promotes a positive social climate and smooth operation and may enhance productivity of the undertakings. The concept of working culture is intended in this context to mean a reflection of the essential value systems adopted by the undertaking concerned. Such a culture is reflected in practice in the managerial systems, personnel policy, principles for participation, training policies and quality management of the undertaking (International Labour Office 1998).

These objectives might imply that occupational health is a medical issue, whereas in reality the second and third parts of the statement can only be achieved through application of engineering and human factors and ergonomic solutions. Occupational health and safety is thus an engineering problem, not a medical one, so it is essential that the mining engineer has an understanding of the health hazards that are inherent in mining.

Management is responsible for operating the mine and its associated processes in such a way that it does not pose a risk to the health and safety of the work force and the surrounding community. The focus should be on control of exposure to health hazards through the application of the hierarchy of controls from the design stage onward (see Table 15.2-1). Utmost attention to monitoring and maintaining those controls must be observed. This control must be supported by a program of environmental monitoring and medical surveillance of exposed people. None of this can be effective without the active involvement of all employees. Everyone should be informed, trained, and involved in the control and prevention measures that are put in place.

HEALTH RISK ASSESSMENT

The health hazards associated with mining are numerous and cover the entire spectrum of physical, chemical, biological, ergonomic, and psychological stressors. The mining process itself exposes people to dusts, fumes, and vapors of various

Table 15.2-1 Hierarchy of controls

Elimination Eliminate an unsafe process or substance (e.g., use ultrasound to clean components instead of chemicals).
Substitution Substitute a process or chemical with one that is safer (e.g., use water instead of chemical solvents).
Engineering controls Use physical controls that eliminate or reduce exposure (e.g., enclose the process, separate the worker, provide adequate ventilation [exhaust, directional, and natural], soundproof areas where there is a high noise level).
Administrative controls Practice safe work procedures and good housekeeping (e.g., cover containers, clean up spills, rotate jobs, reduce shifts, restrict eating or drinking to specific areas, maintain washing facilities, provide training).
Personal protective equipment Provide appropriate personal protective equipment for workers (e.g., gloves, hearing protection, overalls).

compositions and particle sizes; noise; vibration; radiation (ionizing and nonionizing); and ergonomic factors. Associated with this are ancillary engineering processes that present an additional set of hazards. Factoring in the location of the mine gives a complete picture of the occupational health risks of mining.

The first step is developing a program to ensure health and safety is risk assessment, followed by a program to control, monitor, and mitigate the residual risk. Health risk assessment (HRA) can be a complex process performed by a multidisciplinary team, but it can also be a basic process aimed at identifying the need for expert advice, intervention, and a more formal approach.

Typically, an HRA will take place in three stages: (1) a baseline or initial assessment to identify and prioritize potential risk; (2) an issue-based assessment to refine and quantify the risk identified in the initial assessment; and (3) continuous risk assessment. This final stage is integral to the ongoing risk management program and is a process of renewal that monitors the effectiveness of controls and continually assesses risk against process changes over time. Ultimately, an HRA should allow managers and workers in any industrial environment to answer these questions:

- What are the hazards in my operation or area of work?
- What am I doing to control exposure?
- What am I doing to monitor the controls and are they effective?
- Can I, and should I, do more?

HRA requires an understanding of the process, the hazards, and possible exposures inherent in the mining operation and an understanding of the potential health effects of any exposure. The team that undertakes an HRA therefore needs input from a process engineer, the medical staff, occupational hygiene personnel, line management, human resources, and the workers.

THE MEDICAL SIDE OF OCCUPATIONAL HEALTH

The medical component of occupational health is concerned with the contribution to HRA, assessment of fitness for work, medical surveillance, management of occupational diseases and injuries, and wellness of the work force.

Depending on the infrastructure in the area, the mine may also provide medical treatment for employees, their dependants, and, in some cases, the community. This may extend to public health issues such as disease control and management programs and, in remote sites where the mine provides all the infrastructure, sanitation and drinking water.

Fitness for Work

Assessment of fitness for work has a large impact on safety as well as productivity. It also is a means of preventing exposure of individuals with certain preexisting medical conditions to situations in the workplace that cause them undue risk. An example is the exposure of people with asthma to environments with irritant gases or sensitizing agents. In order for this process to be fair, it is essential that fitness criteria be based on the task and risks inherent in the particular position within the mine. This requires a job specification with fitness criteria derived from the HRA.

Fitness for work can also be extended into the wellness arena. Here the focus is on maintaining fitness through management of lifestyle (diet and exercise), stress, and chronic diseases. This may be achieved through specific wellness and employee assistance programs, or the company's in-house medical services. The athletic facilities provided in many mining towns support this approach to wellness.

Medical Surveillance

Medical surveillance is the process of screening for early signs of occupational disease and any signs of excessive exposure to hazardous agents in the workplace. The process involves recording an individual's occupational and medical history, undertaking a physical examination, conducting certain special tests (such as audiometry and spirometry), and, in some cases, biological monitoring (measurement of chemicals, metals, or metabolites in body fluids). In all cases this should be based on knowledge of the hazards and exposures in the workplace, with only necessary tests being done. In many countries, medical surveillance is a legal requirement, but regardless of location, all employees should be informed of the reason for testing and given the results with an explanation.

Occupational diseases are conditions that arise out of and as a consequence to exposure to a hazardous agent in the working environment. Typically there is a dose–response relationship between the exposure and the onset of the disease; that is, the exposure must be high enough and long enough to cause the condition. Examples of this are the dust diseases of the lung (pneumoconiosis) where an accurate diagnosis is based on exposure to a certain amount of dust over an appropriate period of time. In some conditions there may not be a clear dose–response relationship (such as allergies), and the condition is diagnosed on the basis of exclusion. Although the traditional occupational diseases have largely disappeared through better control of workplace exposures, there is still a risk from the many new chemicals and processes that are being discovered, and it is impossible to predict idiosyncratic reactions to chemical exposure. The mining industry needs to remain vigilant through continuous risk assessment with regard to exposure to potential health risks.

In most countries, exposure to hazardous agents in the workplace is regulated through the use of occupational exposure limits. These are typically based on a time-weighted average exposure over 8 h/d, 40 h/week. Management of exposure to health risks is through the application of engineering controls according to the hierarchy of controls.

The specific engineering approach to some of the health and safety issues falls into the disciplines of occupational (industrial) hygiene and ventilation engineering and is beyond the scope of this chapter.

Emergency treatment and management of occupational injuries is also a part of any medical service on a mine, and is too often the only consideration given. The scope will vary according to the site and the extent of the operation, but adequate preparation must be made for the emergency care and subsequent treatment of all possible injuries on the mine. Services may range from essential emergency care on-site with evacuation to a hospital to comprehensive on-site medical facilities that can provide sophisticated care quickly and efficiently.

Occupational Disease

Occupational disease may be acute or chronic, and despite the preventive measures outlined previously, occupational disease remains all too common, particularly in developing countries where legislation may not be as developed or effectively enforced. Acute conditions due to exposure to hazards in the workplace (such as muscular strains and sprains, dermatitis, and others) require timely diagnosis and treatment. Conditions such as silicosis and asbestosis (which occur after prolonged exposure) remain significant causes of both morbidity and mortality around the world, and despite having been almost eradicated in many countries, new cases of silicosis continue to be common in the developing world. Mining is an inherently dusty operation, and prevention of occupational disease requires a sustained long-term commitment to implementing and maintaining the hierarchy of controls. (Unfortunately, there is often a reliance on personal protective equipment as the main protection strategy.) The insidious onset of most occupational diseases contributes to the lack of a sense of urgency around prevention, and the overlap with some community diseases (e.g., asthma, skin disease, and TB) may contribute to the lack of recognition of the problem. The most common exposures throughout industry and mining include noise, heat, manual handling, vibration, and chemicals, leading to noise-induced hearing loss (NIHL), musculoskeletal conditions, and dermatitis as perhaps the most common diseases. Emerging risks include whole-body vibration, diesel particulate, nanoparticles, and psychological stress. Fatigue (often related to shift work) is also an important factor to consider, from both a safety and health point of view.

While this is not intended to be a text on occupational disease, a few conditions are worthy of brief mention, although this should not detract from the importance of any other condition.

Silicosis

Silicosis is one of the oldest recognized lung diseases due to dust exposure. In its typical form it is caused by exposure to crystalline silica dust at moderate levels over a period of 10 to 20 years. It is identified as a diffuse nodular pattern on the chest X-ray. This is due to the silica particles that provoke an inflammatory reaction and cause scarring of the lung tissue. In its milder forms it may not cause any appreciable symptoms, but with higher levels of exposure the scarring can be so severe that it interferes with the function of the lungs and the heart. In addition, there is an increased risk of TB in workers with silicosis, and silica has also been linked to lung cancer. There is no treatment, and the only solution is prevention through reduction of dust levels and avoidance of exposure.

Despite the large drop in the number of cases of silicosis in the developed world, there is no room for complacency. Surveillance in the United States showed a large reduction in the number of deaths attributable to silicosis between 1968 and 2005, but the incidence has leveled off since 1998 (Attfield et al. 2009). Although the incidence of silicosis has dropped significantly in developed countries through strict control, it cannot be assumed that current occupational exposure limits are entirely safe, and therefore it remains a risk (Park et al. 2002). In fact, the incidence of pneumoconiosis appears to be more closely correlated with the number of people employed in mining rather than the reduction in dust levels (Attfield et al. 2009). Silica is ubiquitous in soil and rock, and since it is not only hard-rock mining that poses a risk, it must be considered a hazard wherever mining is undertaken.

Noise-Induced Hearing Loss

Hearing loss from exposure to noise has been known since biblical times, and tinnitus (ringing in the ears) in blacksmiths is described in the book of Ecclesiastes. In more modern times it was described in coppersmiths and millers by Ramazzini (1713) in the 18th century. Despite its long history, NIHL remains one of the most common occupational diseases today, and it is a significant cause of morbidity.

Hearing loss can present in two ways: (1) acute, from exposure to very loud noise such as an explosion, and (2) chronic, from exposure to noise above 85 db for many years. The mechanism of damage is different between the acute and chronic types of hearing loss, with the acute form associated mostly with damage to the conduction system (the eardrum and small bones in the ear) and the chronic form associated with damage to the hair cells in the cochlea. Of the two forms, the chronic form of hearing loss is commonly referred to as NIHL. It typically presents with a slowly progressive loss of hearing, first in the higher frequencies and then in the frequencies used for speech. In many cases this is accompanied by tinnitus, which makes the disability even worse. The slow onset and the late age at which the condition occurs means that it may be confused with hearing loss due to aging. Occupational exposure to noise is not the only cause of NIHL, as any other source of loud noise (music, gunfire, etc.) can produce the same symptoms. In addition, some drugs and infections may cause a similar pattern of hearing loss. Modern hearing aids may provide some assistance with deafness, but in the presence of tinnitus this is doubtful. The best solution is prevention.

Heat Stress

Exposure to heat is a common problem in mining, whether on the surface or underground, and can lead to significant health and safety risks if not correctly managed. Any situation where there are high temperatures, high humidity, poor ventilation, or high radiant heat sources can result in heat stress.

There are four typical presentations of heat stress: heat fatigue, heat cramps, heat exhaustion, and heat stroke. Heat fatigue is a vague condition of impaired general performance and may be associated with mood changes. The behavioral effects of heat exposure should not be underestimated as they can lead to poor decision making that, in the mining and

industrial setting, can have a significant impact on safety. Heat cramps occur in the muscle groups that are most used in work and are painful spasms that last several minutes but are usually self-limiting. Heat exhaustion is the condition that results from excessive fluid loss and presents with dizziness, sweating, headaches, weakness, nausea, and vomiting. Heat stroke is the most serious of the conditions and results from failure of the thermoregulatory center in the brain. It is almost always associated with prolonged physical exertion in a hot environment and presents with extreme hyperthermia (body temperature above 41.1°C or 106°F); confusion; collapse; and, typically, hot, dry skin (although this is not always the case). If not treated effectively, heat stroke can be rapidly fatal. Heat exposure can also cause a skin condition known as prickly heat, which is an acute itchy dermatitis.

Heat exposure is a combination of the ambient environmental conditions, the heat generated internally by physical effort, and the ability of the body to cool itself. There are four basic mechanisms of heat exchange involved: convection, conduction, radiation, and cooling through evaporation.

The management of risk from heat exposure starts with awareness of the problem, environmental controls where possible, increased fluid intake (200 mL/20 min), and control of physical exertion (increased work breaks) in hot environments. Salt tablets are often mentioned, but this may do more harm than good; simply increasing the amount of salt in the diet is all that is required. Acclimatization does occur after a period in a hot environment, and many deep-level mines have acclimatization programs for new workers. This reduces the risk, but there are some individuals who will remain at high risk for heat disorders. Age (over 50), obesity (body mass index >30), certain medical conditions, and a previous history of heat disorders all increase the risk of heat stroke and should be considered as barriers to working in hot environments. For a more complete review of the management of risk due to heat in the mining environment, see the chapter by Johan Kielblock in the *Handbook of Occupational Health Practice in the South African Mining Industry* (Kielblock 2001).

Fatigue

Mine work, with its physical nature, remote locations, and the need for continuous production, creates an environment in which fatigue is an ever-present risk. Fly-in/fly-out work rosters with 12-hour shifts over prolonged periods and sometimes long commutes make it difficult to avoid fatigue. Despite increased mechanization of the work, the rough terrain and long shifts make the work physically tiring.

The term *fatigue* is used in various ways to describe localized tiredness of muscle systems or in the general sense of tiredness. It can be acute or chronic, and in this chapter the term is only used in the general sense.

Fatigue manifests as increasing difficulty in performing physical or mental activities. This in turn results in poor productivity and poor decision making, which can be a safety risk. In its acute form, fatigue may simply present as sleepiness, but chronic fatigue may lead to more general effects such as mood disorders, stress, digestive problems, heart disease, and mental illness. The causes of fatigue are many, but put simply, fatigue in the workplace is the sum of the interaction between the shift system, the physical workload, and personal factors (such as diet, sleep, overall health, drug use, etc.). These can be combined into an equation that provides a useful reference for managing the risk from fatigue in the workplace (Schutte 2008):

$$F_t = F_{ss} + F_{ew} + F_{pf} \quad (15.2\text{-}1)$$

where

F_t = total fatigue
F_{ss} = fatigue due to the shift system or roster
F_{ew} = fatigue due to ergonomic and work factors
F_{pf} = fatigue due to personal factors

The management of the risk from fatigue starts with recognition and assessment of the risk followed by implementation of an integrated plan to deal with the three components of the equation. Shift rosters should be designed to minimize sleep loss and the accumulation of sleep deficit. Shift lengths should be considered in conjunction with travel time as it is time awake that is important rather than just the length of the shifts. Tasks should be designed to reduce repetitive work, and work requiring sustained physical or mental effort should be broken up with short breaks. Personal factors must also be taken into account and are managed mostly through education, but some arrangements to improve quality of sleep through provision of decent accommodations and recreation facilities at the work site can be made. Where there are rotating shifts, education of the family about the social adjustments needed may also help in ensuring good quality rest for the worker. Diet, general health, and use or misuse of drugs and alcohol should also be addressed in the plan. Numerous guidelines are available regarding the prevention and management of the risks associated with fatigue. An Internet search for government documents on fatigue management will generate many reliable sources for up-to-date information on the subject.

Wellness

Employee wellness is a common part of many occupational health programs, particularly in developed countries, and is concerned with maintaining and improving the health and productivity of employees. This is achieved through targeted interventions on lifestyle management, stress management, and assisting employees in managing chronic illnesses. Employee assistance programs providing access to counseling services are a common intervention. The objective is a fit and healthy work force that has a direct impact on improved productivity and reduced health care costs to the company. In the context of a remote mine site, these programs may cross over into other aspects of community life such as recreational facilities and opportunities, provision of family accommodations, drug and alcohol programs, and many other interventions.

COMMUNITY HEALTH

The community surrounding any mine is intimately linked with the process through employment, emissions from the process, and the impact the mine has on the economy of the area. The influx of people seeking employment creates a demand and a strain on existing health care infrastructure and may provide the stimulus for the creation of additional or new infrastructure.

The mine may have some direct effects (both positive and negative) on the health of the community as well as some indirect effects. The health and welfare of the community also has an important influence on the mine's license to operate, and increasingly there is a call for health impact assessments to be carried out, both before and during operation of the mine.

These impact assessments should address the infrastructure needs, the potential health impact of the mine on the community, and the impact of any common diseases in the community on the mine. Malaria, tuberculosis (TB), and HIV/AIDS fall into this last category and there is a significant interaction in both directions.

Malaria, TB, and HIV/AIDS are perhaps the three most important communicable diseases in the world today; combined, they account for some 4 million deaths worldwide (WHO 2008; UNAIDS 2008; Global Malaria Partnership n.d.). The areas where they occur overlap considerably, and there is some interaction between the three diseases: HIV increases the risk of TB, TB hastens the onset of AIDS, and it would appear that malaria may increase the viral load in HIV infection (although this is not yet well understood). Exposure to silica dust in mining increases the risk of TB, and the in-migration generated by mining employment has a direct effect on increasing the prevalence of malaria and HIV. Since mining often occurs in countries where these diseases are prevalent and there is a direct relationship between mining and the risk of these diseases, it is important that the mining engineer has some basic understanding of the possible effects and interventions required.

The business case for managing these three diseases is compelling: companies that have good programs for managing these diseases in the workplace experience a range of bottom-line benefits that include

- Reduced employee turnover,
- Reduced absenteeism,
- Improved productivity,
- Decreased costs of health care,
- Access to international funding for mine development, and
- Enhanced company reputation and community relations.

The approach to managing these three diseases or any other disease that may be of concern to the mine should be based on a structured assessment of the risk leading to the development of a management program based on that assessment (see Table 15.2-2). Again, risk assessment is the starting point for management. It is beyond the scope of this chapter to describe the approach in detail, and only a brief overview of each disease is given. Because the three diseases have much in common, a case can be made for having an integrated approach to management. An extremely useful reference for an approach to these three diseases is the International Council on Metals and Mining's *Good Practice Guidance on HIV/AIDS, Tuberculosis and Malaria* (ICMM 2008).

Table 15.2-2 Management planning process for HIV/AIDS, TB, and malaria

Risk Assessment (Do we need the program?)	
1. Screening	Decide whether (or not) one or more of the diseases needs to be managed.
2. Scoping	Increase understanding of the nature and extent of the disease and the associated risks.
3. Situation analysis	Develop a health baseline.
4. Stakeholder analysis	Participate in a process of information sharing, problem solving, and identification of potential partners.
Risk Management (What do we need to do?)	
5. Priorities, goals, and objectives	Decide whether (or not) one or more of the diseases needs to be managed.
6. Scoping	Increase understanding of the nature and extent of the disease and the associated risks.
7. Situation analysis	Develop a health baseline.
8. Stakeholder analysis	Participate in a process of information sharing, problem solving, and identification of potential partners.

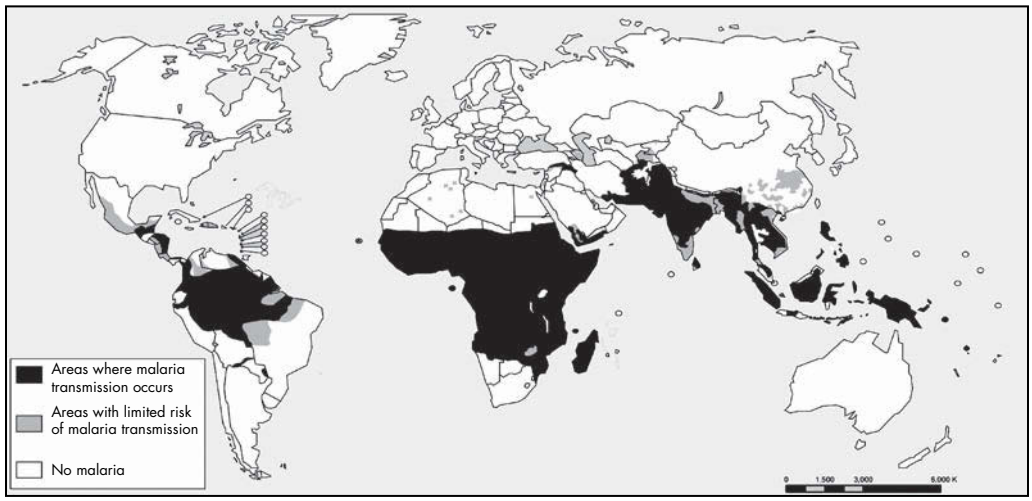
Malaria

Malaria is an infectious disease caused by an intracellular parasite that is spread by the bite of the female *Anopheles* mosquito. The distribution of the disease is mainly tropical (see Figure 15.2-1), but it is also found in other parts of the world, carried by travelers returning from areas where the disease was picked up.

Four species of the plasmodium parasite cause malaria in humans: *Plasmodium falciparum, Plasmodium malariae, Plasmodium ovale,* and *Plasmodium vivax.* Of these, *P. falciparum* is the cause of the most severe form of malaria and has a significant mortality in nonimmune people. It is also becoming resistant to many of the more common drugs used to treat malaria.

The symptoms of malaria mimic those of influenza in the early stages and include headache, chills, fever, malaise, and vomiting. These usually start about 10–15 days after infection, and diagnosis and effective treatment is essential to prevent severe illness (which may have fatal complications).

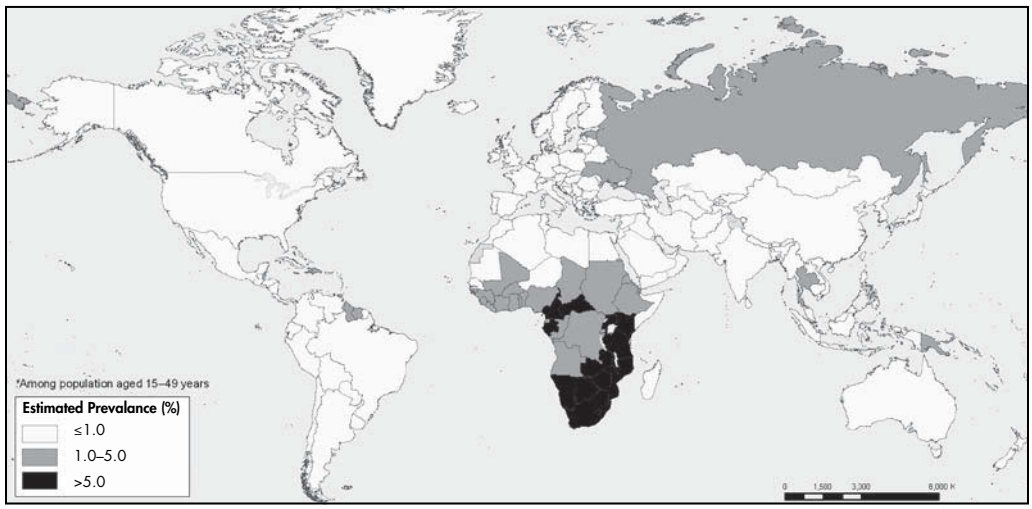
The diagnosis is made through the use of tests similar to a pregnancy test and examination of blood under a microscope (looking for the parasite in red blood cells).



Treatment of uncomplicated cases is with combinations of a drug based on the Chinese plant *Artemisia annua* and another drug, lumefantrine. Complicated cases are usually treated with quinine. Depending on the parasite, further treatment to clear the parasite from the liver may also be required.

People who have not been exposed to malaria all their lives are regarded as nonimmune, whereas those who have been born in and grown up in malarial areas may develop some immunity. This does not mean they do not get malaria; it merely means they are less likely to get the severe forms of the disease.

Malaria Control Programs



Three components of malaria control are control of the vector, control of exposure to the vector, and chemical prophylaxis. The vector is the female *Anopheles* mosquito, which breeds in stagnant water. It also has certain habits (such as settling on window and door frames) that facilitate transfer to humans. Vector control therefore involves management of sources of stagnant water and spraying campaigns. This is an engineering solution, as drains, sewers, and other sites for stagnant water have to be actively managed. Spraying of buildings with residual insecticides is an important part of many programs, and the specific insecticide used varies depending on the time and place. DDT (dichlorodiphenyltrichloroethane) is still advocated in some areas as it has long residual effects on buildings, but must obviously be used with extreme caution because of its environmental impact.

Control of exposure involves behaviors such as wearing long-sleeved shirts and long trousers, avoidance of being outdoors at dusk when the mosquitoes are most active, the

Source: WHO 2009.

Figure 15.2-1 Global distribution of malaria in 2009

Source: WHO 2007a.

Figure 15.2-2 Estimated HIV/AIDS prevalence in 2007

use of mosquito repellents (both on the person and airborne), and barrier methods such as insecticide-treated bed nets. Chemoprophylaxis involves taking medication to suppress the parasite before it can grow in the bloodstream. These drugs should not be the same as those used to treat the condition, and medical advice should be sought on which is the most appropriate drug for the area and the period of use. It may only be practical for expatriate (nonimmune) employees, but there may be some use for general prophylaxis in the community surrounding the mine, which will reduce the reservoir of the parasite. Expert advice in this regard is essential.

A common myth surrounding malaria is that taking malaria prophylaxis hides the disease and makes the diagnosis more difficult. This is untrue and, in fact, dangerous as the complications are more likely in the nonimmune person who is not taking prophylaxis. It is true that no single prophylactic measure is 100% effective, but these all rely on human behavior. A high degree of suspicion and prompt diagnosis and treatment of malaria is essential.

HIV/AIDS

In 2007, UNAIDS reported that there were an estimated 33.2 million people living with HIV/AIDS, 2.5 million new infections, and 2.1 million deaths worldwide. More than 68% of people living with HIV/AIDS are in sub-Saharan Africa, and 76% of all deaths from AIDS occurred in this region (Figure 15.2-2).

AIDS (acquired immunodeficiency syndrome) is a condition caused by infection with the human immunodeficiency virus (HIV) and has collectively become known as HIV/AIDS. The virus is a lentivirus, one of a group of viruses known as retroviruses that attack the white blood cells of the body (specifically the CD4+ T-lymphocyte). The infection results in a gradual deterioration of the immune system, leaving the individual susceptible to a variety of opportunistic infections and some cancers. Transmission of the virus occurs through contact of a mucous membrane or the bloodstream with infected body fluids such as blood, semen, vaginal secretions, and breast milk. Contact can occur through sexual intercourse,

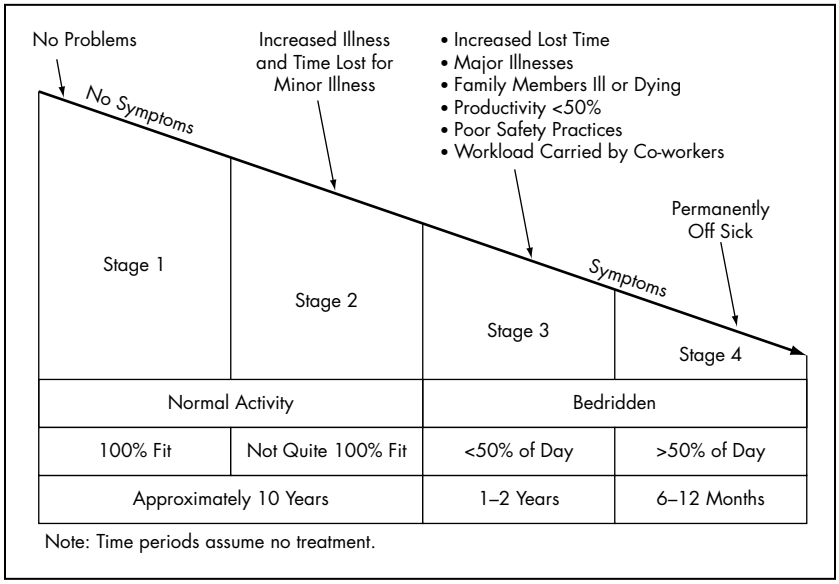


Figure 15.2-3 Stages of HIV infection

blood transfusion, use of contaminated hypodermic needles, and between mother and baby.

HIV infection carries no specific symptoms; in the primary infection it causes a short flu-like illness, but after that, the symptoms are those of the particular opportunistic infection that the person may have. The diagnosis of HIV infection is made by testing a blood (or saliva) sample for the presence of antibodies to the virus. There are various methods for antibody detection and usually the diagnosis is confirmed by a second test using a different test for the antibody. There are also tests for the presence of the virus, and viral counts are done using recombinant DNA techniques, normally used for monitoring the response to treatment.

HIV is no longer the death sentence that it was 15 years ago, and combination therapy with highly active antiretroviral drugs has made this just another chronic disease for many people. However, it is important that treatment is started before the disease has progressed too far. It is also important to prevent the spread of the virus from mother to child during childbirth and breastfeeding, and effective drug regimens exist for this purpose.

Workplace HIV Programs

HIV is preventable, and the primary goal of any workplace program should be to prevent new infections in employees. In addition to this, workplace programs should seek to provide care and support for those who are infected, and build capacity in senior managers to deal with the workplace issues of people living with HIV/AIDS. Any workplace programs developed should be aligned with and support the efforts of the local state health services.

A strong commitment and concerted efforts from management and unions, backed up by company policy, is essential for success. As a minimum, the policy should address the issues of stigma and discrimination, confidentiality, care and support, employment, and workplace voluntary counseling and testing.

The disease typically goes through four stages, and the intervention at each point is different. Figure 15.2-3 shows the stages from an employer's perspective. In the early stages of infection, there are no symptoms and relatively minor illnesses only. This may have little or no impact on productivity; however, this is perhaps the most dangerous stage as the individual is infected, infectious, and very often ignorant of their condition. They are also on a downward slope as far as health is concerned (as measured by the CD4 cell count). Voluntary counseling and testing (VCT) programs not only create an awareness of the disease among those who are HIV negative but also creates opportunities for those who are infected but still well enough to prevent further spread of the disease and maintain their health. Treatment with antiretroviral drugs can be started at the optimal time, and mother-to-child transmission prevented, but only if the infection status is known.

When the disease has progressed to the symptomatic stage, the only option is treatment and prevention of transmission. With early recognition of the infection through VCT and initiation of antiretroviral treatment at an appropriate point, Stages 3 and 4 can be almost indefinitely delayed. Unfortunately, many people leave the diagnosis of HIV and appropriate treatment to a late stage when treatment may not be very effective. However, even at this stage many people are able to return to productive employment and continue to support their families.

HIV/AIDS is seldom an infection that involves only one partner and it is essential that any management program involve the dependents of the employee. Education, access to counseling and testing, and possibly even provision of treatment should be considered. State health programs may provide all this but may need support. In addition, there are numerous donor agencies that can offer help and support in setting up and running HIV/AIDS management programs (ICMM 2008).

Tuberculosis

The global distribution of TB is shown in Figure 15.2-4. Note the similarity with both HIV/AIDS- and malaria-prevalent areas.

TB is a disease caused by a rod-shaped bacterium (bacillus) known as *Mycobacterium tuberculosis.* According to the

Source: WHO 2007b.

Figure 15.2-4 Global distribution of tuberculosis in 2007

World Health Organization (WHO), it infects about one-third of the world's population. Most of this is latent infection rather than active, but WHO estimates that in 2006, 1.5 million people died of TB, with another 200,000 dying of HIV-associated TB (Attfield et al. 2009). In latent infection, the body seals off the bacteria in small numbers and the disease remains dormant. However, this dormant infection can become active if the immune system is compromised by, for example, HIV. The estimated risk of an infected person becoming sick is between about 5% and 10% during their lifetime, but when HIV is a factor, the risk rises to between 10% and 15% per year.

Most commonly, TB causes a respiratory illness (pulmonary TB), but it can infect any organ in the body with devastating consequences. The disease is spread by droplet infection through coughing.

TB is a disease with a slow onset, and the symptoms may be insidious and difficult to diagnose, which means the diagnosis may often be late. Typically it will present with a cough, weight loss, and profuse sweating at night. The cough may be accompanied by bloodstained phlegm, but in the early stages this may not occur. The infected person, unaware, may infect many others before the diagnosis is made.

TB is a preventable and treatable condition. Prevention can occur at two places in the cycle of infection, the first being the interruption of the passage of the bacillus from an infected person to an uninfected person, and the second being the prevention of those who are infected (latent infection) from developing active disease. In the first instance, the focus is on finding and treating infectious cases, and in the second, the focus is on maintaining good health.

Treatment consists of a prolonged course (6 months) of multiple drugs (usually three), and good compliance to the treatment regimen is needed for a cure; this requires rigorous follow-up of cases by health care workers. The treatment program devised by WHO to assist with these requirements is known as "directly observed therapy short-course" (DOTS). It aims to ensure that treatment is taken as instructed and may involve family, friends, co-workers, and health care workers assisting the individual to comply with the treatment course. Despite this, poor compliance with the treatment remains a problem, and in resource-constrained countries, where medical staff numbers are low and drug supplies may not be continuous, drug-resistant strains of the bacteria have emerged. This has been complicated by the HIV epidemic, and multidrug-resistant (MDR) and extensively drug-resistant (XDR) cases are becoming commonplace in some countries. This is an extremely serious situation in some locations as XDR cases mostly have a fatal outcome and MDR cases are increasingly difficult to treat. Education, awareness, and an ability to detect cases is therefore essential for both prevention of the spread of TB and the treatment of those who are ill.

From a mining company perspective there are several things that can be done to manage the risk from TB. First, hostel-type accommodations should be avoided if at all possible. Second, education programs, together with active case-finding, should be undertaken. These can be accomplished through collaboration with local health authorities or through the mine's own health services. Where the risk coexists with HIV, the two programs can be combined.

For a detailed and thorough review of this subject, see the ICMM *Good Practice Guidance* document (ICMM 2008).

CONCLUSION

Although the focus may appear to be on HIV/AIDS, TB, and malaria due to their global importance, it must not be forgotten that there are numerous other infectious and noninfectious diseases that can and do affect the productivity and health of miners. These lend themselves equally to the approach advocated in this chapter, namely, risk assessment followed by a structured management program if the condition is found to be a significant problem to the mining operation. The same approach at an individual level is equally important for the management of personal risk due to the possible health risks that may arise.

CHAPTER 15.3

Mine Ventilation

Michael A. Tuck

INTRODUCTION

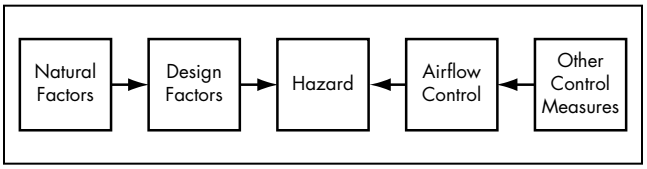
Ventilation in underground mines is an essential element to ensure safe production of minerals. The basic objectives of any ventilation system are clear and simple: to provide airflows of sufficient quantity and quality to provide oxygen, and to dilute contaminants to safe concentrations and remove them from the mine. These basic requirements are enshrined in law in all countries; however, the quantity and quality requirements can vary greatly from country to country depending on a large number of factors as well as the situation being ventilated: coal, metalliferous, industrial minerals, or gassy/nongassy. The overall requirement is that workers must be able to live, work, and travel within an environment that is safe and provides reasonable comfort. Ventilation can also be employed in situations where human intervention is not required, but an adequate oxygen supply is required to operate and/or cool machinery or to provide oxygen to combustion processes.

Mine ventilation can be defined as the application of the principles of fluid mechanics and thermodynamics to the flow of air through mine openings. Air is introduced into the mine from the atmosphere, it flows around the mine, and it is expelled back into the atmosphere by the creation of a differential pressure between the intake and return openings of the mine. To achieve this, the mine ventilation system consists of interconnected airways and working zones within the mine, connections to the surface, fans to produce airflow, and control devices to ensure that the air courses around the mine as required. Controlling a ventilation system requires quantity as well as air quality control, and ventilation planning techniques are employed to achieve this.

This chapter concentrates on the fundamentals of mine ventilation engineering and its application to both coal and hard-rock mining. Other chapters in this handbook deal specifically with individual mine air pollutants.

PURPOSE OF MINE VENTILATION

The primary purpose of ventilation is to maintain an atmosphere that promotes a safe and effective work environment. This includes management of oxygen content and levels of contaminants including toxic gases, combustion products, and dust, plus maintaining workplace temperature conditions at levels where workers can achieve maximum efficiency. Legal limits relating to exact standards for the work environment vary depending on the purpose of ventilation as well as from country to country and state to state within some countries. Other than where prescribed by a definitive legal standard, a useful minimum oxygen concentration to apply to the design of any ventilation system is 19% oxygen by volume.



Pollutants enter a ventilation airstream from a variety of sources. The aim of any ventilation system is to dilute any pollutants to a safe level and then remove them. The range of pollutants that can be released into a ventilation system depends on the situation under consideration. Some of the more common types of pollutants encountered include

- Gases,
- Products of combustion,
- Dusts,
- Heat and humidity,
- Radioactive solids and by-products, and
- Diesel particulate matter.

Figure 15.3-1 shows the factors that contribute to hazards encountered in mine ventilation and the methods of control. The factors are divided into those imposed by natural conditions and those imposed by the design and engineering decisions regarding how the mine is to be developed and how ore is to be produced. The natural factors include geology, depth, surface climate, gases contained in the rock mass, ground water and other fluids, the physical and chemical properties of the rock, and the age of the workings. The engineering design of a mine impacts the hazards through the

- Mining method used,
- Method of fragmentation of rock,
- Rate of fragmentation of rock,
- Use of backfilling materials,
- Types of power used underground,
- Types and number of vehicles in the mine,
- Method of ore and waste removal,

Figure 15.3-1 Factors contributing to hazards and methods of control in mine ventilation

- Types and quantities of materials stored and/or used in the mine, and
- Mine layout and the number and interconnectedness of the airways in the mine.

All mines are different, so the pollutants and their effects vary between mines, locations, and the cycle of operations within a mine (see Appendix B, Coal Mine Gas Chart). As an example, a deep mine in Canada may have issues with cold conditions in the shallower sections of the mine requiring mine heating during the winter months, while at the deeper levels the air has to be cooled by refrigeration. In addition to the ventilation pollutants, other hazards associated within a mine ventilation system are underground fires and explosions.

The main method of controlling the atmospheric conditions in an underground mine is by airflow. Fans generally induce the flow of air in mines, although natural ventilation due to air density changes can provide some airflow in modern mines. Main fans handle the whole mine airflow (singly or in combination) and are commonly sited on the surface, although at a number of mines they are sited underground. Legislation in some areas may require that main mine fans can only be located on the surface and in some cases may have to be reversible. While main fans generally handle all the mine airflow, other fans are used in mines to boost the airflow energy to allow air to be circulated over greater distances. These are called booster fans, and they generally serve specific areas of the mine. In mine development headings, a through-flow of ventilation may not be possible as the drive is single entry. In these cases an intake and return path for the air needs to be developed. In modern mining this is generally undertaken by using auxiliary fans to pass air through ducts to ventilate the blind entries. Alternatives include the use of brattice cloth and in some cases jet fans. Air doors, regulators, stoppings, seals, and air crossings control airflow distribution further.

While airflow is the primary method of achieving the goals of mine ventilation, in some situations the airflow required would become too costly to mine economically. In such cases other methods of control can be employed to reduce the load on the ventilation system so that the ventilation costs can be decreased. These methods include methane drainage, mine heating and cooling systems, dust suppression systems, and various other monitoring and control systems. These basic elements of a mine ventilation system are described in the video *Breathe and Live*, which can be viewed on the Mine Safety and Health Administration Web site (MSHA 1973). This video presentation details the hazards present from a ventilation perspective in underground mining, provides details of ventilation systems and devices, and includes an overview of equipment to provide ventilation and systems of auxiliary control such as heating and cooling systems. It is an old presentation, but it details the fundamentals of ventilation in an easy-to-understand format.

THEORY OF MINE VENTILATION

The background theory of mine ventilation comes from fluid mechanics and thermodynamics, specifically the Bernoulli equation, the steady-flow energy equation, and the Chezy–Darcy law for frictional pressure drop in a pipe. Atkinson (1854) developed the basis for the theory of mine ventilation that is still in use today. Taking fluid mechanics theory as a base and introducing a number of simplifying assumptions, he developed a series of equations that still form the basis of current ventilation theory and modern mine ventilation planning software. As described here, the theory uses an assumption of incompressibility. As modern mines progress to greater and greater depths, this assumption frequently becomes invalid due to changes in air density. Where changes in elevation and temperature produce changes in density greater than 5%, the assumption of incompressibility becomes flawed and must be taken into account.

Mine Airway Resistance (Atkinson's Law)

The Atkinson equation is based on the fundamental work undertaken by the French hydraulic engineers Chezy and Darcy. The Chezy–Darcy equation states the following for a pipe:

$$p = fL\frac{per}{A}\rho\frac{u^2}{2}$$

where

p = pressure drop (Pa)
f = friction coefficient
L = length (m)
per = perimeter (m)
A = cross-sectional area (m^2)
ρ = density ($kg/m^{3)}$
u = velocity (m/s)

For fully developed turbulent flow, Atkinson assumed that the coefficient of friction was a constant. Also assuming that the air density was a constant, he was able to combine the constants into a single factor known as the Atkinson friction factor, k (kg/m^3),

$$k = \frac{f\rho}{2}$$

giving

$$p = kL\frac{per}{A}u^2$$

This is known as Atkinson's equation and can be written in terms of air quantity Q (m^3/s), where $Q = uA$, giving

$$p = kL\frac{per}{A^3}Q^2$$

For any given airway, the length, L, perimeter, per, and cross-sectional area, A, are known. Ignoring the dependency on density, the friction factor varies only with the roughness of the airway lining for fully developed turbulent flow, so all

these factors can be collected together to form a single variable or characteristic number, R, for that airway, where R is known as the airway resistance.

$$R = kL\frac{per}{A^3}$$

This gives the square law of mine ventilation:

$$p = RQ^2$$

where

p = pressure across airway (Pa)
R = resistance or Atkinson resistance ($N \cdot s^2/m^8$)
Q = air quantity (m^3/s)

The equation assumes a constant density; usually this is standard air density of 1.2 kg/m^3. Values of R quoted in design tables usually refer to this standard density. For other air densities, ρ, the following can be used to give the frictional pressure drop and resistance:

$$p = k_s L\frac{per}{A^3}Q^2\frac{\rho}{1.2}$$

$$R = k_s L\frac{per}{A^3}\frac{\rho}{1.2}$$

where k_s is the friction factor at air density 1.2 kg/m^3.

From these calculations it is clear that the degree of roughness of an opening underground (k) has an important influence on its resistance and the cost of passing air through that opening. It also directly influences the heat transfer rate between the rock and the airstream. The friction factor, k, can be determined in a number of ways, details of which can be found in McPherson (1993):

- By analogy with similar airways, from ventilation surveys
- By direct measurement
- From design tables (see Table 15.3-1)
- From geometric data

Airway resistance (R) is an important concept in ventilation engineering. The square law states

$$p = RQ^2$$

This shows the resistance to be a constant of proportionality between the frictional pressure drop, p, and the square of the airflow, Q, at a specified air density. The parabolic form of the plot on a p, Q graph as shown in Figure 15.3-2 is known as the airway resistance curve.

The cost of passing any airflow through an airway varies directly with the resistance of that airway. This can be determined by evaluating the air power consumed in an airway using air power = $p \times Q$ or knowing $p = RQ^2$, resulting in air power = RQ^3.

Using a cost per kilowatt-hour for electricity, the cost to ventilate an airway can be simply determined. The equation also shows that doubling the airflow in a particular airway has the effect of multiplying the air power and hence the ventilation cost by a factor of 8.

Table 15.3-1 Friction factors (referred to an air density of 1.2 kg/m^3) for a variety of mining situations

Type of Airway/Ducting	Friction Factor k, kg/m^3
Rectangular airways	
Smooth concrete lined	0.004
Shotcrete	0.0055
Unlined with minor irregularities only	0.009

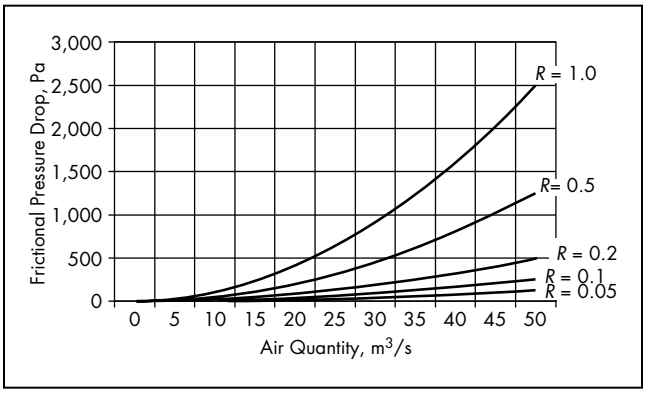
Shock Losses

The theory outlined previously enabled the frictional pressure drop to be evaluated for an airway. In addition to the frictional or rubbing resistance, other losses of energy, termed *shock losses*, can be incurred. Whenever airflow is required to change direction, additional turbulent vortices are set up. These consume energy as they propagate and the resistance of the airway can increase significantly. These losses occur at bends, junctions, and changes in cross sections due to obstructions and regulators, and at points of entry/exit from the system.



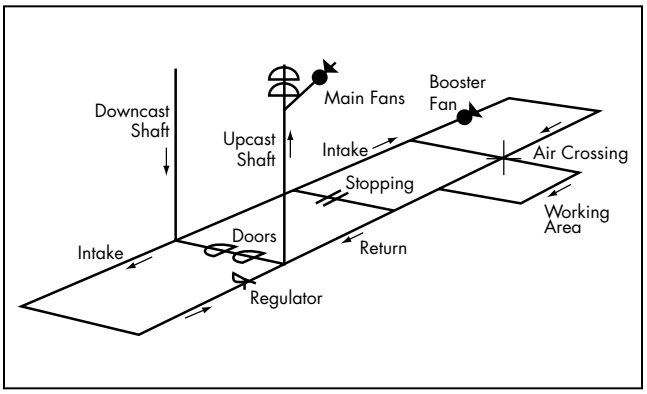


Figure 15.3-2 Mine airway resistance

Source: McPherson 1993; with permission from Springer Science and Business Media.

Figure 15.3-3 Simple mine ventilation system

The effects of shock losses are the most uncertain of all the factors affecting resistance. Two methods are applied to the assessment of the additional resistance caused by shock losses. The head loss or pressure loss caused by a shock loss can be expressed as a shock pressure loss or p_{shock}:

$$p_{shock} = X\rho(u^2/2)$$

where

X = shock loss factor
ρ = air density (kg/m^3)
u = air velocity (m/s)

This can be turned into a shock loss resistance, R_{shock}, using the square law:

$$R_{shock} = R_s = X\rho/2A^2$$

This can also be turned into an equivalent length due to shock loss using the Atkinson equation:

$$R_s = (kL_{eq}\,per/A^3)(\rho/1.2)$$

or

$$L_{eq} = 1.2\,X\,A/(2k\,per)$$

Shock loss factors, X, are listed in McPherson (1993).

VENTILATION SYSTEMS

Every underground mine is unique in terms of its geometry/layout, extent/size, geology, and pollutants. As such, the pattern of airflows and pressure drops through the airways that make up the mine workings are also highly variable. However, certain features of all ventilation systems have some commonality, and classifications of ventilation systems and subsystems can be identified. The aim of this section is to discuss the essential characteristics of underground ventilation systems, describe the main elements of ventilation infrastructure, and introduce some of the technical terms employed by ventilation engineers. Ventilation systems can be broadly classified as follows:

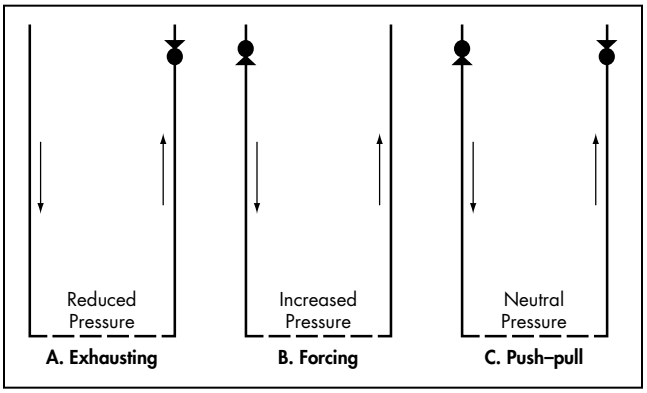
- Mine systems
- District systems
- Auxiliary ventilation systems

Mine Systems

Figure 15.3-3 illustrates a schematic mine ventilation system showing a basic system layout and some of the ventilation control devices that can be encountered. Figure 15.3-3 shows the following:

- Fresh air enters via downcast shafts or other surface connections.
- Air flows along intake airways to working areas where most pollutants are added.
- Contaminated air returns back through the system along return airways.
- The return air passes back up to the surface via upcast shafts or other surface return connections.

However, ventilation is more complicated than this simplistic explanation. Air, like most fluids, will try to follow the path of least resistance from one point to another, and the path to the areas requiring ventilation usually lies along a high-resistance path. In order to get the air to the areas where it is needed, airflow control devices are required. These fall into two main categories: active devices that add energy to air to direct it to where it is needed, or passive devices that add resistance to flow routes to encourage the air to flow along other routes. Examples of active devices include main fans and booster fans. Examples of passive devices include air doors, regulators, air crossings, stoppings, and seals, which by adding resistance increase pressure drop. Both types are discussed in the following sections.



Active Devices

Main fans. Fans are the primary means of producing and controlling the ventilation airflow. Main fans (singly or in combination) handle all the air passed through the mine and are usually located at or near the surface. Main fan systems can be

- Forcing,
- Exhausting, or
- Push–pull (a combination of the two).

Surface fans have the following advantages:

- Simpler installation
- Simpler testing
- Simpler maintenance

Source: McPherson 1993; with permission from Springer Science and Business Media.

Figure 15.3-4 Possible locations for main fans

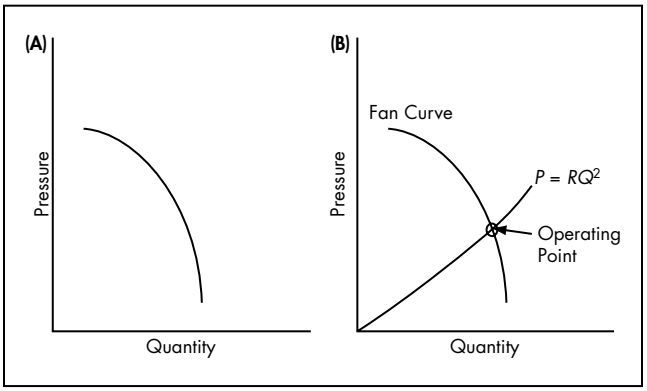


Figure 15.3-5 (A) Fan pressure–quantity characteristic curve, and (B) superimposed mine resistance characteristic and fan operating point

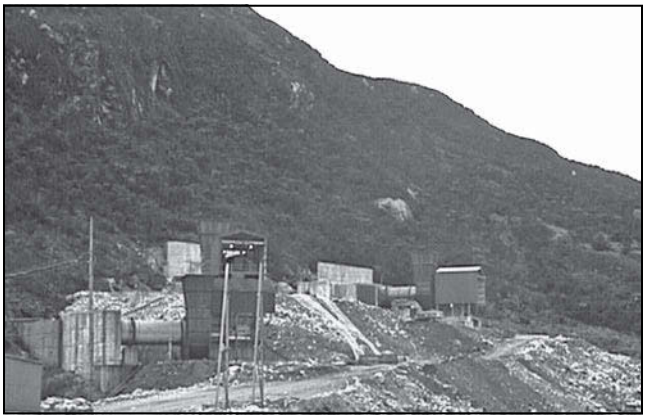
- Easier access
- Better protection in an emergency situation

Main fans can be located underground when fan noise is considered a problem or if shafts need to be completely free of airlocks. Underground fans incur additional problems associated with additional doors, airlocks, and leakage paths.



The choice of surface main fan location is illustrated in Figure 15.3-4. In Figure 15.3-4A, exhaust ventilation connects the main fan to the upcast shafts; in Figure 15.3-4B, forcing ventilation connects the main fans to the downcast shaft; and in Figure 15.3-4C, push–pull ventilation connects main fans to both the upcast and downcast shafts.

Most mines ventilate using exhaust ventilation (i.e., connecting the main fan to the exhaust shaft). The choice of whether to force or exhaust depends on four factors:

1. Gas control (control during falls of barometer and fan stoppage favors exhausting)
2. Transportation (selection depends on whether transporting mineral through intake or return airways)
3. Fan maintenance (exhaust fan subjected to air carrying dust, warmer air, and water droplets, thus the combined effects of impaction and corrosion are greater than in forcing case)
4. Fan performance (cooler air implies lower mass flow duty for a forcing fan and hence for a certain airflow, a reduced pressure and running costs). However, this effect is usually not great.

The combination or push–pull system of ventilation is most generally applied in metalliferous mining situations such as where caving techniques are employed and where the zone of fragmentation has extended to the surface. Maintenance of a neutral pressure underground minimizes the leakage of air between the workings and the surface. This is of particular concern where the fragmented rock is liable to spontaneous combustion. Push–pull systems are also employed in multishaft mines where multiple main fans are employed. In this case it offers the potential to achieve a better distribution of airflow, better control over pressure and leakages, greater flexibility, and reduced operating costs. However, multifan systems require skilled adjustment, planning, and balancing.

Fans generate energy and airflow by converting rotational mechanical energy into hydraulic energy. Numerous types of

Courtesy of Calizaya et al. 2000.

Figure 15.3-6 Main ventilation fans at PT Freeport DOZ mine

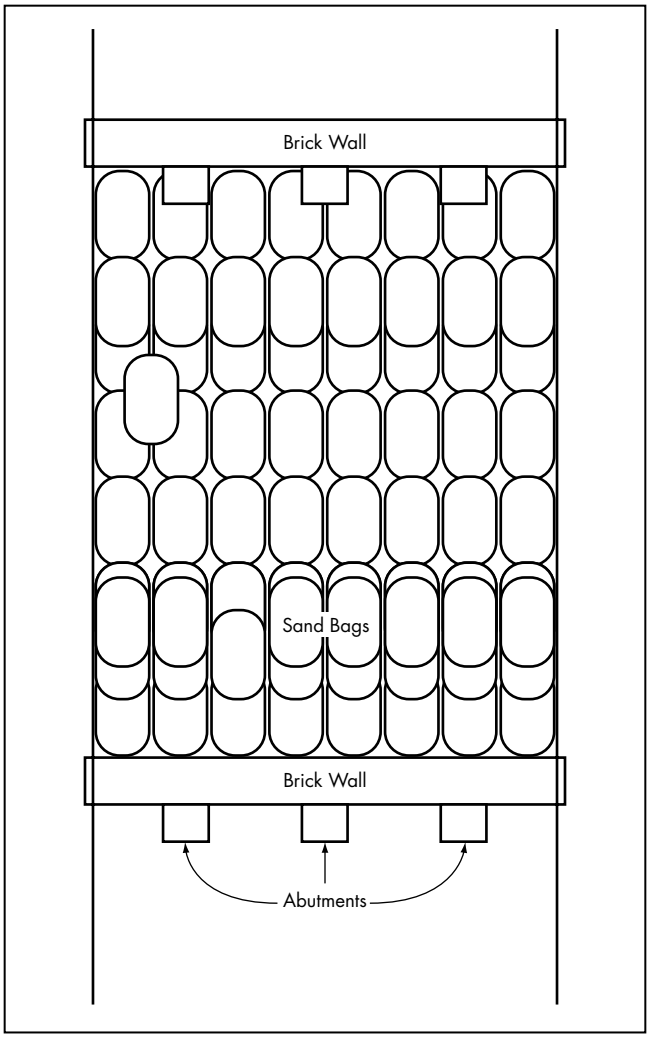
fans exist; the two most commonly applied fans in mine ventilation are centrifugal fans and axial fans, although in some situations mixed-flow fans are used. Every fan has its own characteristic set of performance or characteristic curves in terms of pressure–quantity, power–quantity, and efficiency–quantity curves. Figure 15.3-5A illustrates a typical pressure–quantity curve for a fan, while Figure 15.3-5B shows a mine system resistance curve superimposed on the fan curve. The point at which the two curves intersect is termed the *operating point* for the fan showing the fan pressure and associated flow. A typical main fan installation is illustrated in Figure 15.3-6.

Booster fans. As air flows through a ventilation network, it loses energy. As mines become deeper and more extensive, the mine resistance increases and the reliance on a single main (i.e., its energy input) results in a reduction in the ventilation volume delivered to the extremities of the mine. Rather than upgrading the main fans to overcome this loss in energy, it is better to boost the energy of the airflow in sections of the mine by adding additional booster fans underground. This has numerous advantages including

- No need to upgrade existing main fan facilities, avoiding capital and operating cost increases; and
- Only a proportion of the whole mine airflow is boosted, saving operational costs compared to having to boost the whole mine airflow.

Courtesy of De Souza et al. 2003.
Figure 15.3-7 Booster fan installation

Figure 15.3-7 shows a typical booster fan facility. De Souza et al. (2003) provide a good example of the design and performance of a booster fan facility and the benefits that can be obtained. These include increased ventilation flows in remote mining sections, improved pressure control, improved energy use, and increased air velocities providing enhanced cooling power in hot mines.



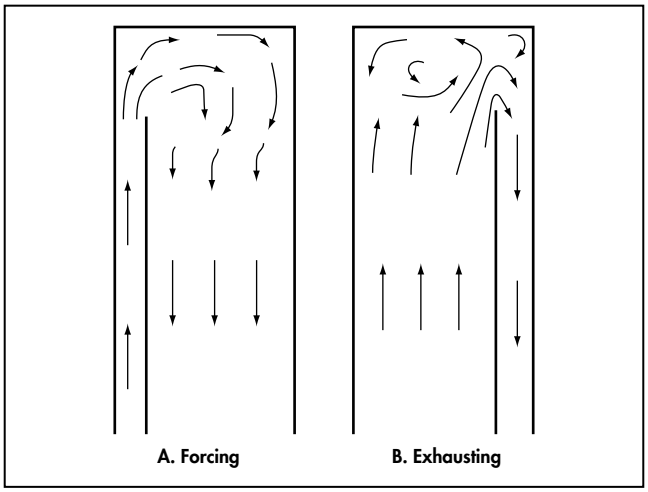
Passive Devices

Air doors and airlocks. When access is still required between intake and return, air doors are employed to minimize short-circuiting of ventilation flow by increasing the resistance of a potential short-circuit route. Ventilation doors between main intake and returns are usually in the form of two or more sets of air doors and termed *airlocks*. Doors should always be hinged to open toward the higher pressure so that they are self-closing. Doors can be constructed with a variety of materials including wood or steel.

Regulators. A passive regulator is simply an air door fitted with an adjustable orifice, the purpose of which is to reduce the airflow in a particular section downstream to a defined airflow by increasing the resistance of the airway. When the airflow in a section of a mine needs to be higher than that normally obtainable, active regulation by the installation of a fan to boost the airflow is required. These are termed *booster fans* and can also be called "active regulation" as the energy of the airflow is increased.

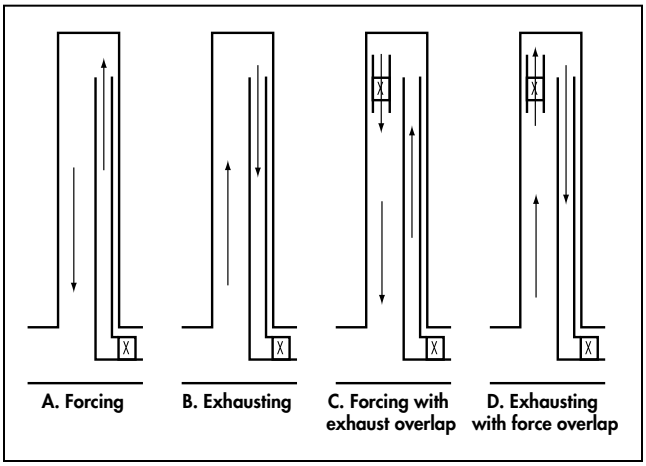
Air crossings. Where intake and return airways need to cross over each other, the leakage between the two must be controlled by means of an air crossing. Air crossings can take the following forms:

- **Natural:** one of the airways is elevated above the other leaving a beam of strata separating the two airways.
- **Intersection:** this is the more usual method. Both airways intersect during construction, and the roof of one or the floor of the other is excavated to expand the zone of intersection. Masonry or concrete blocks or a steel structure with metal or timber shuttering separates the two airways. The high-pressure side is further sealed by the application of shotcrete or another sealant.
- **Prefabricated air crossings**



Source: Chalmers 2008.
Figure 15.3-8 Explosion-proof seal

In all cases the material from which the crossing is fabricated should be fireproof and capable of maintaining its integrity in case of a fire. Aluminum and other low-melting-point materials should not be used to construct an air crossing.



Stoppings and seals. In developing a mine, connections are necessarily made between the intake and return airways for a number of reasons including to provide quick access during mine development and to provide through ventilation. When these are no longer required for access they should be blocked by stoppings. These should be well constructed, keyed into solid rock, and leakage through should be minimized (e.g., by being coated with a sealant). As a short-term method, brattice curtains can be used when pressure differentials are low.

When required to isolate abandoned areas of the mine, seals should be used. Chalmers (2008) details the requirements for sealing abandoned coal mining areas, and many of the details discussed in his paper also apply to other forms of mining. Seals are constructed for a number of reasons, such as preventing unwanted air loss from a ventilation system and to preclude oxygen from entering mined-out areas to prevent spontaneous combustion. Regardless of the reason for the

Source: McPherson 1993; with permission from Springer Science and Business Media.

Figure 15.3-9 Line brattices used in auxiliary ventilation

Source: McPherson 1993; with permission from Springer Science and Business Media.

Figure 15.3-10 Auxiliary fan and duct systems

seal, Chalmers presented a number of characteristics that a good seal should have:

- Highly resistant to airflow
- Strong
- Fire resistant
- Easily and rapidly deployed
- Ability to cope with strata convergence
- Insolubility
- Nonreactive
- Sampling points installed
- Stable, not easily blown over

The exact construction depends on local conditions and materials available; however, a distinction can be made between seals that are designed to purely stop air leakage and a seal that is required to be explosion proof. Figure 15.3-8 shows the typical construction of an explosion-proof seal.

Backfill is becoming more widely used, particularly in hard-rock mining. Backfilling worked-out stopes can also act as a very effective seal.

District Systems

District systems are discussed later in this chapter in the "Coal and Metaliferrous Ventilation" section.

Auxiliary Systems

Systems used to supply air to the working faces of blind headings, sublevels, and so on comprise three basic types: line brattices, fan and duct systems (forcing, exhausting, or overlap systems), and air movers and jet fans.

Line Brattices

Brattice cloth, hung from floor to ceiling, creates an artificial intake or return in a dead-end drive. Commonly employed in room-and-pillar operations, its major disadvantage is the resistance added to the mine ventilation network at the most sensitive point in the system. Also these systems are very leaky. The advantages are that they are cheap, require no power, and produce no noise. Figure 15.3-9 illustrates the use of line brattices.

Fan and Duct Systems

These systems consist of a duct or a multiplicity of ducts connected together to form a ventilation network with a fan or fans to provide the air movement. As such, fan and duct systems can be simple or complex ventilation networks. The main difference between these systems and the ventilation systems discussed previously is that they rely on open atmospheric connections in a factory, mine, or other context to complete the ventilation circuit.

Fan and duct systems basically come in four forms as shown in Figure 15.3-10:

1. Forcing systems
2. Exhausting systems
3. Forcing systems with an exhaust overlap
4. Exhausting systems with a force overlap

Within such systems the usual choice of fan is an in-line axial fan. In mining situations, if the dead-end heading is greater than 30 m in length, such systems are usually the only means of ventilation applicable. Care should be taken to ensure that the pressure and quantity characteristic of the fan is commensurate with the resistance offered by the duct and the airflow required. The latter of these depends on the pollutants to be removed. The resistance of the duct is established in the same way as for other ventilation systems by determining the frictional losses associated with the duct and adding extra losses incurred at bends, changes in the cross section, and entry and exit losses.

The choice of which system to choose depends on the pollutants of greatest concern. The higher velocity emerging from the exit of a forcing duct provides a scouring action, which effectively sweeps the area. This is good for removing gases by providing turbulent mixing. Where heat is the main concern, forcing systems provide high airflows and enhance air-cooling power. The main disadvantage of the forcing system is that pollutants added to the airstream pass back via the open atmosphere along the heading in mines, thus polluting the general atmosphere relatively slowly.

Where dust control is the primary hazard, the exhausting system is preferred as the dust is contained within the ducting and fresh airflows along the heading. The main disadvantage of the exhausting method is the lack of an effective scouring

action as there is no high-velocity jet of air to achieve this. Another disadvantage of exhaust systems is that rigid or reinforced ducting needs to be used. These are more expensive than the flexible ducting types that can be used in forcing systems. The force/exhaust and exhaust/force overlap systems have been developed to overcome the disadvantages of the single forcing or exhausting systems. The selection of which of these methods to use depends on the pollutants under consideration.

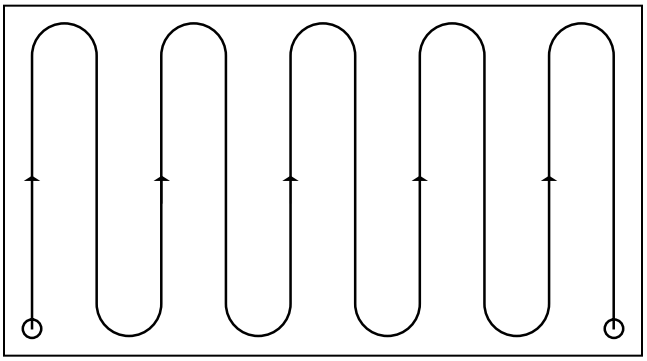
Where long lengths of ducting are required (e.g., in tunneling work), the resistance of the duct may be such that multiple fans connected in series may be needed. As ducting leaks, it is not advisable to cluster fans at one end of the ducting system as the pressures developed will enhance leakage. The preferred method is to space the fans out along the duct to avoid excessive gauge pressures. Multiple fans must be interlinked electrically and airflow or pressure transducers used to detect accidental severing or blockage of the duct.

Air Movers and Jet Fans

Air movers are used to enhance and/or control air movement within localized areas. They are freestanding and can be powered by a number of sources including electricity, compressed air, and water. Jet fans, otherwise known as ductless, vortex, or induction fans, are common and come in a number of forms and sizes. A spray of water can also generate airflow.

VENTILATION SURVEYS

A ventilation survey is an organized procedure to acquire data to determine the quantity, pressure, and air quality distribution within a mine. The accuracy and required detail of the survey depend on the purpose of the survey. Surveys are undertaken for a variety of reasons, including



- Mandatory requirements,
- Ensuring that working areas of the mine receive the airflow required in an efficient and effective manner,
- Keeping ventilation plans and network models up to date,
- Verification purposes, and
- Planning purposes.

A major objective of ventilation surveys is to measure and obtain the frictional pressure drop, p, and corresponding airflow, Q, for each branch within the ventilation network. From these data the following may be calculated for both planning and ventilation control purposes:

- Distribution of airflows, pressure drops, and leakage
- Air-power losses and the distribution of ventilation operating costs around the network
- Volumetric efficiency
- Branch resistances
- Natural ventilation effects
- Friction factors

In addition to pressure and airflow measurements, other measurements are taken either as an integral part of the survey or separately. These will include airway area, airway perimeter, wet and dry bulb temperatures, barometric pressures, dust levels, radon levels, and concentrations of gaseous pollutants.

There are two main aspects to a ventilation survey: the determination of air quantity, and pressure drop.

Figure 15.3-11 Path of an anemometer traverse

Air Quantity Surveys

The volume of air passing a given point in an airway or duct, Q, is normally determined as the product of the cross-sectional area of the airway or duct, A, and the mean air velocity, u:

$$Q = u \times A$$

Thus, most common techniques of determining Q are combinations of the methods available for determining area and mean velocity. Modern methods of determining air speed or velocity can be divided into three groups depending on

1. Mechanical effects,
2. Dynamic pressure, and
3. Thermal effects.

Mean velocity at a point can be determined either by a traversing instrument that integrates measurements as the cross section is traversed or mathematically combining fixed-point measurements to arrive at an average air velocity. Details of the methods used to undertake such measurements are described by numerous authors such as McPherson (1993) and are summarized in the paragraphs that follow.

Figure 15.3-11 shows a typical method used to undertake an anemometer traverse measurement. These are undertaken with a vane anemometer or similar type of integrating instrument. The anemometer should be attached to a rod about 1.5 m in length or greater to allow the whole cross section to be traversed. Anemometers are relatively insensitive to yaw; this is misalignment with the airflow, so long as the angle of yaw does not exceed about 5°.

The observer faces the airflow and holds the instrument at least 1.5 m away from his or her body by attaching the instrument to an extendable arm. The instrument is then started while another observer starts a stopwatch. The instrument is then moved as shown in Figure 15.3-11, the aim being to sweep equal areas of the traverse in equal times. The traverse should not take less than 60 seconds. After the whole area is swept, the anemometer is stopped, the total flow through the instrument noted and the time taken, allowing the average velocity to be computed. The process is repeated until three readings yield the same average velocity to within ±5%.

At least two sets of traverses are recommended to be taken at different locations within the airway. The measuring locations should be chosen to avoid potential problems wherever possible. Booking of results should include the following:

- Observers' names
- Location of station, time, and date
- Anemometer readings and corrections
- Air dry and wet bulb temperatures and barometric pressure
- Dimensioned sketch of the cross section
- Calculation of area
- Calculation of air volume flow

An anemometer traverse can also be undertaken at the ends of ducts but not if the duct diameter is less than six times the anemometer diameter. Anemometers can also be used for fixed-point measurements with corrections applied to obtain the real flow. These corrections are determined via traverses undertaken previously at the same location. When the duct/anemometer ratio of 6 precludes application of an anemometer survey, pitot tube techniques are most commonly employed, as described in McPherson (1993).

The measurement of a cross-sectional area can be done in a number of ways:

- Simple taping
- Offset method
- Profilometer
- Photographic methods

Pressure Surveys

The purpose of a pressure survey is to determine the frictional pressure drop corresponding to a certain flow in an airway. Basically there are two methods, the more accurate being the trailing hose or gauge and tube method, which is time-consuming but preferred where foot travel is relatively easy. The second method is the barometer or altimeter method, used where access is difficult such as in multilevel mines and in shafts. Details of these methods can be found in Hemp (1989) and are briefly described in the following paragraphs.

The principle of the trailing hose method is simple: A hose is laid along the length of the airway being surveyed and a manometer or other suitable differential pressure gauge is connected to one end of the hose. In the case of a horizontal airway, this gauge will indicate a differential pressure exactly equal to the pressure loss. When the airway is not horizontal, the differential pressure will differ from the pressure loss; however, methods are available to calculate the pressure loss derived from the airway equations, which are modified versions of the steady-flow energy equation for mining conditions.

In its simplest form, the barometer method involves the simultaneous measurement of barometric pressures and wet and dry bulb temperatures at either end of the airway. Airflow also needs to be measured. If the elevations of the two measuring stations are accurately known, the pressure and/or energy loss can be determined from the airway equations.

MINE VENTILATION NETWORK ANALYSIS

An essential component in the design of new mines is the quantified planning of the distribution of airflows, determining the location and duties of fans and other ventilation control devices to achieve the goal of providing acceptable environmental conditions throughout the ventilation system. In existing mines it is better to plan ahead to ensure that new fans, shafts, and other airways are available in a timely manner for efficient ventilation of the mine and extensions to the mine. Operating mines are dynamic operations with new workings continually being developed and older ones ending their productive life. Ventilation planning should, therefore, be a continuous and routine process.

The laws of fluid mechanics control the behavior of air in airways, ducts, and pipes. As shown previously, with regard to mining this involves using Atkinson's equation, the square law, and in some cases the laws of thermodynamics. Ventilation network analysis is concerned with the interactive behavior of airflows within the branches of a complete and integrated network. Ventilation network analysis problems can be addressed and formulated quite simply as stated by McPherson (1993):

- If the resistances of the branches of a network and how these branches are interconnected are known, how can the distribution of airflows for given locations and duties of fans be predicted?
- If the airflows in specific branches are known, how are the combination of fans and the structure of the network to provide these airflows determined?

Ventilation network analysis is a generic term for a number of techniques, a family, which enable such questions to be addressed. For a ventilation network there are theoretically an infinite number of combinations of fans, regulators, and airway resistances that will produce the desired flow distribution. Practical considerations will limit the number of acceptable alternatives. One essential aspect of any technique to be employed is that it must be easy to use, and be sufficiently rapid and flexible to allow investigation of multiple solutions.

Fundamentals of the Ventilation Network Analysis

The fundamental relationships that govern the behavior of electrical current within a network of conductors were first recognized by Gustav R. Kirchhoff (1824–1887). These same basic relationships are now known as Kirchhoff's laws and are also applicable to fluid networks.

Kirchhoff's first law (hereafter referred to as Kirchhoff 1) states that the mass flow entering a junction equals the mass flow leaving that junction (a consequence of the law of conservation of mass) and can be written as

$$\sum_j M = 0$$

where M is the mass flows, positive and negative, entering junction j. However,

$$M = Q\rho$$

where Q is the volume flow (m^3/s) and ρ is the air density (kg/m^3), thus,

$$\sum_j Q\rho = 0$$

If the density variation around the ventilation network is negligible (i.e., the flow can be regarded as incompressible), then

$$\sum_j Q = 0$$

This provides a means of checking the accuracy of airflow measurements taken around a junction when undertaking a ventilation survey.

Kirchhoff's second law (hereafter referred to as Kirchhoff 2) stated in its simplest form is that the algebraic sum of all pressure drops around a closed path, or mesh, in the

network must be zero, taking into account the effect of fans and/or natural ventilation pressures, a consequence of the law of conservation of energy. The steady-flow energy equation for a single airway can be written as

$$\frac{\Delta u^2}{2} + \Delta Zg + W = \int VdP + F \text{ J/kg}$$

where

u = air velocity (m/s)
Z = height above datum (m)
g = acceleration due to gravity (m/s^2)
W = work input from fan (J/kg)
V = specific volume (m^3/kg)
P = barometric pressure (Pa)
F = work done against friction (J/kg)

Considering a number of branches forming a closed loop or mesh within a network, the algebraic sum of all ΔZ must be zero and the sum of all the changes in kinetic energy, $\Delta u^2/2$, is negligible. Summing the remaining terms around the mesh, m, gives

$$\sum_m \int VdP + \sum_m (F - W) = 0$$

The summation of the $-VdP$ terms is the natural ventilation energy, NVE, which originates from thermal additions to the air, thus

$$\sum (F - W) - \text{NVE} = 0$$

This calculation is in joules per kilogram and can now be converted to pressure units by multiplying by density, ρ.

$$\sum (F - W)\rho - \rho\text{NVE} = 0$$

But if $\rho_F = p$, the frictional pressure drop, and $\rho W = p_f$, the rise in total pressure across a fan, and ρNVE = NVP, the natural ventilation pressure, then Kirchhoff's second law becomes

$$\sum (p - \rho_f) - \text{NVP} = 0$$

Kirchhoff's laws can be applied to fluid networks that have either compressible or incompressible flow. In the case of compressible flow, the analysis is undertaken on the basis of mass flow; in the case of incompressible flow, the analysis is undertaken on the basis of volume flow.

From this point forward, incompressible flow will be assumed. The square law needs to be incorporated within Kirchhoff's laws for incompressible flow.

Kirchhoff 1

$$\sum_j Q = 0$$

Kirchhoff 2

$$\sum_m (RQ\,|Q| - p_f) - \text{NVP} = 0$$

where

R = resistance (N·s^2/m^8)
$|Q|$ = the absolute value of airflow

This ensures that the frictional pressure drop always has the same sign as the airflow and removes the complication of squaring or square-rooting negative numbers.

Deviations from the Square Law

The fundamental relationship of mine ventilation is the square law $p = RQ^2$. This is developed from the Chezy–Darcy relationship and is valid for fully developed turbulent flow. The resistance, R, is a function of the friction factor, k, which is itself related to the Darcy friction factor, f. If the flow regime falls into the transitional zone or the laminar flow zone, f, and, hence, k becomes a function of the Reynolds number, Re, the value of R varies with airflow. In these cases, the square law is inapplicable.

For the transition zone the following relationship applies:

$$p = RQ^n$$

Values of n have been reported to be in the range of 1.8–2.05. In the case of laminar flow, the following equation can be used:

$$p = R_L Q$$

where R_L is laminar resistance.

In the following sections it is assumed that the square law applies.

Methods of Solving Ventilation Networks

Basically there are two methods for solving ventilation networks:

1. Analytical methods formulate governing laws to produce equations that yield exact solutions.
2. Numerical methods iterate until a solution is found to a required degree of accuracy.

Analytical Methods

The following paragraphs describe analytical methods to solve ventilation networks.

Equivalent resistances. This is the most elementary method of network analysis. When two or more airways are connected together in series or parallel, each of these resistances can be combined into a single equivalent resistance in a similar manner to electrical circuits. A mine ventilation network is made up of a number of roadways connected together; these connections between branches can be broken down into roadways connected in series and in parallel.

- Series circuits—The common element is that the air quantity flowing in each branch is the same. The equivalent resistance of n branches connected in series is

$$R_{\text{total}} = R_1 + R_2 + \ldots + R_n \text{ (N·s}^2\text{/m}^8\text{)}$$

- Parallel circuits—The common element is that the pressure drop across every branch is the same. The equivalent resistance if n branches are connected in parallel is

$$1/\sqrt{R} = \sum_1^n 1/\sqrt{R}\,n \text{ (N·s}^2\text{/m}^8\text{)}$$

The square root term in the equation results from the square law of mine ventilation rather than the linear Ohm's law for electrical circuits.

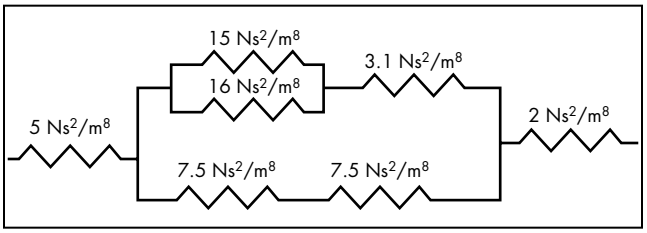

Figure 15.3-12 Ventilation network for equivalent resistance calculation (Example 1)

Example 1. A section of a mine ventilation system is connected together as shown in Figure 15.3-12. If the pressure drop across the system is 1.1 kPa and the resistances are as indicated, determine the flow in each airway.

Solution. First the equivalent resistance of the circuit needs to be determined. Taking the bottom line of the parallel portion of the circuit first, the equivalent resistance is $7.5 + 7 = 14.5$ N·s^2/m^8. The equivalent resistance of the top line now needs to be determined.

Taking the parallel portion first,

$$\frac{1}{\sqrt{R}} = \frac{1}{\sqrt{15}} + \frac{1}{\sqrt{16}} = 0.508$$

Thus $R = 3.875$ N·s^2/m^8, thereby showing the advantage of placing airways in parallel as the resistance of the combination is less than the individual resistances that make up the parallel combination.

This is in series with the 3.1 N·s^2/m^8 resistance, so the resistance of the top line is 6.975 N·s^2/m^8.

The equivalent resistance of the whole parallel section can now be evaluated:

$$\frac{1}{\sqrt{R}} = \frac{1}{\sqrt{14.5}} + \frac{1}{\sqrt{6.975}} = 0.641$$

Thus, $R = 2.433$ N·s^2/m^8.

Combining this in series with the intake resistance of 5 and the return resistance of 2 gives a total system resistance of 9.433 N·s^2/m^8.

The total inlet and outlet flow for the system can now be evaluated from the square law of mine ventilation, $p = RQ^2$.

$$Q = \sqrt{\frac{p}{R}} = \sqrt{\frac{1{,}100}{9.433}} = 10.8 \text{ m}^3/\text{s}$$

Knowing this, the pressure drop for the intake and outlet can be evaluated to determine the pressure drop acting over the parallel element of the circuit:

$$p = 7 \times 10.8^2 = 816.5 \text{ Pa}$$

So the pressure drop over the parallel element of the circuit is 1,100 – 816.5 = 283.5 Pa. This acts across both legs so the flow in the bottom leg is

$$Q = \sqrt{\frac{p}{R}} = \sqrt{\frac{283.5}{14.5}} = 4.42 \text{ m}^3/\text{s}$$

and the flow through the upper leg is 6.38 m^3/s.

To determine the pressure drop over the parallel portion of the upper leg, the pressure drop through the 3.1 N·s^2/m^8 resistance needs to be determined. This is

$$p = 3.1 \times 6.38^2 = 126 \text{ Pa}$$

So the pressure drop over the parallel portion of the upper leg is 283.5 – 126 = 157.5 Pa. The flows can now be determined. Through the 15 N·s^2/m^8 resistance it is

$$Q = \sqrt{\frac{p}{R}} = \sqrt{\frac{157.5}{15}} = 3.24 \text{ m}^3/\text{s}$$

and through the 16 N·s^2/m^8 leg the flow is 3.14 m^3/s.

This example shows the effect of placing resistances in parallel to reduce the overall mine resistance and the dominating effect that the entry and exit from the system has on the overall pressure drop in the system. In other words, the entry and exits from a mine ventilation system are primary consumers of air power in a mine ventilation circuit—not surprising as they carry the full system flow.

Direct application of Kirchhoff's laws. Kirchhoff's laws allow equations for each independent junction in a network and for each independent mesh. Solving these two sets of equations obtains the branch airflows that satisfy both laws. If b branches exist in a network, then b airflows need to be determined, and b independent equations are required.

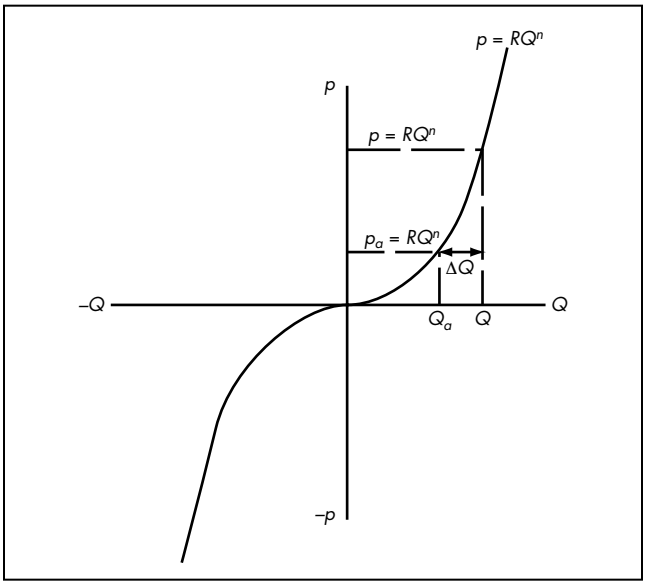
If a network contains j junctions, Kirchhoff 1 can be written down for each in turn. But as each branch is assumed to be continuous with no intervening junctions, a branch airflow denoted by Q_i entering a junction will automatically imply that Q_i leaves a neighboring junction at the other end of that same branch. Therefore, by the last junction, all airflows will have been symbolized; thus, the number of independent equations from Kirchhoff 1 is $j - 1$.

This leaves $b - (j - 1)$ or $b - j + 1$, with further equations to be established from Kirchhoff 2. It is, therefore, necessary to choose $b - j + 1$ independent closed meshes around which to sum the pressure drop. The direct application of this method to mine circuits may result in hundreds of equations to be solved simultaneously. Computer assistance is required, as manual solution is limited to small networks.

Numerical Methods

Numerous numerical methods exist. The main differentiation between the methods revolves around mesh selection and numerical solving of the equations. The most robust—though not always the most efficient—method was devised by Professor Hardy Cross in 1936 at the University of Illinois (United States) for water distribution systems. This technique is the most widely used and was modified for use in mine ventilation systems by Professors F.B. Hinsley and D.R. Scott at the University of Nottingham (England) in 1951.

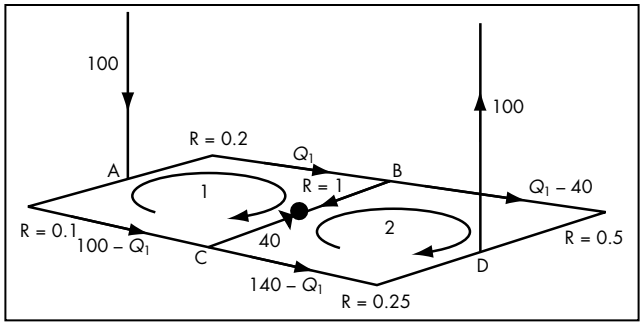
Example 2. Figure 15.3-13 shows the system resistance curve for a single representative branch of a ventilation network. If airflow Q is reversed, the frictional pressure drop, p, also becomes negative. When establishing a flow distribution, the true airflow in the branch, Q, is initially unknown. Assume a flow, Q_a, that is less than the true value by an amount ΔQ:



$$Q = Q_a + \Delta Q$$

Now find ΔQ. The square law can be written as

$$p = R(Q_a + \Delta Q)^2$$



More generally,

$$p = R(Q_a + \Delta Q)^n$$

Source: Adapted from McPherson 1993; with permission from Springer Science and Business Media.

Figure 15.3-13 Iterative technique to solve ventilation networks

Source: McPherson 1993; with permission from Springer Science and Business Media.

Figure 15.3-14 Network for worked example of direct application of Kirchhoff's laws

Going back to the square law, this expands to

$$p = RQ_a^2 + 2RQ_a\Delta Q + R(\Delta Q)^2$$

The frictional pressure drop corresponding to the assumed airflow is

$$p_a = RQ_a^2$$

where the error in p is

$$\Delta p = p - p_a$$

Substituting from the equations gives

$$\Delta p = 2RQ_a\Delta Q + R(\Delta Q)^2$$

Assuming ΔQ^2 is small compared to $2RQ_a\Delta Q$, the approximation can be written as

$$\Delta p = 2RQ_a\Delta Q$$

Thus, $\Delta Q = \Delta p/2RQ_a$. The technique of dividing a function by its first derivative in order to estimate an incremental correction factor is a standard method of finding roots of functions and is usually called the Newton–Raphson method. The technique can also be applied to meshes as explained in McPherson (1993). For the general case where $p = RQ^n$, the following is true:

$$\Delta Q_m = \frac{-\sum (RQ_a \mid Q_a \mid - p_f - \text{NVP})}{\sum (2R \mid Q_a \mid + S_f + S_{nv})}$$

where

S_f = slope of the pressure/quantity characteristic curve for the fan
S_{nv} = slope of the pressure/quantity characteristic curve for the natural ventilation effects

The Hardy Cross technique can now be summarized as follows:

1. Draw a network schematic and choose at least $(b - j + 1)$ closed meshes such that all branches are represented. Convergence to a balanced solution will be improved if each high-resistance branch is included in only one mesh.
2. Make an initial estimate of airflow, Q_a, for each branch.
3. Traverse one mesh and calculate the mesh correction factor, ΔQ_m, from the equation.
4. Traverse the same mesh in the same direction and adjust each of the airflows by the amount ΔQ_m.
5. Repeat Steps 3 and 4 for each mesh.
6. Repeat Steps 3, 4, and 5 until Kirchhoff 2 is satisfied to an acceptable degree of accuracy.

An example of this method is given in McPherson (1993).

Example 3. Figure 15.3-14 shows a network. The downcast and upcast shafts pass 100 m^3/s and the resistance of each branch is shown. A booster fan in the central branch passes 40 m^3/s. Determine the distribution of airflow and the total pressure developed by the booster fan.

Solution. Inspection of the figure shows that it cannot be solved by equivalent resistances. Therefore, it is a complex network. The given airflows are shown on the figure with flow from A to B denoted by Q_1. The flows in the other branches are expressed in terms of Q_1. The shafts can be eliminated, as their airflows are already known. Thus,

$b - j + 1 = 5 - 4 + 1$ independent meshes are required

where

b = number of branches in the network
j = number of junctions in the network

Meshes along the closed paths ABCA and BDCB are selected. In order to apply Kirchhoff 2 to the first mesh, consider the pressure drops around that mesh branch by branch. Frictional pressure drops are positive in the direction of flow and p_b:

Branch	Frictional Pressure Drop (RQ^2)	Fan
AB	$0.2\ Q_1^2$	–
BC	1.0×40^2	$-p_b$
CA	$-0.1(100 - Q_1)^2$	–

Summing these up according to Kirchhoff 2 gives

$$0.2\ Q_1^2 + 1{,}600 - p_b - 0.1(100 - Q_1)^2 = 0$$

Collection of like terms gives

$$p_b = 0.1Qt_1^2 + 20\ Q_1 + 600$$

For the second mesh,

$$0.5(Q_1 - 40)^2 - 0.25(140 - Q_1)^2 - 1 \times 40^2 + p_b = 0$$

which reduces to, substituting for p_b from the previous equation,

$$0.35Q_1^2 + 50Q_1 - 5{,}100 = 0$$

Solution of this quadratic equation gives Q_1 = 68.83 or –211.69 m^3/s. The only practicable solution is 68.83 m^3/s, thus the flows are

Branch	Air Quantity, m^3/s
AB	68.83
BD	28.83
BC	40
AC	31.17
CD	71.17

The required booster fan pressure is

$$p_b = 0.1(68.83)^2 + 20\ (68.83) + 600 = 2{,}450$$

Ventilation Network Simulation Programs

There are numerous ventilation network simulation packages on the market. These are mathematical models and are designed to simulate real systems. Use of these packages has revolutionized mine ventilation planning (Mine Ventilation Services 2007; Ventsim 2010).

MINE VENTILATION PLANNING

Planning of new mines and extensions to existing mines is a critical part of overall mine planning. Without adequate airflow provided in a timely and efficient manner, likely outcomes include poor environmental conditions for the work force, with associated health and safety issues, and reduced production. Ventilation planning is also essential in the testing of emergency and evacuation procedures.

A generalized approach to mine ventilation planning is shown in Figure 15.3-15. The figure has been simplified for clarity and indicates that a step-like approach should be taken with constant feedback between stages, similar to other mine design problems. All mines are different in terms of the pollutants to be diluted and removed, so generic rules are not applicable to all situations. Ventilation planning should be an integral part of overall mine planning, as well as production planning. With regard to ventilation planning, the following factors should be considered:

- The method should fit with the remainder of the mining operation.
- The method should be flexible.

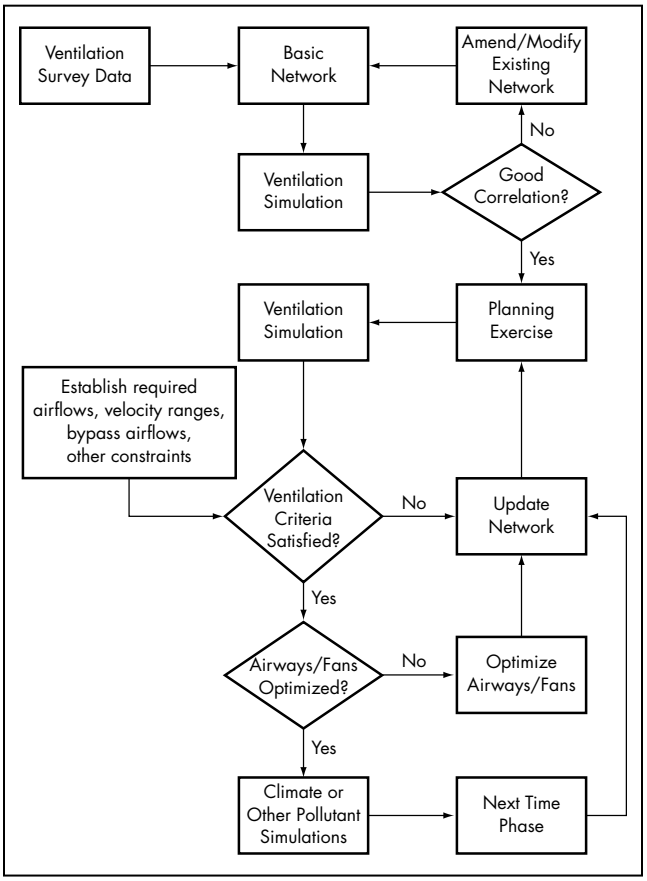


Figure 15.3-15 Generic mine ventilation planning

- The method should be economical.
- The method must be adaptable for extensions and future mining activities.

With reference to Figure 15.3-15, the initial stage is to create a simulation model of the mine. For an existing mine, this should be created using the results of ventilation surveys. For a new mine, typical design data such as friction factors should be combined with geometric data and layout data from other mine planning activities. For extensions to existing mines, a combination of survey data and design data will need to be used. After this has been achieved, the next stage is to test the ventilation network for existing mines to ensure that the results of the simulation correlate well with the real ventilation survey data. If a reasonable correlation (±5%) is not achieved, the ventilation network needs to be modified by examining assumptions and data against reality until a suitable correlation is achieved. Possible reasons why correlation is not achieved include compressibility occurring in the network while an incompressible analysis is being undertaken, airways not conforming to actual design specifications, shock losses not being accounted for, and numerous other reasons. For a new mine, after underground workings exist, ventilation surveys should be undertaken and compared against the simulated network to ensure that the simulations match the mining reality.

After a suitable network simulation has been developed, the next stage is to ensure that the predicted flows are reaching the production and other areas that require ventilation. To do this, the required airflows, air velocity limits, bypass

Table 15.3-2 Recommended maximum air velocities

Area	Velocity, m/s
Working faces	4
Conveyor drifts	5
Main haulage routes	6
Smooth-lined airways	8
Hoisting shafts	10
Ventilation shafts	20

airflow, requirements to eliminate recirculation, and other requirements such as establishing limits for the concentration of pollutants need to be established. In some cases these limits are dictated by law, in other cases not. In some countries and states, best practice is mandated by health and safety legislation.

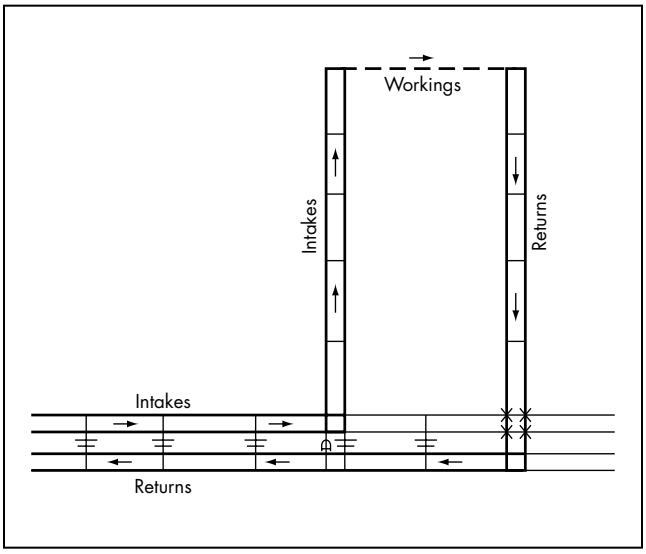
In the case of gases, the required airflow can be simply determined if the release rate of the gas is known and the required maximum concentration is known as detailed by McPherson (1984). For dust and some other requirements such as bypass airflows, air velocity limits such as those shown in Table 15.3-2 can be applied. Minimum velocity standards can also be fixed; a commonly applied standard is 0.3 m/s (McPherson 1993). For diesel dilution, a common method is to specify airflow per rated kilowatt of diesel power in a location. See Table 15.3-3 for a list of these requirements for several countries (Brake and Nixon 2008). For heat and humidity, heat stress indices need to be applied to define safe work, to reduce work and stop-work conditions, and to undertake climate simulations in addition to ventilation simulations (Tuck 2008).

Other limits can also be applied; for example, in wet exhaust shafts where condensation or water flow results in airborne droplets, the air velocity should not lie in the range from 7 to 12 m/s as water blanketing can occur between this range of velocities (McPherson 1993).

After the required air velocities, quantities, and other criteria have been set, the results of the ventilation simulation need to be carefully checked against these criteria. If the criteria are not satisfied, amendments need to be made to the network such as changing the duty of fans, changing airway lining or other inputs, and the simulation rerun until the criteria are realized.

The third stage involves an economic overview of the system. Mine ventilation systems can be major electricity consumers, so trying to optimize the system to minimize the total capital and operating cost is prudent.

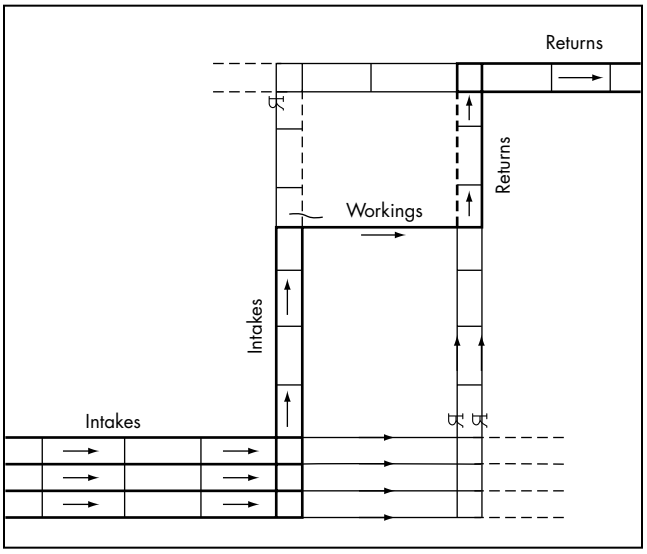
Following this stage, if ventilation alone is not sufficient to dilute and remove the contaminants, the design requirements for auxiliary systems such as methane drainage, mine cooling, and mine heating can be investigated as required.



These considerations give a broad, simple overview of the ventilation design process; a fuller treatment can be found in numerous textbooks and conference proceedings (McPherson 1993). However, planning of mine ventilation is not simple, and a lack of care and attention at each stage of the process can result in a system that fails to deliver the outcomes required. A good illustration of this is provided by Brake and Nixon (2008), who examined the requirements to correctly estimate the primary airflow requirements in underground metaliferrous mines. Brake and Nixon found that airflows were underestimated for failure to

Table 15.3-3 Diesel dilution requirements for selected locations

Location	Diesel Airflow Requirement	Comments
Western Australia	0.05 m^3/s per kW	
Queensland, Australia	None	Was 0.04 m^3/s per kW
Ontario, Canada	0.06 m^3/s per kW	
Manitoba, Canada	0.92 m^3/s per kW	Uses 100/75/50 rule
United Kingdom	None	
United States	0.032 to 0.094 m^3/s per kW	Typically design to 0.08 m^3/s per kW
Chile	0.063 m^3/s per kW	
South Africa	None	Exhaust/overlap system required for firing anytime. Typically design to 0.06 m^3/s per kW.
Indonesia	0.067 m^3/s per kW	



- Provide for leakage in the auxiliary ventilation ducts,
- Provide for leakage in the workings,
- Supply essential anti-recirculation bypass flows,
- Provide for diesel equipment mobility,
- Provide for ramps and other underground fixed plant and infrastructure travelways,
- Understand the relationship between airway dimensions and minimum wind speeds,
- Recognize which is the critical airborne contaminant to be diluted,
- Plan for reasonable capacity increases and other contingencies,
- Provide for likely changes in diesel technology,
- Provide for increased mine resistance,
- Understand the impact of both increased mine resistance and leakage on airflow requirements and fan performance,
- Understand that providing extra capacity in a ventilation system at the start of the project while it is an initial additional capital expenditure is less expensive than fixing the ventilation at a later date, and
- Properly assess ventilation planning and implementation lead times.

An important part of mine ventilation planning is that it should be a continual process and that the effects of time need to be carefully assessed. A good example of this has been reported by Sedlacek (1999). In this paper, four scenarios were investigated to enable the Kidd Creek mine (Canada) to develop to greater depths with the potential to extend to 2,987 m below the surface. The situation in 1998 involved the use of several fans arranged in a series of parallel arrangements to provide the required airflow. In total, 220 intake and return level exhaust fans were in use. In addition, the airflow within the system was seriously constrained by an inadequate return airway system. Sedlacek details four possible solutions to the long-term ventilation needs for Kidd Creek; of these, the preferred option involved the mine being separated into 15 distinct ventilation districts or circuits, each controlled by a single major supply fan. The overall volume of air is controlled by strategically located single exhaust fans placed at or close to the top of the major exhaust raises. This system reduced the number of main fans from more than 200 to 18 and enabled considerable savings in operating costs.

Figure 15.3-16 U-tube ventilation

Source: McPherson 1993; with permission from Springer Science and Business Media.

Figure 15.3-17 Through-flow ventilation

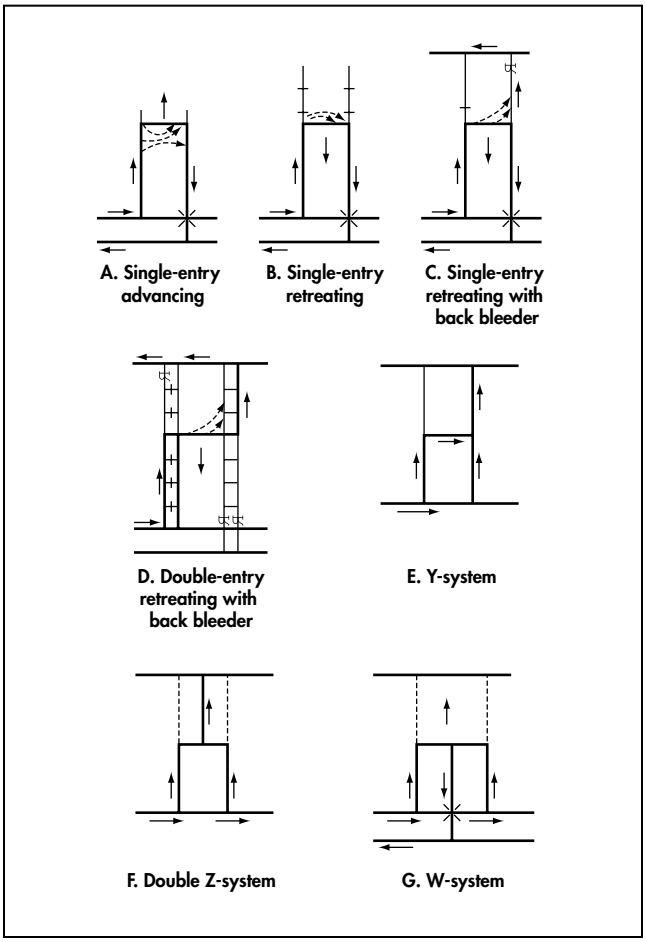
A more modern approach to ventilation design is the potential to apply ventilation on demand to working stopes (Hardcastle et al. 1999). The principle can also be applied to mine cooling systems (Gundersen et al. 2005). Production stopes in mining do not require the same amount of air continuously; currently, ventilation design assumes worst-case conditions for specifying the airflow required—good from a safety perspective, but poor regarding economics. The principle of ventilation on demand is to match the air supply to the requirements of individual stopes depending on the point in the production cycle where they are currently operating. This has the potential to reduce overall mine airflows and to achieve considerable savings in power costs. The principle is still in the early stages of development. One main concern is that mine ventilation systems are highly inertial in nature and the changes induced to provide ventilation on demand for a specific stope could have a poor impact elsewhere in the system, even if only for a short, transient period of time. This could have serious safety implications.

COAL AND METALLIFEROUS VENTILATION

Before describing some of the main points of ventilating coal and metalliferous mines, a general overview of the two main forms of ventilation applied in both cases will be made. There are two broad classifications: U-tube systems (Figure 15.3-16) and through-flow systems (Figure 15.3-17).

Figure 15.3-16 shows the principle of U-tube ventilation. Air flows toward and through the workings, then returns along adjacent airways separated from the intakes by stoppings and doors. Room-and-pillar (R&P) layouts and advancing longwalls tend to be of this type. A problem with this system is the close proximity of the main intake and return airways; there can be a high pressure drop across the control devices separating these, such as doors and stoppings, which can lead to high leakage losses from the main intake to the main return before the working areas.

Figure 15.3-17 illustrates the through-flow system. In this system, intakes and returns are separated geographically, and adjacent airways are all intakes or returns. There are far fewer stoppings and air crossings, but additional regulators are required to control the airflow through the working area. Examples include the parallel flows from downcast to upcast across the multilevels of metal mines and the back-bleeder system of longwall retreating. In these systems, although leakage occurs, it is generally smaller and can be used to enhance flows as, for instance, at the return end of the working zone, which in a hot and humid mine is generally one of the main problem areas; the leakage flow increases the air velocity, enhancing the cooling power of the airflow.



Division can be made between stratified deposits (longwall or R&P systems) such as coal, gypsum, potash, and trona, and metalliferous ore-body deposits (also known as hard-rock deposits). Stratified deposits usually have a simpler two-dimensional system; ore-body deposits tend to be more complicated. This is due to their three-dimensional nature and the need to have more numerous working sections, not all of which are working at a particular time (in other words, air requirements are on a day-to-day basis, and air must be directed to where it is needed).

Stratified Deposits

Underground coal, potash, and other tabular forms of mineral deposits use either the longwall method of mining or the R&P (bord-and-pillar) mining method. Layouts can vary from country to country, however, the following sections highlight the modes of airflow distribution used. Other differences between these types of mines and hard-rock mines are the dominant pollutants that need to be accounted for. In coal mines, methane gas, dust, and in some cases diesel emissions are the dominant pollutants. In hard-rock mines, diesel pollutants, dust, and blast fumes are of concern. Because all mines will have different critical pollutants, assessment should be made on a mine-to-mine basis.

Longwall Systems

Two main features have influenced the design of longwall systems: methane and other gas control from the waste areas, and the high rate of rock breakage. Both have increased the

Figure 15.3-18 Longwall district ventilation systems

production of dust, gas, heat, and humidity. A typical layout is shown in Figure 15.3-18.

With reference to Figure 15.3-18, single-entry systems are common in Europe where the deposits are mined at considerable depth and geotechnical issues would require very large pillars to be left if multiple access systems were used. With the advancing system, some leakage occurs through the waste area; control of this is achieved by roadside packing. This leakage air flushes gas out of the waste and can cause problems of high gas concentration at the return end of the face. Leakage of air through the waste can cause gob fires. In the retreating system in Figure 15.3-18B, the amount of air leaking through the waste is generally reduced, but the same problems can occur as in the advancing case.

The back-bleeder system employs a back or bleeder return to constrain the gas fringe back in the waste to prevent flushes of gas onto the face. The method illustrated in Figure 15.3-18C is a combination of U-tube and through-flow ventilation. Multiple opening systems such as those illustrated in Figure 15.3-18D are more common in the United States, South Africa, and Australia, where shallower coal seams are mined. Two or more entries are driven using R&P mining; these serve as the lateral boundaries of the longwall panel. If retreat mining is used, back bleeders can be used to control

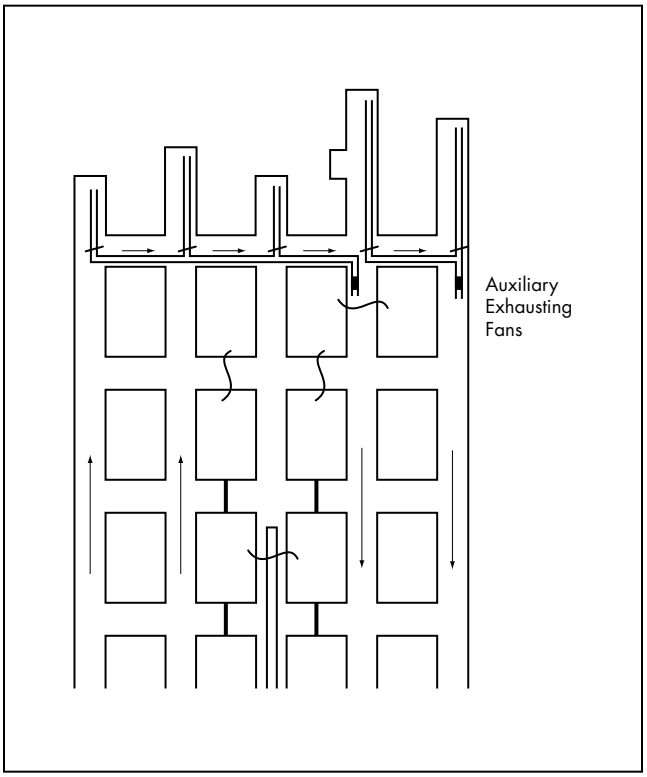
Figure 15.3-19 Room-and-pillar development with line brattices (high face resistance)

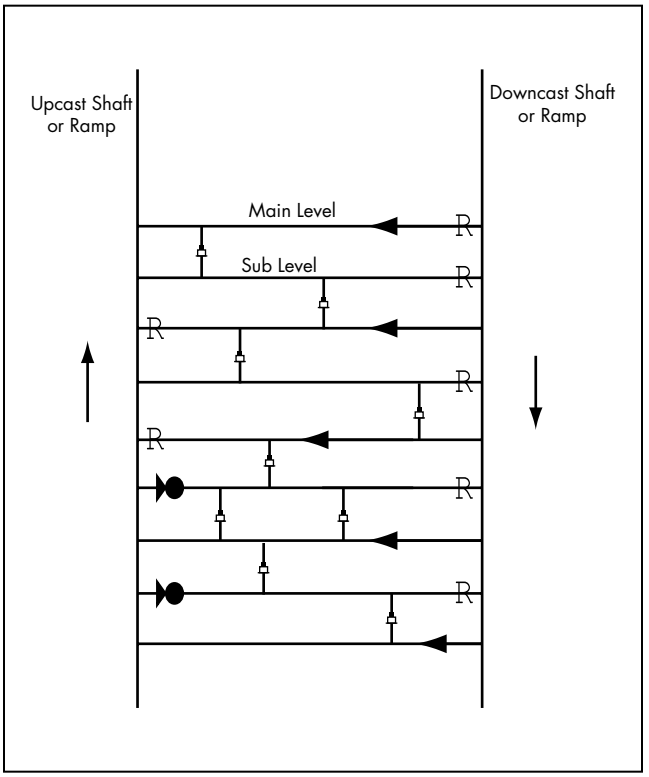
waste or gob gas. In some states, air from conveyor belt drives cannot be used to actively ventilate production areas; use of multiple entry systems enables this requirement to be achieved.



The types shown in Figures 15.3-18E through 15.3-18G are used when the gas is very heavy. An additional fresh air feed helps to maintain gas concentrations to safe levels by feeding fresh air directly to the return end of the face. These systems can also be applied in hot workings.

Room-and-Pillar Systems

In R&P (bord-and-pillar) mining, the potential for leakage is high because of the large number of interconnected entries as shown in Figure 15.3-19. The figure illustrates two methods of ventilating R&P development: a bidirectional or W-system in which intake air passes through one or more central airways with return airways on both sides, and a unidirectional or U-tube system in which intake and return airways are on opposite sides of the panel. In both cases the conveyor is sited in the middle airway and line brattices regulate the air through it.



The bidirectional system offers the advantage that the air splits at the end of the panel and each airstream only has to ventilate half the panel. In addition, the rib side gas emission is likely to be heavier in the outer airways. Its disadvantage, however, is that it requires double the number of stoppings, and hence has more leakage paths than the unidirectional system. Thus, the unidirectional system has a higher volumetric efficiency. In both cases the use of brattice cloth to control air distribution at the face end offers a high resistance. This problem can be overcome by employing auxiliary fans and ducts at the face end to force or exhaust air from the headings; the resistance of the face end effectively becomes zero. This is illustrated in Figure 15.3-20.

All the methods shown in the previous figures for longwall mining can also be applied to R&P workings. There are different strategies between R&P and longwall mining. The large number of interconnected airways and high leakage result in R&P layouts offering less resistance to airflow than longwall layouts. Thus, R&P layouts tend to require higher volume flows at lower fan pressures. Volumetric efficiencies of R&P layouts are very low.

Figure 15.3-21 Principle of through-flow ventilation applied to the levels of a metal mine

Ore-Body Deposits

The irregular geometry of metalliferous deposits, coupled with grade variation and fluctuating market prices, results in highly complex mine development in metal mining. Mine development can in a number of cases be related to chasing the grade, dictated by commodity prices at a particular point in time. These factors and the fact that drill-and-blast operations are cyclic in operation also necessitate many more stopes than would be required in a stratified deposit mine, some of which may not be worked on a particular shift. Consequently, metal mines are characterized by a three-dimensional aspect and require much more flexible ventilation arrangements.

Ventilation networks in metal mines are more complex than those for stratified deposits. Figure 15.3-21 illustrates the basic principles of ventilating a metal mine. Air moves in a through-flow manner from a downcast shaft or ramp, across the levels, sublevels, and stopes toward return raises, ramps, or upcast shafts. Airflow control is via fans and/or regulators (represented by R in the figure). Ascentional ventilation takes advantage of natural ventilation effects caused by temperature and humidity variations and avoids uncontrolled recirculation.

Airflow distribution in various stoping systems is highly variable. The guiding principles are as follows:

- Use ascentional ventilation.
- Through-flow ventilation should be used wherever possible; however, use of fan and duct systems is recognized as a need in certain systems.
- Series ventilation should be avoided.
- Leakage through orepasses is a problem; attempt to avoid large pressure drops across orepasses to minimize leakages.
- Wherever practical, every level and sublevel should be provided with its own through-flow of air between shafts, ramps, or raises.

CHAPTER 15.4

Gas and Dust Control

Pramod Thakur

INTRODUCTION

The provision of an adequate air environment to promote the health, safety, and comfort of mine workers has always been and will continue to be a prime requisite for successful mining operations. Although the definition of an adequate environment varies from country to country, it generally means the provision of sufficient circulating air, often at specified velocities, to maintain at least 19.5% oxygen in the working areas; concentration of solids (dust) and gaseous pollutants such as methane, carbon dioxide, and respirable dusts below specified limits; and temperature and humidity below specified limits.

This chapter will deal only with the techniques used to control solid and gaseous contaminants in the mine air. Liquid contaminants, such as mists, are not an issue in the mining industry. Table 15.4-1 shows the maximum allowable concentrations of contaminants normally encountered in mine air (CFR 2003).

Methane gas is a big concern primarily in coal mines, but some salt and potash mines also have excessive methane emissions. Special techniques have been developed over the past 50 years to keep the mines safe. Respirable dust is a problem common to all mining and processing operations. In the past, diesel particulate matter was a health concern only in metal and nonmetal mines, but it is becoming a health concern in coal mines as the population of diesel equipment in coal mines is increasing. Diesel haulage is likely to replace all trolley wire haulage, leading to improved safety in mines.

Traditionally, all solid and gaseous pollutants in mines are rendered safe by dilution with adequate ventilation air. In deeper mines, methane emission is so high that it is drained prior to mining and postmining. Respirable dusts also need to be controlled before they become airborne. Diesel exhaust is often oxidized to remove carbon monoxide and unburned hydrocarbons, and the diesel particulate matter is collected on specially designed filters to keep its concentration in air below the threshold limit value.

GAS CONTROL STRATEGY

All gas emissions in mine airways must be controlled to keep their concentrations below the statutory limits. The control strategy depends on the type of contaminants, their sources, and rates of emission. It can range from simple dilution with ventilation air to complex procedures for removal of the contaminant prior to mixing with the mine air or suppression/elimination at the source. An overall strategy comprises the following steps (Hartman et al. 1997):

1. Prevention (e.g., proper blasting, internal combustion engine maintenance)
2. Extraction (e.g., methane from coal mines)
3. Chemical absorption—use of catalytic converter in diesel engines
4. Isolation—sealing of areas in coal mines to contain methane emissions
5. Ventilation—including local dilution at the source with auxiliary ventilation and disposal via the mainstream ventilation

Four cases will be discussed in greater detail to illustrate these strategies:

1. Methane control in coal mines
2. Respirable dust control
3. Diesel exhaust control
4. Radon gas control

Methane Control in Coal Mines

Coal seams and coal-bed methane are syngenetic in origin because they originate from the same plant material. All coal seams are gassy, but they vary in their degree of gassiness (gas contained per ton of coal). Typical gas contents of coal seams vary from negligible to 25 m^3/t (see Appendix B, Coal Mine Gas Chart). Methane and sometimes carbon dioxide are the major components of gas in coal comprising 90%–95% by volume. The remaining gas is primarily nitrogen, helium, argon, and hydrogen. Methane is released into coal mines from coal seams as mining proceeds. It is colorless, odorless, and combustible, and it forms an explosive mixture with mine air in the concentration range of 4.5%–15% by volume. The maximum permitted concentration of methane in mine air is restricted by law to between 1% and 2% in all major

coal-producing countries, but methane–air explosions are quite common even today. Table 15.4-2 shows a list of mine explosions in the United States from 1970 to 2006. In these explosions, lives were lost in spite of methane drainage in some of the mines. When methane drainage was not practiced and ventilation was the only method of methane control, mine explosions were much more disastrous with very high numbers of fatalities. To minimize the risk of methane explosion, mine ventilation must be supplemented by methane drainage from coal seams prior to mining and postmining when the gas content of coal exceeds 3 m^3/t.

The amount of gas contained in a coal seam depends on a number of factors, such as the rank of coal, the depth of burial, immediate roof and floor, geologic anomalies, tectonic stresses, and temperatures during the coalification process. For methane control, all coal seams can be divided into three categories: mildly gassy, moderately gassy, and very gassy, as shown in Table 15.4-3.

For mildly gassy and moderately gassy mines, ventilation is the primary technique for diluting and disposing of methane emissions. A large mine may have several fans circulating

Table 15.4-3 Gassiness of coal seams

Category	Depth, m	Gas Content, m^3/t
Mildly gassy	≤200	<3
Moderately gassy	200–500	3–10
Very gassy	>500	10–25

50,000–100,000 m^3/min of air in the mine airways to keep methane concentration below statutory limits. Gassiness of a mine is also expressed as total methane emissions divided by the total daily coal production, and the ratio is called specific emissions. It is generally economically feasible to handle specific emissions as high as 30 m^3/t with a well-designed ventilation system, but with increasing methane emissions, a stage is reached when it becomes impossible to stay within statutory limits with mine ventilation alone. Methane drainage then becomes necessary. With a well-planned methane drainage scheme and a good ventilation system, even very gassy mines with specific emissions in excess of 100 m^3/t can be safely operated.

In gassy mines it is best if most of the methane is recovered by carrying the gas in pipelines without mixing it with mine air.

Properly designed and carried out, methane drainage has the following benefits:

- Enhanced mine safety
- Improved coal productivity leading to a lower cost of production
- Reduced number of entries in development sections, which leads to faster development and an improved longwall/development coal ratio
- Reduced number of ventilation shafts, size of fans, and power cost
- Controlled respirable dust due to boreholes drilled in coal seams providing a channel for advance exploration and water infusion
- Defrayed costs through marketing of produced gas and boosting energy production from coal mines

The Gas Emission Reservoir and Its Properties

Methane emissions during the mining process take place in two stages: during development and during actual longwall mining. In the development phase, all methane emissions are realized from the coal seam being mined. Methane emissions on the longwall face are also realized only from the coal seam being mined. In order to achieve a high rate of advance in longwall gate roads as well as the mains, the working coal seam must be properly degassed prior to mining. The most important reservoir properties that must be determined for designing an optimum degasification scheme are

- Gas content and gas isotherm of the coal seam;
- Water content of the coal seam and its chemical composition;
- Reservoir pressure;
- Directional permeability of the coal seam;
- Magnitude and directions of principal horizontal stresses; and
- Compressive strengths and elastic moduli of the coal seam, the roof, and the floor.

For most efficient mining, the gas content of very gassy coal seams must be reduced to <3 m^3/t and reservoir pressures should be reduced to <0.5 MPa. The amount of gas retained

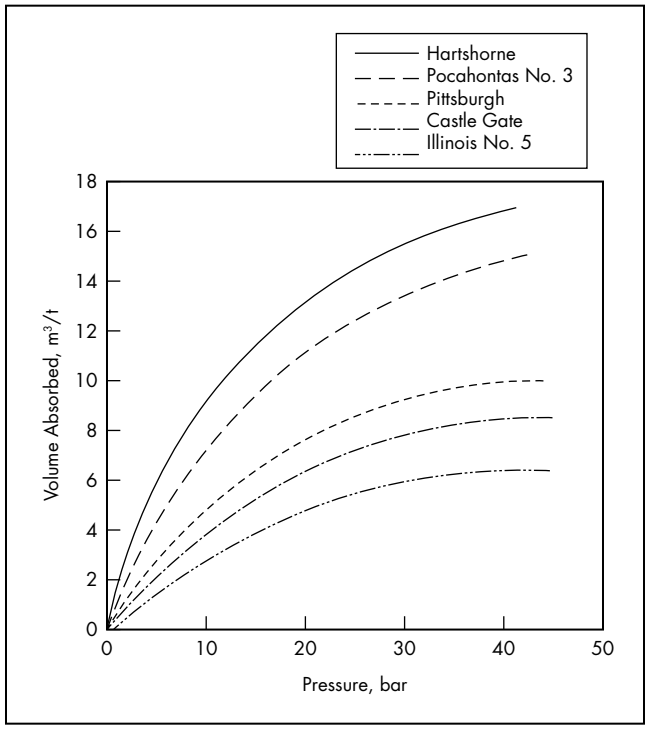

Figure 15.4-1 Gas isotherms for U.S. coal seams

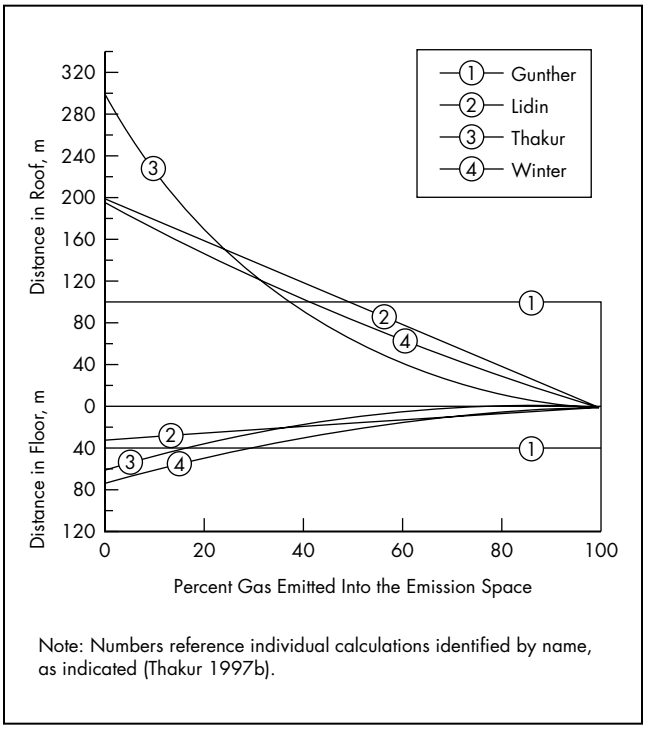

Figure 15.4-2 Vertical limits of the gas emission space

by coal seams at any given pressure can be determined from their gas isotherms. Typical gas isotherms for some U.S. coals are shown in Figure 15.4-1.

In the postmining phase, the gas emission reservoir is considerably expanded. Figure 15.4-2 shows the vertical extent of the gas emission space created by longwall mining and the percentage of gas contents released by various coal seams into the gas emissions space as a function of their distance from the mined coal seam. The vertical dimension of the gas emission space is highly dependent on the width of the longwall face. In general, the wider the longwall panel, the greater the vertical extent of the gas emission space and, consequently, the higher the specific gob gas emissions (volume of gas emitted per unit area of the gob). For optimum methane capture, the specific gob gas emissions for the longwall panel must be calculated from Figure 15.4-2 and subsequently verified by direct measurement of postmining methane emissions.

A very gassy coal seam is usually underlain and overlain by equally gassy, but generally nonmineable, coal seams. Longwall mining fractures them all, and their gas contents are released into the mine. Specific gob gas emissions can be as high as 2 million m^3/ha of the gob area, but it depends on the following conditions:

- Total thickness, gas contents, and proximity of other coal seams to the mined seam in the gas emission space
- Width of the longwall panel
- Presence of geological disturbances (e.g., lineaments, faults)
- Thickness and properties of noncoal strata above and below the mineable coal seam

Coal Seam Degasification

Coal seam degasification can be broadly classified into two phases: premining degasification and postmining degasification. Some of the premining degasification techniques can also be used for commercial coal-bed methane production (see Chapter 11.6). Premining degasification is usually done 3–5 years ahead of mining, but for commercial coal-bed methane production the coal seams should be drilled at least 10 years ahead of mining. This maximizes the return on investments.

Premining degasification. At present there are three techniques commonly used for premining degasification: in-mine horizontal drilling, vertical hydrofractured (hydrofraced) wells, and horizontal boreholes drilled from the surface. Depending on the gas content and depth of the coal seams, one or a combination of these techniques is used to reduce the gas content and reservoir pressure to <3 m^3/t and 0.5 MPa, respectively. Vertical hydrofraced wells and horizontal boreholes drilled from the surface can also be used for commercial coal-bed methane production.

In-mine horizontal drilling. Figure 15.4-3 (plan view of a longwall face) shows a commonly used pattern of drilling in a moderately gassy coal seam (with a gas content >3 m^3/t). The drilling rig follows the continuous miner driving the development section and drills ahead of the mining face to degas the section. Next, a cross-panel borehole is drilled in the longwall panel from the same site to degas it. This pattern is repeated approximately every 300 m. In a permeable coal seam (permeability ≥10 millidarcies), nearly 50% of in-situ gas can be removed prior to mining. A detailed description of this technique is available in published literature (Thakur and Davis 1977; Thakur and Zachwieja 2001). This technique of degasification is equally suited to the room-and-pillar type of mining.

Vertical hydrofraced well. In very gassy, deep coal seams (gas content > 10 m^3/t) it becomes necessary to first drill with vertical hydrofraced wells in order to reduce the reservoir pressure and partially degas the coal seam. Secondary

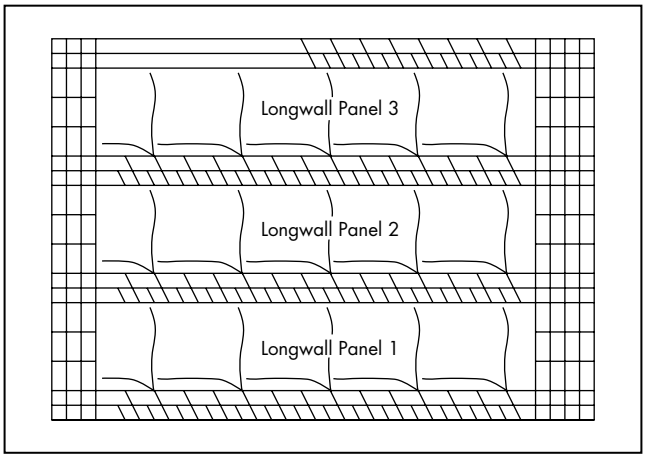

Figure 15.4-3 Coal seam degasification with in-mine horizontal drilling

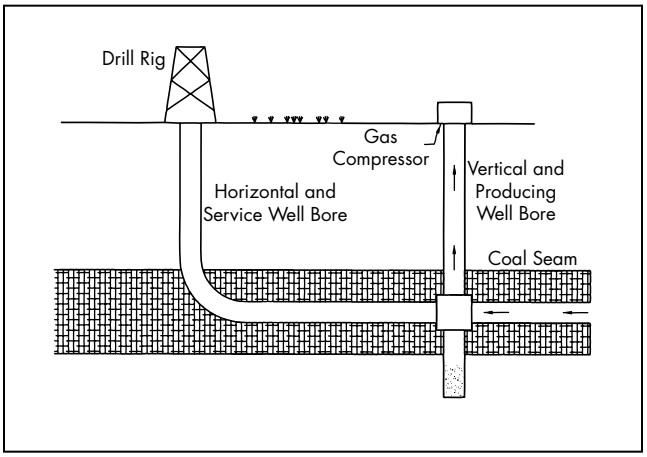

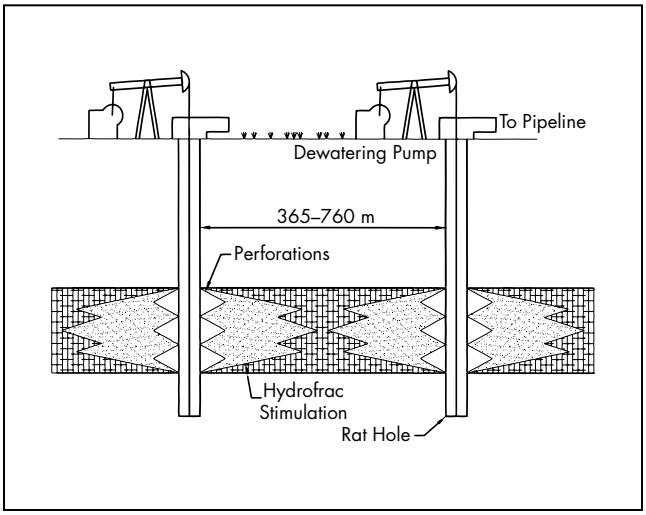

Figure 15.4-5 Horizontal boreholes drilled from the surface

Source: Thakur 2005.

Figure 15.4-4 Vertical hydrofraced wells

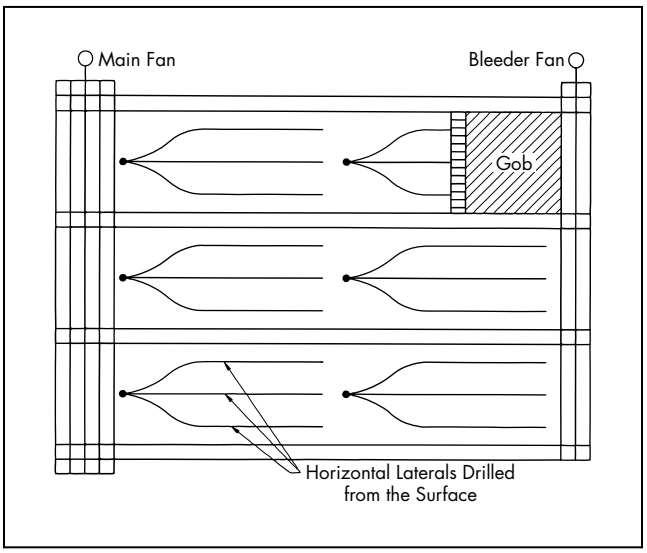

Figure 15.4-6 Coal seam degasification with horizontal boreholes drilled from the surface

degasification is performed by horizontal drilling, either from the surface or underground mine workings. Figure 15.4-4 shows a vertical section of hydrofraced wells. If drilling is done 3–5 years in advance, nearly 50% of in-situ gas can be drained by these wells prior to mining. A 300 × 3,000 m longwall panel in a very gassy mine may need 10–12 vertical hydrofraced wells to achieve this goal. When the reservoir pressure is reduced to <1.5 MPa, the longwall panel is drilled horizontally to remove an additional 25%–30% of in-situ gas content of the coal seam. Well-designed hydrofraced wells can create a vertical fracture in a coal seam that has a length of 300–600 m. Hydrofracing is typically done with nitrogen foam, but plain water, gelled water, and cross-linked gels have also been used depending on the specifics of the coal seam. This technique can be used for both coal seam degasification and commercial gas production.

Horizontal boreholes drilled from the surface. Figures 15.4-5 and 15.4-6 show the common design and application of horizontal boreholes drilled from the surface for coal seam degasification. For successful operation, water produced by the horizontal laterals must be removed. A production well with a sump (drilled below the coal seam to be degassed) is first drilled. Nearly 100 m away, a vertical well is drilled, and when the borehole approaches the target coal seam, it is deviated by 90° to intersect the coal seam and the production well horizontally. The borehole can be laterally extended to a distance between 1,000 and 2,000 m depending on the depth of the coal seam. A water pump is installed in the production well to remove water as well as coal fines, and gas production is maintained. Very expensive instruments are needed to articulate a horizontal borehole to intersect the production well and keep it in the coal seam for most efficient methane drainage. The cost of drilling horizontal boreholes from the surface is, therefore, much higher than the cost of drilling in-mine horizontal boreholes. However, this is the best technique for commercial coal-bed methane production from all coal seams, and its application is increasing (Thakur et al. 2002b).

Postmining degasification. Longwall mining creates a much larger gas emission space than the mined coal seam. Besides the specific gob gas emission of the longwall, the other factor that has the greatest influence on the postmining methane emission rate is the rate of longwall face advance.

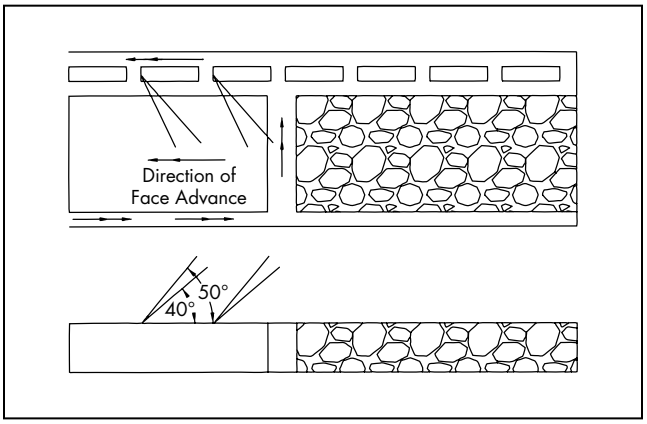

Figure 15.4-7 Methane drainage with cross-measure boreholes

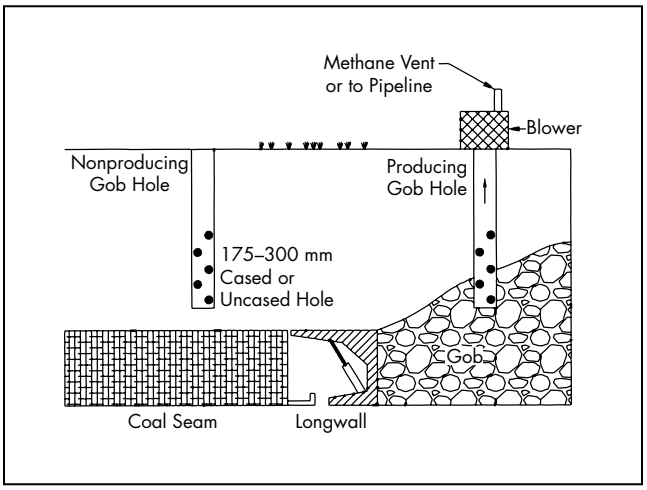

Figure 15.4-8 Methane drainage with vertical gob wells

Methane emission from the gob is linearly proportional to the rate of face advance in hectares per day. Approximate gob emissions in million cubic meters per hectare can be calculated from these two data points. At present there are only two viable techniques for postmining methane drainage: cross-measure boreholes and vertical gob wells.

Cross-measure boreholes. Figure 15.4-7 shows a typical layout of methane drainage from retreating longwall gobs using cross-measure boreholes. Inclined boreholes, 50–100 mm in diameter, are drilled from longwall gate roads into the roof (and sometimes into the floor). These boreholes are inclined at 40°–50° to the horizontal plane and are also slanted toward the gob; they are drilled roughly at 30-m intervals. All boreholes are manifolded to a 100–200-mm diameter pipeline and gas is conducted to the surface. Gas production is often assisted by applying negative pressure of 100–1,000 mm of water gauge. This system of methane drainage is best suited to slow-moving longwall faces in mildly gassy mines. It is popular in European mines but generally unsuitable for gassy and highly productive U.S. and Australian longwall faces.

Vertical gob wells. Figure 15.4-8 shows upward gas movement in the well over the gob. Steel casings of 175–300 mm diameter are anchored in competent rock strata nearly 100–300 m above the working seam, and the bottom 100–300 m is slotted to permit gas entry. Gas production is generally assisted with powerful blowers.

In U.S. coal mines, longwall panels in very gassy coal mines can be 240–400 m wide and can advance 15–30 m/d. The specific gob gas emission in the central and southern Appalachian basin of the United States can be 1–2 million m^3/ha. Hence, the gob gas emission rate can range from 0.5–1.2 million m^3/d. The bleeders with a limited number of entries and ventilation air (8,000–10,000 m^3/min) can capture only 0.1–0.2 million m^3/d of methane. The remaining gob emissions must be captured by vertical gob wells resulting in methane capture ratios of 65%–85%. Completion techniques for these gob wells are described elsewhere (Davis and Krickovic 1973; Mazza and Mlinar 1977). Although the spacing of these gob wells on a longwall panel can be calculated if good data are available, the best method is to go by direct experience in the local basin and the mine. Generally, a spacing of 3–6 ha per well should yield 70%–80% of methane capture if assisted with well-designed blowers.

This method of postmining degasification has also been successfully used in retreat mining of room-and-pillar sections.

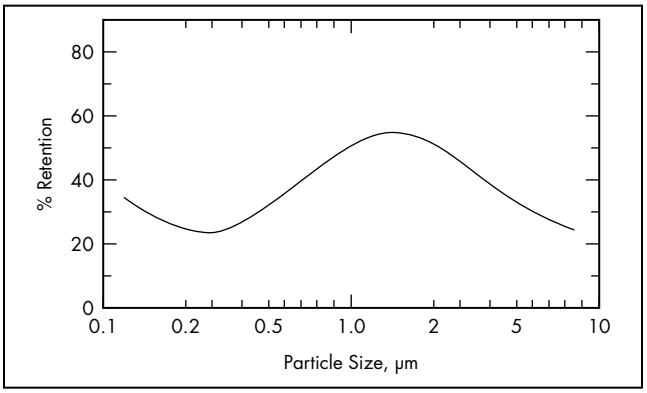

Table 15.4-4 Classification of dusts

Classification	Minerals
Fibrogenic dusts (harmful to respiratory system)	Silica (quartz, chert), silicates (asbestos, talc, mica), metal fumes (nearly all), beryllium ore, tin ore, iron ores (some), carborundum, coal (anthracite, bituminous)
Carcinogenic dusts	Radon daughters, asbestos, arsenic
Toxic dusts (poisonous to body organs, tissue, etc.)	Ores of beryllium, arsenic, lead, uranium, radium, thorium, chromium, vanadium, mercury, cadmium, antimony, selenium, manganese, tungsten, nickel, silver (principally the oxides and carbonates)
Radioactive dusts (injurious because of alpha and beta radiation)	Uranium ore, radium ore, thorium ore
Explosive dusts (combustible when airborne)	Metallic dusts (magnesium, aluminum, zinc, tin, iron), coal (bituminous, lignite), sulfide ores, organic dusts
Nuisance dusts (little adverse effect on humans)	Gypsum, kaolin, limestone
Inert dusts (no harmful effect or cellular response in lung)	None

Respirable Dust Control

When mineral (metal and nonmetal) and sedimentary deposits such as coal are mined, processed, or transported, fine dust is produced by the crushing of the original material. Dust has been defined as solid particles <100 μm in size that can be disseminated and carried by air in suspension. Dust clouds in mine airways constitute two well-known hazards, namely, dust explosions and dust-related lung diseases such as silicosis and coal workers' pneumoconiosis. Table 15.4-4 shows a list of different kinds of dust encountered in mines. They are classified as pathogenic or explosive dusts but in decreasing order of severity (Hartman et al. 1997). Some rate multiple listings.

Dust concentrations in air to sustain an explosion ranges from 20–500 g/m^3. Such high concentrations cannot be created or sustained under normal working conditions. Most dust explosions are preceded by a gas explosion that can kick up the deposited dust, creating a dangerous situation. Dust explosions have been made almost nonexistent by the process of

Source: ILO 1965, © International Labour Office.

Figure 15.4-9 Alveolar retention of particles of unit density

mixing inert dust such as gypsum or limestone dust with combustible dust in very high proportions. For example, mixing limestone dust with deposited coal dust so that the incombustible content is at least 60% will render the mixed dust nonexplosive.

Dust particles finer than 10 μm (unit density spheres) do not generally settle in the turbulent airflow in the mine airway. This size range is called respirable dust. The human respiratory system consists of a series of branching passages decreasing in size but increasing in number. Thus, starting with inhalation either through the nose or mouth, the air passes in succession through the trachea, bronchioles, alveolar ducts, and finally into alveolar sacs where gaseous exchange of oxygen takes place. The lungs act as both a filter and a scavenger for dust particles.

When dust-laden air is inhaled, only a small fraction of it is deposited in the lungs. The mechanisms of deposition are impaction, sedimentation, and diffusion, much the same as in the case of a simple paper filter. Figure 15.4-9 shows a typical deposition and retention curve for the portion of the lungs below the bronchioles, popularly known as the pulmonary deposition curve (ILO 1965). Thus particles >10 μm are deposited by impaction in the nose and the top of the trachea. Particles <10 μm are deposited by sedimentation in the upper respiratory region with progressively increasing efficiency as the size decreases. A maximum is reached around 2 μm, below which there is a decline. A minimum is reached around 0.3 μm, beyond which there is further increase in depositional efficiency due to diffusion forces.

The scavenging action of the lungs is equally important. Practically all dust particles deposited in the upper respiratory tract are trapped by cilia (hair-like structures lining the trachea) and transported to the mouth where they are spat or sneezed out or swallowed. Since the digestive system is sturdier than the lungs, the swallowed particles seldom do any harm. Dust particles deposited in the alveolar ducts and sacs are ingested by migratory cells, the phagocytes, and transported to lymph nodes with varying degrees of efficiency.

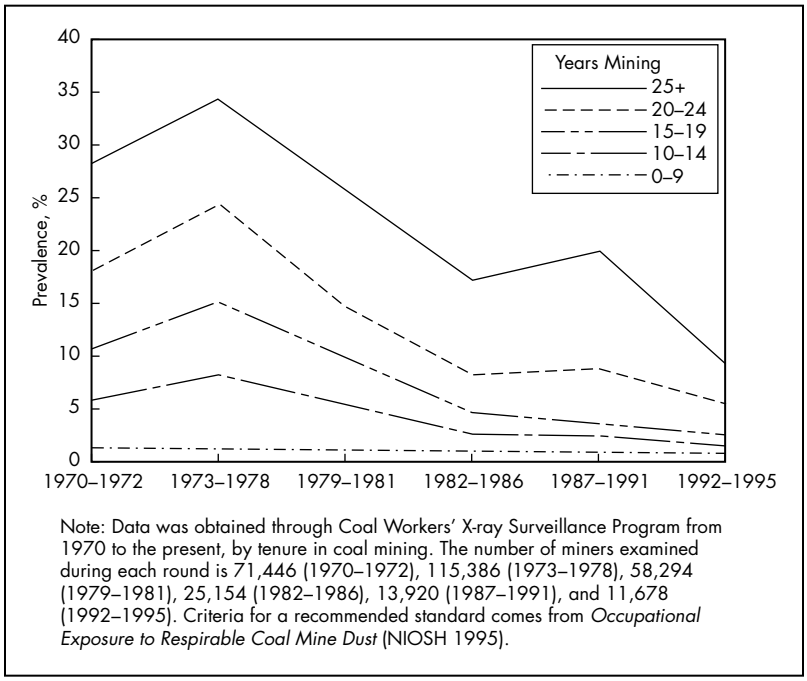
With continued exposure to high concentrations of dust, the lungs' parenchyma accumulates a critical mass and body tissues begin to react to the dust particles causing lung diseases. Depending on the type of dust inhaled, the lung disease is commonly called silicosis (for silica), asbestosis (for asbestos), silicatosis (for silicates), siderosis (for iron ore), and coal workers' pneumoconiosis (for coal dust, also known as black lung). Almost all industrialized nations have set up

Table 15.4-5 Respirable dust permissible exposure limits

Dust Type	PEL	Comments
Crystalline silica	0.1 mg/m^3	U.S. standard; other standards are less stringent
Silicates		
Asbestos	5 fibers/cc	>5 μm
Mica	706/million m^3	
Cement	1,056/million m^3	
Talc	706/million m^3	
Coal dust	2 mg/m^3 or 10/% crystalline silica	When silica <5% When silica >5%; U.S. standard is the most stringent
Metallic Dusts		
Mercury	0.05 mg/m^3	
Lead	0.15 mg/m^3	
Antimony, arsenic	0.5 mg/m^3	
Manganese	5 mg/m^3	
Iron, zinc molybdenum	5 mg/m^3	
Uranium (insoluble)	0.2 mg/m^3	
Vanadium (V_2O_5)	0.5 mg/m^3	

Source: Adapted from ACGIH 1972.

a permissible exposure limit (PEL) for the exposure to various dusts. The PELs for various respirable dusts are shown in Table 15.4-5. They are adapted from the general guidelines provided by the American Conference of Governmental Industrial Hygienists (ACGIH 1972).



These PELs were developed and implemented during the past 40 years. In general, they are more stringent than the old standards, and the impact on workers' health has been favorable. A fine example is the 70% decline of coal workers' pneumoconiosis (CWP) in U.S. coal mines during the past 40 years as shown in Figure 15.4-10.

In order to minimize, if not totally eliminate, the incidence and prevalence of any dust-related lung diseases, a holistic approach comprising the following requirements are necessary (the last two requirements will not be discussed in this chapter) (Thakur 1997a):

1. Better personal exposure monitoring (daily and cumulative)
2. Better mining and dust control technologies
3. Recognition of disease-causing characteristics of each dust, particularly epidemiological data on dust exposure (dosages) and related occurrence and progression of lung diseases
4. Lifestyle intervention program including cessation of smoking and medical surveillance

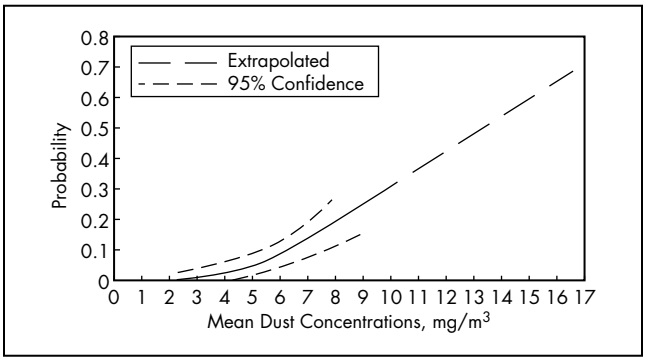
Personal Exposure Measurement

Earlier dust sampling instruments such as the impinger and konimeter were nonsize selective and simply measured the number concentration of dust in the air. The concentration of respirable dust was expressed as the number of dust particles per unit volume of air. Other instruments based on the same principle of particle counting were introduced later, namely, the membrane filter and the thermal precipitator. All of them took a long time to determine the dust concentration, in addition to which they were labor and laboratory time-intensive.

Note: Data was obtained through Coal Workers' X-ray Surveillance Program from 1970 to the present, by tenure in coal mining. The number of miners examined during each round is 71,446 (1970–1972), 115,386 (1973–1978), 58,294 (1979–1981), 25,154 (1982–1986), 13,920 (1987–1991), and 11,678 (1992–1995). Criteria for a recommended standard comes from *Occupational Exposure to Respirable Coal Mine Dust* (NIOSH 1995).

Figure 15.4-10 Prevalence of CWP Category 1 or higher

A simple but real-time dust measuring device was needed that could be used for evaluating dust conditions underground. Several dust concentration measuring instruments were developed in the 1970s that were based on light-scattering measurements. The tyndalloscope was the first instrument designed on this principle, but it did not perform very well compared to other instruments. It was very sensitive to the size distribution of dust particles and needed frequent calibration. Subsequently three instruments—the Tyndallometer, Simslin, and GCA Ram—were designed to measure scattered laser light in Germany, the United Kingdom, and the United States, respectively. They were also sensitive to the size distribution of dust particles. But their biggest drawback was their inability to distinguish between dust and water particles. Water sprays used to suppress dust significantly affected the dust concentration readings (Thakur et al. 1981). During the same time period, the dust measurement technology was required to be size selective. The new criteria for sampling and measurement of dust concentration were as follows:



- The sampling device should be size selective and it should mimic the human nose.
- The dust concentration should measure the "mass" of dust per unit volume of air.

Hartman et al. (1997) compared size-selective curves for respirable dust from the British Medical Research Council (BMRC)/Johannesburg and the U.S. Atomic Energy Commission. The BMRC/Johannesburg had 0% collection for 10-µm particles, 50% collection for 3.5-µm particles, and 100% collection for particles <2 µm. This was achieved by classifying the respirable dust with a horizontal elutriator. The U.S. Atomic Energy Commission developed a size-selection device using a cyclone that had 0% collection at 7.1 µm, 50% collection at 3 µm, and 100% collection at 2 µm or smaller particles.

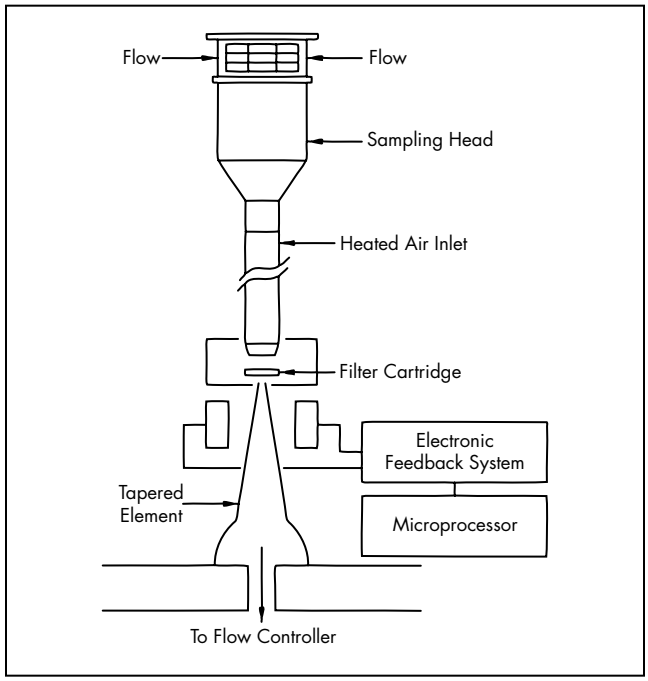
The second criterion required that dust samplers should measure the mass of dust per unit volume in air. This conclusion is based on the findings of the National Coal Board's (United Kingdom) pneumoconiosis field research study (Jacobsen et al. 1971). Dust exposures of a large cohort of coal miners were measured and correlated with changes in their lung radiographs. Figure 15.4-11 shows a quantitative relationship between the coal mine dust exposure and the risk of developing simple CWP. The latter is characterized by the presence of small nodules in the lung and classified as Category 1, 2, or 3 according to the profusion of the nodules. Simple CWP Categories 1 and 2 can be reversed by moving the mine worker to an area with much less or no dust exposure. In Category 3, pulmonary massive fibrosis sets in, and it is generally irreversible.

MRE gravimetric dust sampler. The MRE gravimetric dust sampler was developed by the Mining Research Establishment (MRE) of the National Coal Board. It is the standard dust sampling instrument for most industrialized nations, including the United States, Canada, the United Kingdom, and Australia. It is based on the BMRC/Johannesburg size-selection curve and uses a horizontal elutriator for this purpose. The classified dust particles are collected on a membrane filter. The preweighted filter is weighed again after sample collection, and the differences in weight divided by the volume of air sampled yields the gravimetric dust concentration. The only drawback of this instrument is its size and weight. It measures the mass concentration of respirable dust but cannot be conveniently carried by a mine worker.

The U.S. personal gravimetric sampler. This sampler follows the U.S. Atomic Energy Commission size-selection curve and uses a nylon/metal cyclone to classify dust particles. It consists of two basic components: a cyclone assembly with a preweighed filter cassette, and a rechargeable battery-operated diaphragm pump with calibrated flow rates. The

Source: Jacobsen et al. 1971.

Figure 15.4-11 Probability that a worker with no pneumoconiosis will be classified as Category 2 or higher after 35 years of exposure to various concentrations of coal mine dust



pump is worn on a miner's belt but the cyclone-filter assembly is clipped onto the miner's collar to be as close to his or her nose as possible. Thus, the sampler collects the dust particles that the wearer is likely to breathe and gives a better measure of mine worker's exposure.

The two instruments have excellent correlation. The personal sampler operating at a flow rate of 2 L/min yields a respirable dust concentration that is multiplied by a factor of 1.38 to make it compatible to the MRE sampler measurement. The 2.00 mg/m^3 dust standard for U.S. coal mines is based on the MRE sampler reading. For noncoal mines, the personal sampler draws air at 1.7 L/min and the measured dust concentration is the dust standard; that is, no correction is applied (CFR 2003).

Instantaneous dust monitors. Although the MRE sampler and the personal sampler are required instruments for compliance with dust standards, they are not able to give instantaneous dust readings that can be used for immediate engineering control. Two instantaneous reading instruments are currently in use in the mining industry, the MINIRAM and the TEOMB.

MINIRAM (miniature real-time aerosol monitor). The measuring principle is based on the detection of scattered electromagnetic radiation in the near-infrared region. The MINIRAM senses the radiation scattered by respirable dust particles by means of silicon-photovoltaic hybrid detectors, within a 1-m^3 volume of air. Air passes freely through the open sensing chamber induced by personal movement, ventilation, convection, or a combination of all three. No pump is required. The instrument measures particle diameter in the range of 0.1–10 μm and is independent of air velocity. It is controlled by a single-chip complementary metal-oxide semiconductor microprocessor that provides continuous real-time reading of airborne dust concentration. The instrument is light and small in size and can be easily used anywhere in the mine.

TEOMB (tapered-element oscillating microbalance). As the name implies, the instrument is a real-time mass monitor of respirable dust based on the principle of a tapered-element oscillating microbalance. This instrument consists of a replaceable filter cartridge mounted on the narrow end of a hollow, tapered tube (Figure 15.4-12). The wider end of the tube is fixed. Air is drawn through the filter and dust particles are deposited on it. The tapered tube oscillates but the frequency

Source: Schmitz 1994, courtesy of the IEA Clean Coal Centre.

Figure 15.4-12 TEOMB ambient particulate monitor

of oscillation (initially 252 Hz) depends on the mass of the tapered element, including the filter. The frequency changes as the dust is deposited on the filter, increasing the total mass of the tapered element. The change in frequency translates into dust concentration. A microprocessor collects data on air volume sampled and corresponding dust mass collected, does the calculation, and displays dust concentration in real time in milligrams per cubic meter.

The instrument is sensitive to mechanical vibrations and should not be mounted on mining machines. It is best carried on a person. It is also sensitive to moisture. The intake air stream is maintained at 50°C to minimize this problem.

The TEOMB can operate with flow rates from 0.5 to 5 L/min. The data can be displayed instantaneously, hourly, or at the end of an 8-hour shift. It is highly recommended for engineering control of respirable dust in mines.

Engineering Control of Dust

Because the respirable dust in suspension behaves like a gas, the engineering control of respirable dust, in principle, is similar to that for gases discussed earlier. The sequence of control techniques (listed in descending order of importance and effectiveness) are

1. Prevention of generation of dust and its suspension in air,
2. Suppression of airborne dust on-site,
3. Collection of dust that could not be suppressed, and
4. Dilution with auxiliary and main ventilation.

Use of protective equipment/administrative control in special situations is the last resort, but it is not regarded as a dust-control technique. The following steps illustrate this strategy for dust control in underground coal mining:

1. Coal seams are infused with water and cut with very sharp bits to minimize dust generations.

2. Water mixed with surfactants is sprayed at high pressure to suppress dust on-site.
3. In many cutting and drilling operations, the airborne dust is collected and scrubbed before discharge.
4. Adequate ventilation is provided to dilute the remaining dust and keep the dust concentration below statutory limits.
5. For persons working in return airways, well-designed personal equipment, such as air helmets, is used to protect the workers.

Engineering control of dust is divided into the following types of mining and processing operations:

- Coal mining—continuous mining sections
- Coal mining—longwall sections
- Coal mining—surface
- Metal mining
- Mineral in transport
- Mineral/coal processing

Coal mining—continuous mining sections. All four techniques to control respirable dust have been used in continuous mining sections. Infusing the coal seam with water or water-soluble gels (e.g., sodium silicate and sodium bicarbonate) has been done on a very limited basis because of high cost. Using large and sharp cutting bits also reduces dust generation.

Most common dust control techniques comprise use of water sprays to suppress dust, use of water scrubbers in some cases, and use of ventilation air to dilute the respirable dust concentration below statutory limits.

Water spray systems. Water sprays installed on continuous miners deliver 120–240 L/min water at 0.5–1 MPa pressure at the nozzle. Besides suppressing dust, the sprays also wet the coal, keep the cutting bits cool, and serve as an emergency fire suppression system. Spray nozzles are strategically installed on the continuous miner to achieve these goals. A well-designed spray system can reduce respirable dust concentration by 60%; typical reductions range from 30% to 50%. Ideally, there should be a spray behind each cutting bit delivering 2–4 L/min at 0.3–0.8 MPa. Such machines are known as wet-head continuous miners and they achieve the best dust control.

Water scrubbers. Where seam height permits, the flooded-bed-type scrubber is becoming increasingly popular for use on continuous miners. It is mainly used with blowing-type face ventilation. The dirty air is drawn into a water scrubber by fans and collects the dust. The airflow in the scrubber must be properly matched with the airflow in the heading. A well-designed system with remote operation can cut down respirable dust exposure by 80% (Goodman and Listak 1999). Often, a demister is used to remove water from the scrubber discharge.

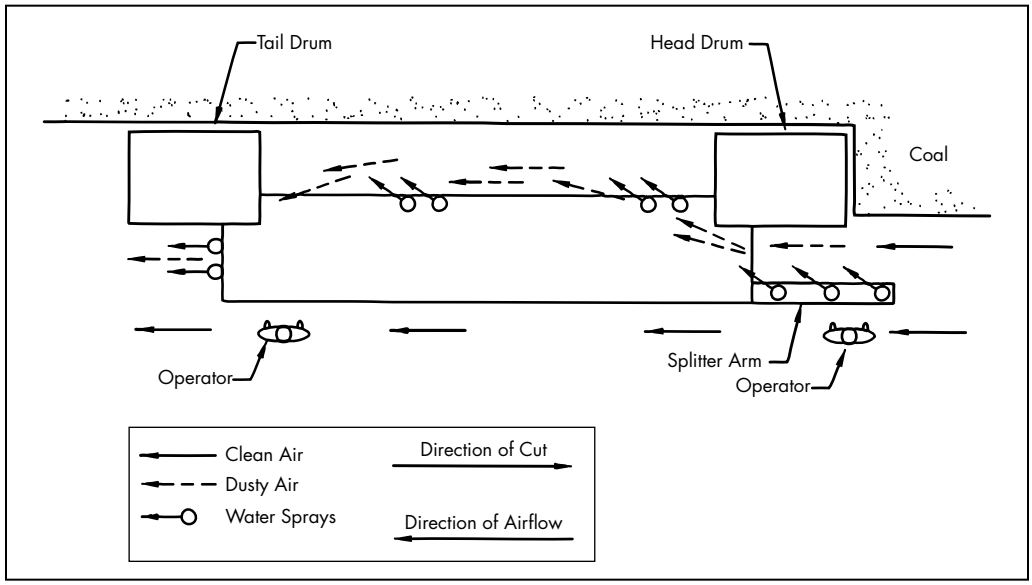
Ventilation air. The quantity of ventilation air at the face is perhaps the most important factor in controlling dust exposures. Average air velocity in the face area ranges from 20 to 150 m/min. Air is brought to the face using either line brattice or auxiliary fans and tubing. For best results the end of the line brattice or ventilation tubing should be kept within 4.5 m from the face. When face ventilation is done with auxiliary fans and tubing, it can be either a blowing or exhausting ventilation. Sometimes a combination of both blowing and exhaust ventilation is used for optimum results.

Table 15.4-6 Dust source contribution on longwall faces

Source	Average %	Concentration (median value)
Intake	9	0.33 mg/m^3
Stage loader–crusher	15	0.78 mg/m^3
Shields	23	1.80 mg/m^3
Shearer	53	3.50 mg/m^3

Coal mining—longwall sections. The sources of dust on a longwall face are the intake air, the stage loader–crusher, the shearer, and the shields.

The intake air is usually a minor source of dust unless the belt air is used on the face. Confinement and well-designed water sprays usually at <0.5 MPa pressure can generally keep the contribution of dust from the stage loader–crusher at a minimum. The dust created by shield movement is also contained by mounting water sprays on the shields. The biggest source of dust on longwall faces is the shearer. Table 15.4-6 gives a summary of data obtained from thirteen longwall faces (Kissell 2003).



Water infusion. Excellent dust control can be achieved by drilling the longwall for degasification, as discussed earlier, and using the horizontal boreholes for water infusion. Slow infusion at pressures of 0.5–2 MPa has given excellent results, often reducing dust generation by 80% (Nagy et al. 1957). Larger and sharper cutting bits also reduce dust generation. Use of very high pressure water (30–70 MPa) jets to assist coal cutting has also significantly reduced dust generation.

Water sprays. Well-designed water sprays are the next best way to control dust on longwall faces. A minimum of 400 L/min at 0.7 MPa is recommended (Colinet et al. 1997). Ideally, there should be a spray behind each cutting bit but, in general, the larger the number of sprays, the better the dust control. The water sprays, on and around a longwall shearer, can be so arranged that they direct the dust cloud away from the operators and hold it against the face (Figure 15.4-13). This arrangement of sprays is called a shearer–clearer spray system and it reduces shearer-generated dust by 30%–50% (Jayaraman et al. 1985).

Coal mining—surface. Respirable dust in surface mining is created by a number of operations such as drilling, mobile excavation equipment, and haul roads. The situation can become serious under dry and windy conditions.

Drill rigs. Two well-established practices for dust control on drill rigs are dry collection and wet suppression. In a dry collection system, an enclosure is created around the well bore being drilled, which is hooked up to a fan and a filtration system. The negative pressure created by the fan helps contain the dust within the enclosure. The filtration system collects most of the dust and clean air is exhausted to the atmosphere. In the wet collection system, water (often treated with some surfactants) is mixed with the compressed air used to bring drill cuttings out of the hole. Typically less than 4 L/min of water is used for this purpose. The collection efficiency appears to increase from a low rate of 0.8 L/min to a limit of approximately 4 L/min (Zimmer et al. 1987).

Mobile equipment. The operators of mobile equipment such as bulldozers, front-end loaders, and haulage trucks can be best protected by tightly enclosed cabs. In extremely dusty

Source: Adapted from Kissell 1992.

Figure 15.4-13 Air currents when using the shearer–clearer system

situations, filtered air can be pumped into the driver's cab and a slightly positive pressure maintained within the cab.

Haul roads. Wetting the haul roads frequently with water is the most commonly used procedure. To improve the wetting capacity of plain water, hygroscopic salts such as calcium chloride, sodium silicates, or surfactants are often added. The other approach is to create a film of impervious material that can contain the dust. Most commonly used materials are portland cement and bitumen derived from coal or polymers. The best dust control method really depends on the type of road aggregate involved.

Metal mining. Main sources of respirable dust are drilling rigs; blasting; ore- and waste passes; and conveyor belts, transfer points, and roadheaders, if used. Fundamental principles of dust control in metal mines are similar to those for coal mining (i.e., prevention of generation, suppression onsite, collection of airborne dust, and dilution with ventilation).

Drilling rigs. Wet drilling is far superior to dry drilling and can reduce dust concentration by 95% (MSA Research Corp. 1974).

Blasting. Water can be important in controlling blasting dust. The area to be blasted should be thoroughly wetted with water spray beforehand. Good ventilation is also necessary for efficient control of blasting fumes and dust. However, perhaps the best technique to avoid exposure to blasting dust and fumes is to carry out the operation off-shift, when there are no miners in the section.

Ore- and waste passes. Ore- and waste passes create large quantities of respirable dust. Falling ores create a pressure wave discharging dusty air into mine workings. The first step in controlling dust is to design an orepass that is connected with other ore- and waste passes. This relieves the intensity of the pressure wave. The second step in controlling dust is to put the orepasses on exhaust with air velocity at about 60 m/min and discharge the air into a return airway (MAC 1980).

An alternative approach is to confine the dust in the orepass and use sufficient amounts of water to suppress the dust. Water sprays can be installed at the tipping site and the ore can be wetted prior to delivery to the tipping site. However, excessive use of water can create additional problems such as plugging of the chutes, excessive water accumulation in the orepass, and adverse milling conditions.

Conveyor belts, transfer points, and roadheaders. Conventional water sprays are used to suppress dust on conveyor belts, transfer points, and roadheaders. All dust control techniques discussed for continuous mining sections can be used to control dust from roadheaders.

Mineral in transport. Fugitive dust created in mineral transport can be successfully controlled by identifying the points of origin and installing proper control equipment. Major points of origin are loading, transportation, unloading, and stockpiles. Loading and unloading use silos, cranes, front-end loaders, and belt conveyors. For transportation, trucks, trains, and conveyor belts are used. Stockpiles are located at various points in the mineral chain, but primarily at the mines, ports, and the consuming plant. General principles of dust control in transportation are discussed in great detail elsewhere (Schmitz 1994), but they are similar to the guidelines discussed earlier for in-mine dust control.

Prevent dust generation. Every effort should be made to design loading, unloading, and transporting equipment to minimize dust generation. Stockpiles can also be designed to minimize total surface area for a given volumetric content.

Use dust suppressants. Increasing the moisture content of the mineral increases the force of cohesion. Water sprays are the most common devices used to control dust. Sometimes the water is atomized using compressed air or high-frequency sound to improve the efficiency of dust control. Adding surfactants to water also improves dust control. Besides water, many other liquids and chemical additives can also improve dust control. Oil and oil products are highly suited to use as coal dust suppressants because of their surface chemistry. Agglomeration agents such as polymer emulsions are also used for dust control. The main advantage of an agglomeration agent is its longevity of use. Effective dust control may be sustained over several transfer points. Coating agents such as

polymers are mixed with water or are sprayed on bulk materials to form a water-insoluble crust on the material. This prevents the effects of weathering and wind erosion. Foams are used where the use of excessive water can create problems. Only water, compressed air, and foaming agents are needed to achieve this. Foaming agents are high-foaming surfactants, and they may also contain wetting and binding agents.

Contain and capture. Suppressants can successfully prevent dust from becoming airborne but can have high cost and some environmental concerns. They can be supplemented, or at times replaced, by containing and capturing fugitive dust. Capturing techniques require an exhaust fan, hoods, ducts, and fabric collectors/filters. Very high collection efficiency, up to 99%, can be achieved by proper design. The fabric collectors must be cleaned periodically. Wet scrubbers and electrostatic precipitators are also used for dust collection. In an electrostatic precipitator, the dust particles first receive a negative charge from high-voltage DC electrodes, and then they are collected by a positively charged collecting plate. The collecting plates are vibrated to release the dust into a discharge system. Electrostatic precipitators are not recommended for combustible dusts such as coal because of the risks of explosions or fire.

Mineral/coal processing. Sources of dust in a processing plant include belt conveyors, loading/unloading points, transfer chutes, crushers, bucket excavators, chutes, and stockpiles. A very good reference for additional information is the *Dust Control Handbook for Mineral Processing* (Mody and Jakhete 1987).

Personal Protection Equipment

In many countries, approved respiratory protection equipment is required for those working in an area where the respirable dust concentration exceeds the statutory limits. Mainly, they use a filtration system to clean up the air to be inhaled, or they provide filtered intake air with a positive pressure to the workers.

Replaceable filter respirator. A respirator consists of a mask that fits a miner's face and forms a seal against the dusty air. Dirty air is drawn through replaceable filters that can collect 80%–98% of all dust in the air. The filter-holding unit is often plastic but can also be made of metal or hard rubber. Although the respirator does an excellent job of respirable dust control, some personal discomfort may arise owing to breathing resistance and facial irritation caused by the face seal. It also tends to interfere with normal voice communication, as well as eyeglasses and goggles. To eliminate these difficulties, sometimes a much lighter, single-use respirator is used. The whole mask is made of the filter material and covers the entire nose and mouth area of the wearer. However, it does not form a perfect seal against the dusty air nor is it as efficient as the replaceable, heavier filters.

Air helmet. The air helmet is a special hardhat (somewhat bigger than the conventional hardhat) that contains a battery-powered fan, a filtration system for dust, and a face visor. It provides protection for head, eyes, and lungs in a single unit. Although the air helmet is much more expensive than mask filters and weighs about 1.4 kg, it is finding wearer acceptance in many mining operations.

In the air helmet, dust-laden air is drawn through the filtration system by a battery-powered fan and the clean air is directed to the full-face visor over the wearer's face. The air exits the wearer's face at the lower end of the visor. The battery is normally smaller than the miner's cap-lamp battery and is carried on the belt.

If air velocity is not high, the air helmet performs almost as well as the replaceable filter mask with collection efficiencies of up to 84%, but at high air velocity, the collection efficiency appears to go down to about 50% (Cecala et al. 1981). This may be due to excessive turbulence created by the high velocity of air forcing dusty air into the visor.

Personal protective devices are meant for situations when a miner enters and works in an area with dust concentrations above the statutory limits. They should not be required to be used for an extended period of time or (under normal operations) the entire working shift. Although personal protection devices can be effective in reducing dust exposures, they are vulnerable to human errors in their cleaning, maintenance, fitting, and use.

Diesel Exhaust Control

Mineral transport in metal mines has been done by diesel engines for a long time. It has many advantages, but the exhaust must be treated and diluted properly to keep the air environment safe.

Diesel Engines

Diesel engines were introduced in European, Asian, and Australian coal mines nearly 60 years ago, but more recently in U.S. coal mines. Currently, nearly 5,000 units are working in U.S. metal mines and another 3,000 units in U.S. coal mines. The driving force behind this phenomenal growth is mine safety and productivity. Diesel equipment improves safety by eliminating electric shocks, fire, and explosion hazards from trolley wires and cabled electrical equipment. It can also prevent personal injury by eliminating the need to carry small loads (up to 40 kg) by hand in work areas.

The main drawback of using diesel equipment in mines is the contamination of air with diesel exhaust emissions. The major components of diesel exhaust are carbon monoxide (CO), carbon dioxide (CO_2), unburned hydrocarbons (HCs), nitrogen oxides (NO_x), sulfur oxides, and diesel particulate matter (DPM). PELs for all gaseous components of diesel exhaust have been well established. Ventilation can dilute all these gases to below their respective PELs.

DPM consists of

- Solid carbon (includes elemental and organic carbons);
- Liquid and solid hydrocarbons, including polyaromatic hydrocarbons (PAHs);
- Sulfates; and
- Moisture.

The PAHs attached to solid carbon particles are generally believed to be potential carcinogens, but their concentrations are exceedingly low.

DPM Standards

At present, there are no DPM standards in the world that are based on sound epidemiological studies correlating sustained exposure to DPM and the resulting health effects. However, several countries have set arbitrary standards, mainly to minimize DPM concentrations in mine air as much as possible. Table 15.4-7 shows some of these standards.

DPM Control Strategy

The best strategy, by general concensus, to control DPM in all mines and tunneling is to take an integrated approach, as summarized by Thakur and Patts (1999):

- Reduce DPM generation
  - Clean engines
  - Clean (low sulfur) fuel
- Combust and collect generated DPM
  - A catalytic converter on all engines
  - Soot filters where needed
- Dilute DPM
  - Minimum ventilation air
- Monitor DPM emissions and maintain equipment
  - Routine engine performance check
  - Proper maintenance
  - Adequate training to operators and mechanics

Reduce DPM generation. The amount of DPM emitted in grams per brake horsepower is known as the specific DPM emission for the engine and is a measure for "clean" engines. Table 15.4-8 shows the specific DPM emission for some old and new diesel engines. The new engines with electronic ignitions and turbocharging are remarkably clean. Whereas the older engines had a specific DPM emission of about 0.3 g/bhp-h, the new engines have a specific emission of only 0.02 to 0.1 g/bhp-h.

The improvement is brought out by electronic ignition and turbocharging. Another technique to reduce the DPM emission is to derate the engine by restricting the maximum fuel rating. Even a 10% reduction in horsepower rating can cut down DPM emissions by 50% or so (Schnakenberg and Bugarski 2002).

Concurrent to the development of clean engines, much effort has been made to improve diesel fuel quality. Extensive research in the field (Cowley et al. 1993) has shown that fuel properties that most influence DPM and gaseous emission comprise sulfur content, fuel density, cetane number, aromatic contents, and oxygen content. Besides sulfur content, the other two most influential properties are cetane number and fuel density.

Sulfur in fuel creates both sulfur dioxide (gas) and sulfates (solids, counted as a part of DPM). When the current American Society for Testing and Materials (ASTM) D2 fuel (sulfur at 340–500 ppm) is used, nearly 50% of DPM is sulfate. Recently, the U.S. Environmental Protection Agency required all diesel fuels to have no more than 15 ppm sulfur, creating an ultra-low-sulfur fuel. The low sulfur level not only reduces the mass of DPM emitted by the engine but also considerably reduces the number of nanoparticles (<40 nm). In some countries the health risks of inhaling diesel exhaust is ascribed to these nanoparticles. Thus, the use of ultra-low-sulfur fuel is quite helpful in reducing the relative health risks.

Alternate fuels such as Fisher–Tropsch (F-T) diesel and biodiesel have received attention as additives to the petroleum diesel fuel. F-T diesel is produced from coal, biomass, or natural gas. It is a very high-quality fuel with a potential to further reduce exhaust emissions. It has a high cetane number (up to 70), a low sulfur content (<10 ppm), and very low aromatic content (<3%). The benefits are more pronounced in DPM emissions (Norton et al. 1999), owing to very small sulfur content. The only drawback of this fuel is low lubricity, and the addition of some lubricants to the fuel is usually necessary.

Table 15.4-7 World DPM standards

Country	PEL	Measurement Technique
United States (metal mines)	0.16 mg/m^3	NIOSH 5040 method for total carbon
United States* (Pennsylvania and West Virginia)	0.12 mg/m^3	Total DPM divided by nameplate air as specified by the Mine Safety and Health Administration
Canada	1.5 mg/m^3	Respirable combustible dust
Germany (metal and nonmetal)	0.3 mg/m^3	Elemental carbon (EC)
Proposed limits		
ACGIH	0.15 mg/m^3	All particles <1 μm
ACGIH	0.02 mg/m^3	EC particles <1 μm

Source: Thakur et al. 2002a; Schnakenberg and Bugarski 2002.

*U.S. federal regulations do not put a separate limit on DPM but combine it with the respirable dust standard of 2 mg/m^3. They do, however, put a limit on DPM emission rates (MSHA 2001):

- Light-duty outby engines: ≤5 g/h
- Heavy-duty outby engines: <2.5 g/h
- Heavy-duty (permissible) inby engines: ≤2.5 g/h

Table 15.4-8 DPM emissions from old and new diesel engines

Engine Type	Horse-power	DPM Emission, g/h	Specific Emission, g/bhp-h
Old engines			
Cat 3306	150	45.9	0.306
Cat 3304	100	29.7	0.297

New engines			
DD Series 40	250	5.10	0.020
Deutz F3L912W	40	4.3	0.108
Deutz F3L1011	42	2.6	0.062

Biodiesel is defined as mono alkyl esters of long-chain fatty acids derived from renewable biomass (e.g., corn, soya beans, sugarcane, and switch grass). Pure biodiesels have relatively low sulfur content (<50 ppm) and no aromatics. The cetane number is comparable to D2 diesel fuel (42–48). Since biodiesel is oxygenated (esters contain oxygen molecules), its combustion in diesel engines is more complete than that of petroleum fuels. As a result, there is a substantial reduction in ambient HC, CO, and DPM. A slight increase in the NO_x emissions (caused by a significant increase in nitrogen dioxide, or NO_2) have been observed in neat biodiesels or biodiesel blends (Sharp 1998).

The synthetic diesel and biodiesel fuels can be used in existing engines and fuel injection systems without negatively impacting engine performance.

Combust and collect generated DPM. The second step in the control of diesel exhaust is to combust (oxidize) the gaseous and liquid portions of the exhaust and collect solids on a filtration medium. The process is also known as exhaust aftertreatment. It can broadly be divided into two processes: diesel oxidation catalysts (DOCs) and DPM filters.

The main function of DOCs is to oxidize CO, HC, and some liquids (PAHs) attached to solid particles in the DPM. The by-product is CO_2 and water. It has no impact on solids.

Although the designs of most DOCs are proprietary, they are usually made of either metal or ceramic monoliths

with very high surface area/volume ratios. They are normally coated with proprietary catalysts made of noble metals or base metals that lower the temperature required to oxidize the volatiles in the exhaust. They can reduce the CO and HC concentration in the exhaust by approximately 90%. Even the diesel particulate mass is reduced by about 25% by driving out and oxidizing all liquids attached to solids.

The DOCs usually last the entire life span of the engine. They are relatively cheap, costing less than a few thousand U.S. dollars for the small engines used in mines.

The main reason for the failure of a DOC is deactivation of catalysts by very high temperature (>650°C) and poisoning by lubricating oil additives (phosphorus, zinc, and heavy metals) and sulfur in fuel. Overcatalyzation of a DOC can result in the excessive production of NO_2 and sulfates if the fuel has a high sulfur content. Most DOCs are designed to match a particular diesel engine and, by and large, perform well. They are universally recommended for all diesel engines working in underground/surface mines, especially in conjunction with ultra-low-sulfur fuels. They should be installed close to the engine for best results.

DPM filters are used downstream from DOCs and usually work in tandem. They can be broadly classified in two categories: a ceramic monolith or a fiber filter media.

The ceramic monolith is made of cordierites or silicon carbide. They are often catalyzed using noble or base metals. As the exhaust flows through the monolith, DPM is collected on catalyzed surfaces and eventually burnt to gases by the "auto regeneration" process. Cordierite monoliths are liable to thermal fractures, but silicon carbide monoliths perform better. They have lower thermal shock resistance but their higher melting point makes them more durable. They also create less backpressure because they have a high permeability for gases. The collection efficiency for DPM ranges from 80% to 95% depending on the manufacturer. The life of a ceramic/silicon carbide filter is normally in excess of 5,000 hours. Routine maintenance and periodic "complete regeneration" in an off-board electric kiln is needed. In some less-demanding operations such as diesel equipment working on flat rail tracks, off-board regeneration is becoming the standard and more reliable procedure. The ceramic filters also act as flame and spark arrestors.

When a fiber filter media is used on a diesel engine, it is necessary that the diesel exhaust be cooled in a water bath. The cooled gas goes through a replaceable paper or synthetic fiber filter where solid particles are collected. The collection efficiency ranges from 90% to 97%. Depending on the duty cycle, a paper filter can last one to five shifts in operation, after which it must be replaced. Intake air resistance (usually limited to 7–8 kPa) often warns when a replacement is due. Synthetic filters can be washed, cleaned, and reused. Since the temperature of all significant parts of a diesel engine is regulated to be below 150°C, the exhaust must be cooled to this temperature before being discharged into mine air. Water scrubbers not only cool the exhaust but also act as flame and spark arrestors. Their main drawback is the high maintenance. Recently dry scrubbers have been developed that do not require the exhaust to contact the coolant. The gases are conducted through tubes that are themselves cooled by the bath. In another design, the coolant is conducted in tubes to cool the exhaust. Both designs are commonly used in underground mines. The fiber filter system is usually large in size and quite expensive. They are, therefore, more suited to bigger equipment on the surface or on locomotives in the mines. They would also be essential on permissible diesel equipment such as shuttle cars.

Dilute DPM. The earliest ventilation standard for diesel engines was developed by the United Kingdom's National Coal Board. It required 4 m^3/min of air for each brake horsepower of the engine. The latest standard for ventilation is the Pennsylvania and West Virginia standard. It requires the ventilation air to be the "nameplate ventilation" as specified by the Mine Safety and Health Administration (MSHA). This air is enough to dilute all gaseous components of diesel exhaust to or below their respective threshold limit values. The exhaust treatment system for the engine must reduce the DPM emissions to a level that, when diluted by the nameplate air, the resulting DPM concentration will not exceed 0.12 mg/m^3. With the advent of clean engines, clean fuels, and new DPM filters, it is not difficult to achieve this high standard anymore.

For multiple engines working in one air split, the old MSHA requirement was the 100-75-50 rule. This means that the ventilation air requirement for the first (usually the biggest) unit is the MSHA nameplate air, 75% of the nameplate air is needed for the second unit, and 50% of the nameplate air is needed for the third and each additional unit. The latest requirement is the total sum of all nameplate airs for the diesel units working in each air split (West Virginia Diesel Commission 1998). Ventilation air requirements for diesel engines working in mines in different situations are extensively described in Thakur (1974).

Monitor DPM emissions and maintain equipment. DPM emissions are actually based on the original eight-mode test of the engines in the laboratory. Two factors that may make the original emissions worse are poor maintenance and the age of the engine.

It is obvious to anyone working in a dieselized mine that a poorly maintained engine can aggravate the DPM levels in mine air. This can be avoided by preventive, routine maintenance of the entire diesel fleet. Such maintenance must be carried out by trained personnel on a periodic basis. Daily checking of gaseous emissions should be done to confirm the condition of diesel engines. Ambient air quality examination can also provide a warning that one or more engines are not working properly. All mine personnel should be properly trained in operating the equipment and monitoring its performance. Maintenance of a diesel engine is the key to good performance and cannot be overemphasized.

Unmaintained or poorly maintained diesel engines do show an increase in DPM emissions with age. However, a properly maintained diesel engine (including the change of injectors, if needed) should not suffer any deterioration in DPM emissions during its normal tenure in the mine. Routine maintenance as recommended by manufacturers should be carried out only by trained personnel.

Radon Gas Control

Radon is a chemically inert, gaseous, radioactive product of the disintegration of radium. It is primarily found in uranium mines, although it is present in trace amounts in other mines including coal mines. Both radium and radon are intermediate products in the disintegration of uranium-238 to become lead-206. Table 15.4-9 shows some important steps in the disintegration of uranium to lead with half-lives of the isotopes.

After radon is released into mine air, the decay process continues with formation of radium A, B, C, C′, D, E, F, and G, which is lead. These products are commonly referred to

Table 15.4-9 Uranium disintegration process

Name	Isotope	Type of Radiation	Half-Life
Uranium	$^{238}_{92}U$	Alpha	4.49×10^9 years
Radium	$^{226}_{88}Ra$	Alpha	1,622 years
Radon	$^{222}_{86}Rn$	Alpha	3.825 days
Lead	$^{206}_{82}Pb$	—	Stable

as radon daughters. They are atoms of solid matter having relatively short half-lives. They emit alpha or beta particles and rarely gamma rays, and they are the main cause of health concern.

Radon gas is inhaled and exhaled before large amounts of alpha particles are emitted. The daughter products, however, attach themselves to respirable dust particles and get deposited in the alveolar sacs. Exposure to excessively high concentrations of radon and radon daughters have been linked to lung cancer.

The maximum exposure limit for radon daughters has been set at 1.00 WL (working level), with a yearly cumulative exposure of 4 WLMs (WL months). A working level is defined as that concentration of radon daughter products in 1 L of air that will yield 1.3×10^5 million electron volts (MeV) of alpha energy in decaying to radium C′ (U.S. Department of Health, Education and Welfare 1957).

The average WL for a given 8-hour shift is calculated by dividing the sum of exposure level multiplied by the number of hours by 8. Mathematically,

$$\text{average WL} = \frac{1}{8}\Sigma \text{WL}_i \times h_i$$

where

WL = exposure
h_i = hours

The WLM = {WL × 8} / 173. This is based on the assumption that there are 173 working hours in a working month.

Except for uranium mines, radon gas has not created a health hazard in coal and metal mines. However, it is desirable to check for its presence in all mines and to take action if necessary.

CHAPTER 15.5

Heat, Humidity, and Air Conditioning

Felipe Calizaya and John Marks

INTRODUCTION

In underground mines, heat and humidity can create adverse environmental conditions that can affect worker performance negatively. Such conditions can even limit the depth to which mining can be extended. Although the human body has a self-regulating mechanism against variations of external heat, under extreme conditions this mechanism can break down, resulting in occupational illnesses such as heat exhaustion and heat stroke.

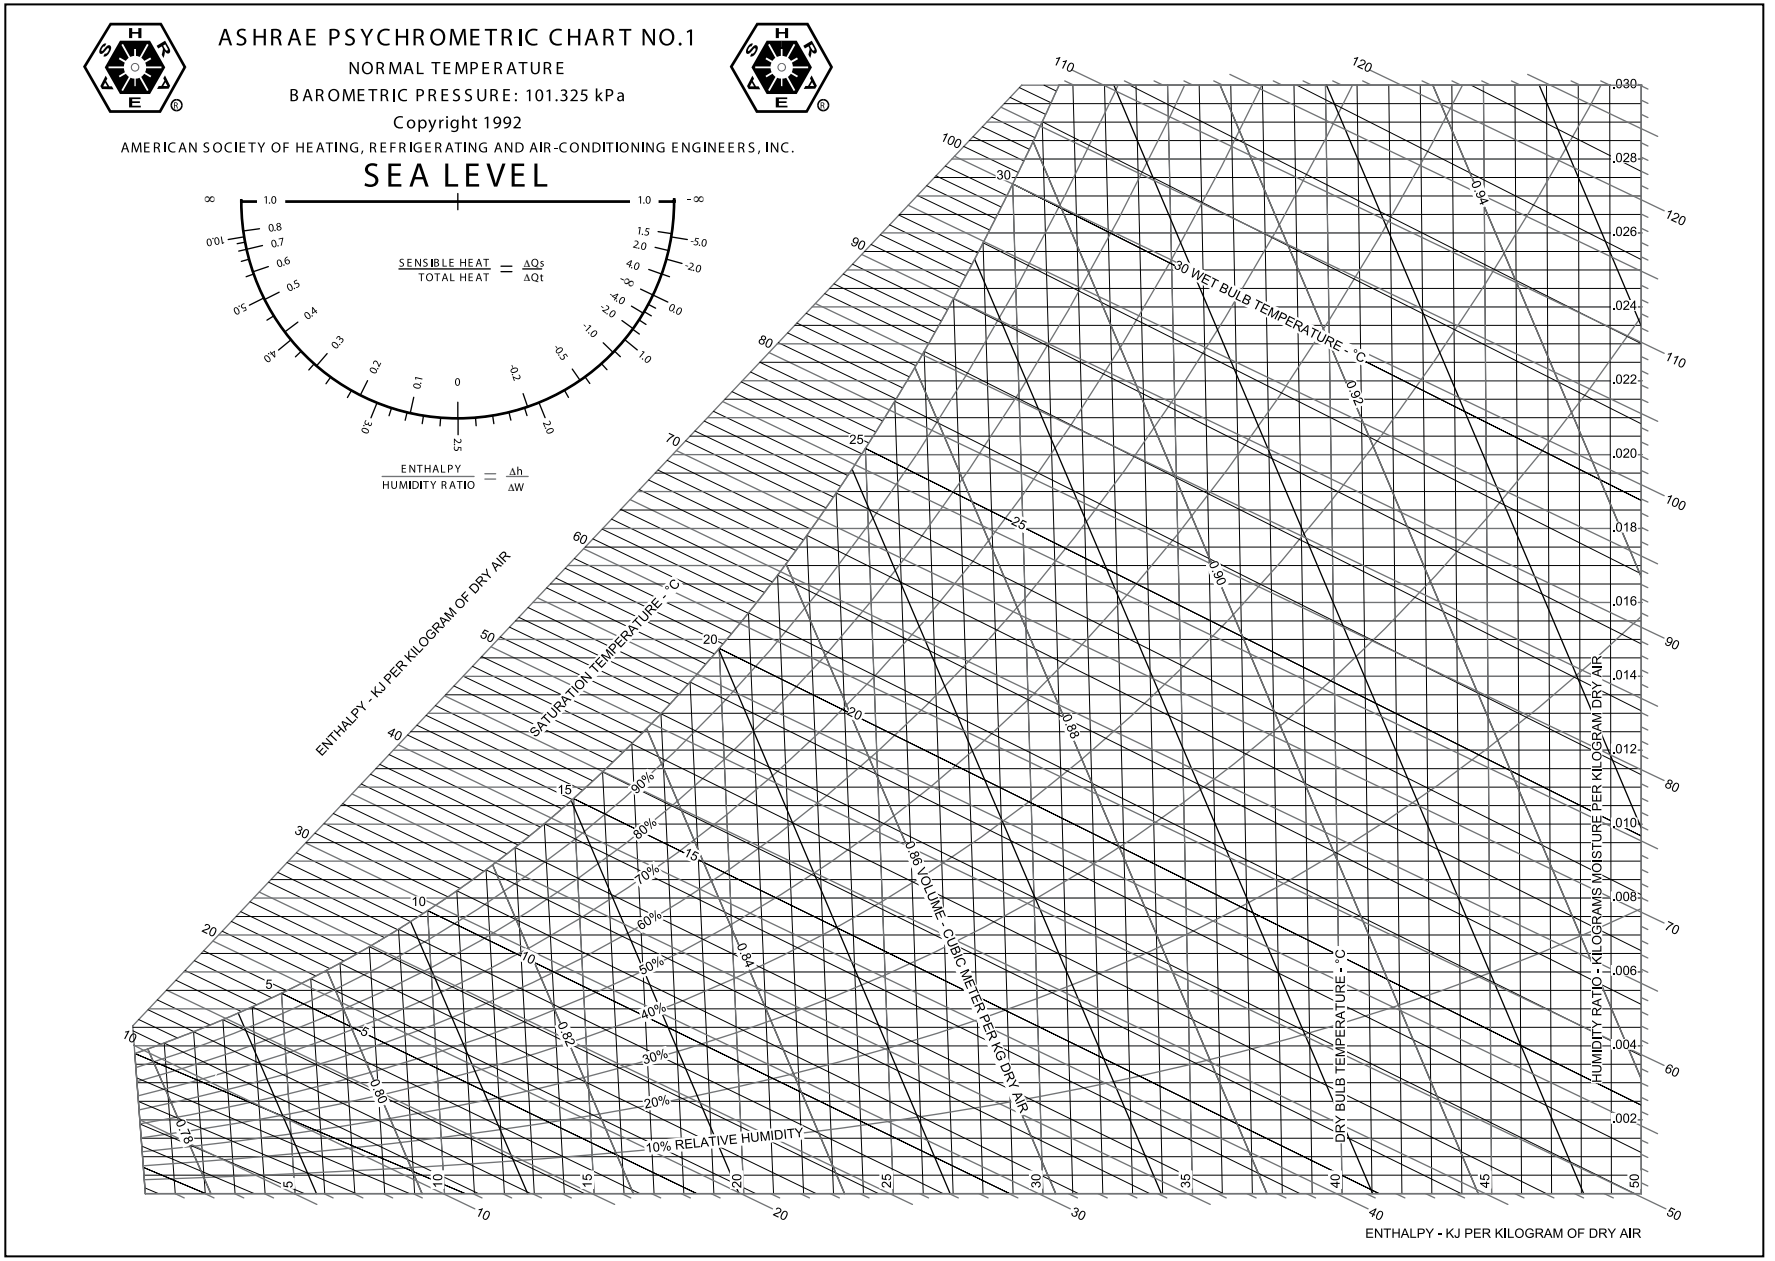
In the United States, with a few exceptions, heat becomes an environmental problem in mines with workings at depths greater than 1,000 m (3,280 ft). In these mines, ventilation is not sufficient to control the heat loads and must be supplemented by some form of air conditioning. The Anaconda mine in Butte, Montana, and the Magma mine in Superior, Arizona, were the first to utilize air conditioning systems. Both mines are at least 1.5 km (0.9 mi) deep. Other U.S. mines that require air conditioning include the San Manuel mine in San Manuel, Arizona, which is 1,000 m (3,280 ft) deep; the Homestake mine in Lead, South Dakota, which is 2.4 km (1.5 mi) deep; the Sunshine mine in Kellogg, Idaho, which is 1.6 km (1 mi) deep, and more recently, the Meikle mine near Elko, Nevada, where heat became a environmental problem at depths ranging from 300 to 600 m (1,000 to 2,000 ft).

In Canada, heat is also an environmental concern in most deep underground mines. These include Inco's Creighton mine, which is 2,400 m (7,870 ft) below the surface; Falconbridge's Kidd Creek mine, which is 3,000 m (9,845 ft) deep; and Agnico-Eagle's Laronde mine, which is 2,000 m (6,560 ft) deep. Autocompression is the main source of heat in these mines. The ventilation systems in these mines are now being upgraded to include refrigeration plants.

This chapter presents summaries of the following topics:

- Psychrometric properties of the air
- Human heat stress indices
- Instrumentation for determining how thermal loads are estimated
- Heat sources
- Mine cooling
- The principles used to estimate airflow and refrigeration requirements

Sample problems are used to illustrate the various steps involved in determining ventilation requirements and the critical depths. The solution to each problem is found using CLIMSIM, a commercial mine climate simulation program from MVS Engineering, Clovis, California. This software is used to predict the properties of the air at various simulated workings, to evaluate the resulting parameters against the target values, and to determine a feasible solution to the problem.



Several books and articles have been written on ventilation and air conditioning. The references at the end of this chapter provide a selected list of publications on this topic. The ventilation engineer is strongly encouraged to study these references.

Definitions

Definitions specific to the control of heat and humidity in underground mines are as follows.

- **Autocompression:** This is the term given to a process by which a column of air moving downward is compressed and experiences a temperature increase. Autocompression is due to the additional pressure of air "stacked" on itself. In a dry shaft, autocompression raises the air temperature by about 1°C (1.8°F) for every 100-m (328-ft) increase in depth.
- **Heat:** Heat is a form of energy and, as such, it can never be destroyed. In mines, heat is produced by chemical reactions such as the oxidation of ores (slow) or the burning of fuels (fast), by friction (pulleys under a stationary belt), and in many other ways.
- **Heat stress:** Heat stress is a qualitative assessment of the work environment based on temperature, relative humidity, air velocity, personal clothing, and radiant energy (environmental factor). Several heat stress indices have been proposed. The most common ones are effective temperature, cooling power, and wet bulb temperature.

Felipe Calizaya, Associate Professor, University of Utah, Salt Lake City, Utah, USA
John Marks, Consultant, Lead, South Dakota, USA

Source: Copyright 2009 ASHRAE Pschrometric Chart Sea Level SI, www.ashrae.org.

Figure 15.5-1 ASHRAE psychrometric chart

- **Heat strain:** The physiological response to heat stress (people factor) is called heat strain. Effects include dehydration, increased heart rate, fatigue, cramps, and heat stroke. Humans have different tolerance levels for heat. They can cope easier with heat than cold.
- **Sensible heat:** This is the heat that when added to or removed from a substance changes its temperature without changing its state.
- **Latent (hidden) heat:** This is the heat added to or removed from a substance that results in a change in state but does not increase or decrease its temperature.
- **Enthalpy:** Enthalpy is the total heat content of the air–vapor mixture per unit weight (sum of latent and sensible heat).
- **Temperature:** Temperature is the degree of hotness or coolness of a substance (measurement of a state).
- **Critical depth:** This is the depth in a mine at which the wet bulb temperature of the intake air exceeds the allowable wet bulb temperature, mainly due to autocompression. Beyond this depth, the mine will require some form of air conditioning.

PSYCHOMETRY AND AIR CONDITIONING

Psychrometry is the science of evaluating the thermal state of moist air. The psychrometric properties of interest to a ventilation engineer are dry bulb temperature (t_d), wet bulb temperature (t_w), dew-point temperature (t_{dp}), barometric pressure (P_b), specific volume (V), humidity ratio (W), and enthalpy (h). Because air is considered a mixture of dry air and water vapor, any three of these are necessary to be known, and the remaining properties can be calculated (McPherson 1993; Hartman et al. 1997). The easiest three to measure are t_d, t_w, and P_b. The determination of all of these properties is a prerequisite to solving air conditioning problems.

Three tools are available for estimating these properties: psychrometric tables, charts, and the fundamental equations. There are several computer programs available that make use of these tools and more advanced numerical solution methods. When tables are not available, the basic properties can be calculated using Equations 15.5-1 through 15.5-8 (McQuiston and Parker 1994).

Specific Volume, V:

$$V = \frac{RT_d}{P_b} \text{ m}^3/\text{kg} \qquad (15.5\text{-}1)$$

where

R = a gas constant, which is 287 J/(kg K)
T_d = the absolute temperature, which is equal to 273 + t_d, K
P_b = barometric pressure, Pa

Saturated Vapor Pressure, P_s:

$$P_s = 0.6105 \exp\left[\frac{17.27 t_d}{t_d + 237.3}\right] \text{ kPa} \qquad (15.5\text{-}2)$$

where t_d is the dry bulb temperature, °C.

It is evident in Equation 15.5-2 that the saturation vapor pressure is a function of temperature only.

Actual Vapor Pressure, P_v:

$$P_v = P_s - 0.000644 P_b (t_d - t_w) \text{ kPa} \qquad (15.5\text{-}3)$$

where

P_s = saturated vapor pressure, kPa
t_d = dry bulb temperature, °C
t_w = wet bulb temperature, °C

Relative Humidity, RH:

$$RH = \frac{P_v}{P_s} 100\% \qquad (15.5\text{-}4)$$

where

P_v = water vapor pressure, kPa
P_s = saturated vapor pressure, kPa

Absolute Humidity (or the "Humidity Ratio"), W:

$$W = 0.622 \frac{P_v}{(P_s - P_v)} \text{ kg/kg} \qquad (15.5\text{-}5)$$

where

P_v = water vapor pressure, kPa
P_b = barometric pressure, kPa

Air Density, d:

This equation gives kilograms of moisture per kilogram of dry air.

$$d = \frac{1}{V}(1 + W) \text{ kg/m}^3 \qquad (15.5\text{-}6)$$

where

V = specific volume, m^3/kg
W = absolute humidity, kg moisture/kg dry air

Enthalpy, h:

$$h = 1.005 t_d + W(2501.3 + 1.86 t_d) \text{ kJ/kg} \qquad (15.5\text{-}7)$$

where

t_d = dry bulb temperature, °C
W = absolute humidity, kg moisture/kg dry air

The *2007 ASHRAE Handbook* gives the following values for standard air: sea level temperature = 15°C and barometric pressure = 101.325 kPa. The barometric pressure, P_b, depends mainly on elevation and can be approximated as follows:

$$P_b = 101.325 (1 - 0.0000225577 Z)^{5.2559} \text{ Pa} \qquad (15.5\text{-}8)$$

where Z is the elevation in meters.

Example 1. Compute the humidity ratio and enthalpy of saturated air at 20°C and at a barometric pressure of 101.325 kPa.

Solution. Perform the following calculations:

- From Equation 15.5-2, for $P_v = P_s$ at 20°C, $P_v = 2.338$ kPa.
- Using Equation 15.5-5, $W = 0.0147$ kg/kg.
- Using Equation 15.5-7, for $W = 0.0147$ kg/kg and t = 20°C, $h = 57.56$ kJ/kg.

Quick estimates of all the psychrometric properties of air can be determined from a psychrometric chart. Each chart applies to air at a given barometric pressure. Figure 15.5-1 shows a psychrometric chart for $P_b = 101.325$ kPa. This is one of a series of charts produced by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) for a range of pressures. Although all psychrometric properties can now be calculated using programs such as HotWork from

MVA (Mine Ventilation Australia, Sandgate, Queensland, Australia) (Brake 2008), charts provide a visual representation of process lines that represent changes in psychrometric conditions of the airstream. Figure 15.5-2 shows how the various processes can be followed from an initial state point (point A). Horizontal lines emerging from this point indicate changes in sensible heat, that is, cooling if the process proceeds from right to left or heating if the process proceeds from left to right. A vertical line indicates changes in latent heat—humidification if the process proceeds upward and dehumidification if the process proceeds downward. Combination processes run diagonally.

Example 2. A flow rate of 120 m^3/s of air at $t_d = 30°C$, $t_w = 20°C$, and $P_b = 101.325$ kPa is to be chilled to $t_d = t_w = 10°C$ at the same pressure. First, calculate the following:

- The mass flow rate of dry air through the process
- The kW(R) required to chill the air
- The liquid water condensed in the air
- The relative humidity of the air entering the process

Solution. For $t_d = 30°C$, $t_w = 20°C$, and the specific volume of air is 0.873 m^3/kg, calculate as follows:

- Mass flow rate: $m = Q/v = 137.3$ kg/s, where Q is the airflow rate in cubic meters per second
- Removed heat: $q = m(\Delta h) = 137.3 \times (57.2 - 29.4) = 3{,}817$ kW(R)
- Condensed water: $q_l = m(\Delta W) = 137.3\ (10.6 - 7.7) = 398.20$ g/s (0.40 kg/s)
- Relative humidity: $RH = 40\%$ (from ASHRAE chart)

HEAT STRESS INDICES

These indices refer to the assessment of thermal conditions to which workers can be exposed repeatedly without developing any adverse health effect. They are expressed in terms of quantitative figures (maximum allowable limits) used by ventilation specialists for designing heat control systems. Since the introduction of the first heat stress index in 1923, more than 90 indices have been developed. Based on their application, these can be divided into two groups: empirical and rational. Empirical indices are expressed in terms of an external or environmental factor, such as the wet bulb temperature and the effective temperature. Rational indices are based on the responses of the workers to thermal stress, such as sweat rates and core temperature increases (internal factors). Only the empirical indices are applicable to underground mining conditions.

In most mining countries, these indices are regulated by code (Hartman et al. 1997; Hardcastle 2006). In U.S. mines, heat stress is not regulated. Management must set and enforce the applicable limits. The following are the most commonly used indices (Van der Walt et al. 1996; Del Castillo and Dawborn 2002; Mutama 2005; ACGIH 2008):

- Wet bulb temperature: $t_w \leq 27°C$ (81.6°F)
- Wet bulb globe temperature: $WBGT \leq 27°C$ for continuous work at moderate rate
- Effective temperature range: ET = 28°C (81.6°F) for reduced work load and a maximum of 32°C (89.6°F) when work must be terminated
- Air-cooling power (ACP) for hard workload: 175 $W/m^2 \leq ACP \leq 275$ W/m^2
- Air velocity: $v \geq 0.50$ m/s

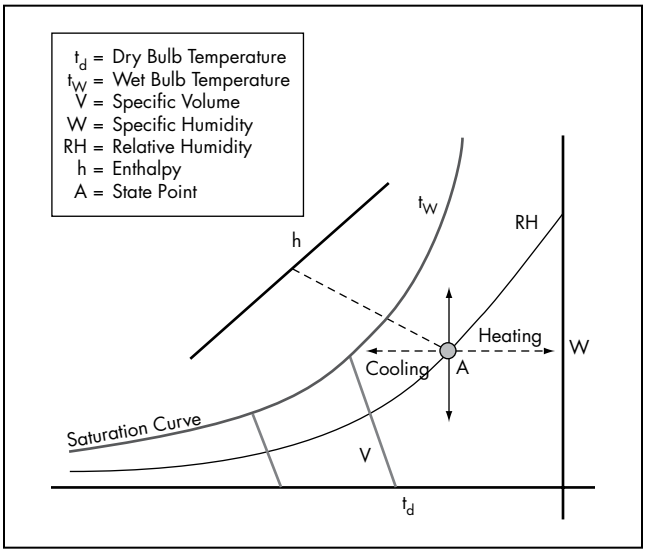


Figure 15.5-2 Psychrometric processes and state point

The wet bulb temperature is the simplest index that can be used by ventilation engineers to assess the work environment. It measures the evaporation of water from a wet bulb thermometer. It can be determined by a sling psychrometer after being whirled or vented at the rate of at least 3 m/s (10 fps).

The wet bulb globe temperature for an indoor environment is measured by a black globe thermometer or calculated using Equation 15.5-9 (ACGIH 2008):

$$WBGT = 0.7NWB + 0.3GT \tag{15.5-9}$$

where

$WBGT$ = wet bulb globe temperature, °C
NWB = natural (or unvented) wet bulb temperature, °C
GT = globe temperature, °C

Effective temperature is an index of relative comfort determined from charts that require the knowledge of three parameters: dry bulb temperature, wet bulb temperature, and air velocity. It is still used in U.S. mines with negligible radiant heat.

Air cooling power is a rational heat stress index based on heat balance between workers and environment. For hard work rates, this index ranges from 175 to 275 W/m^2, depending on air velocity, wet bulb temperature, and type of clothing. For safety, vent systems should be designed for cooling power rates higher than the expected work rate.

Air velocity, as measured by an anemometer, is not an index, but it can be used in combination with the wet bulb temperature. A common lower limit for airways where personnel work is 0.50 m/s (1.6 fps).

The following are sample heat stress indices used in some hot mines:

- Homestake gold mine, South Dakota
  - Wet bulb temperature for acclimatized workers is $26.7°C \leq t_w \leq 29.4°C$ (the lower limit indicates 100% worker efficiency, and the upper limit indicates that a corrective action is needed)
  - The air velocity range is $0.76 \leq v \leq 3$ m/s
  - The wet bulb globe temperature, $WBGT$, is ≤32.2°C

Figure 15.5-3 Digital barometer

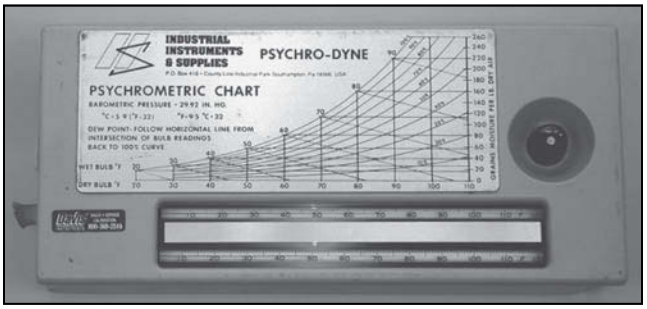

Figure 15.5-4 Portable psychrometer

- Meikle gold mine, Nevada
  - The wet bulb temperature, t_w, for acclimatized workers is ≤27.8°C
  - The effective temperature, *ET*, is ≤26.6°C
- Mindola copper mine, Zambia
  - The wet bulb temperature is 28°C ≤ t_w ≤ 30°C (depending on the air velocity, t_w is 28°C for v = 0.77 m/s and 30°C for 1.99 m/s)
  - Air-cooling power is $ACP \geq 300$ W/m^2

If two heat stress indices of a work environment exceed the design limits, the mine can take one or more of the following actions:

- Install ventilation and/or air conditioning systems (active engineering controls)
- Isolate the heat sources via insulation or blocking off heat sources (passive engineering controls)
- Enact administrative measures

Ventilation and/or air conditioning are generally the preferred control methods for long-term work areas, but they can be very expensive. Isolating heat sources can be done in certain cases, but if active or passive controls are uneconomical, the mine can consider administrative controls. These include

- Increasing workers' heat tolerance by heat acclimatization,
- Assigning workers to hot working areas selectively (on the average about 5% of relatively young workers are heat intolerant),
- Adjusting the work–rest regime by permitting workers to take short breaks to recover sweat rate and body core temperature, and
- Rotating personnel on hot jobs and providing workers with readily accessible cold areas, cold drinking water, and salt tablets. A half-teaspoon of salt per 2 L of water is sufficient.

In every case, the objective is to prevent the body core temperature from rising above 38°C (100°F).

INSTRUMENTATION

The following instruments are used to determine the heat load in underground mines: a barometer, a psychrometer, and thermocouples. Although most of these units are now digital, analog devices are still being used under harsh conditions and as primary standards for calibration.

Barometric Pressure

Barometers are used to measure the absolute pressure of mine air. This pressure is mainly a function of elevation of the working areas. Under standard conditions, the barometric pressure varies by about 500 Pa (0.07 psi) over a 24-hour period. Under special conditions, such as during major storms or cyclones, the pressure difference can be as high as 2,000 Pa (0.3 psi). Aneroid barometers, such as those manufactured by American Paulin System, Cottonwood, Arizona, are still being used for pressure measurement in underground mines. Because of their ruggedness and ease of operation, they are preferred by ventilation engineers. With the advent of electronic technology, digital barometers are gaining a wider acceptance in ventilation surveys, especially in hard-rock mining. They are based on pressure transducers that are highly sensitive to variations of pressure load. Figure 15.5-3 shows a capacitor-type barometer in a rugged enclosure. The instrument basically consists of two closely spaced metal surfaces, one of which is a diaphragm that flexes slightly under applied pressure and alters the gap between them (variable capacitor). This variation in distance is picked up electronically by the sensor. The instrument is highly accurate in the range of 60 to 110 kPa (8.7 to 16.0 psi).

Air Temperature Measurement

The dry and wet bulb temperatures of the air are measured by a psychrometer. This instrument consists of two identical thermometers: one to measure the true air temperature (dry bulb) and the other, covered by a water-saturated wick, to measure the evaporative cooling effect (wet bulb). The drier the surrounding air, the more rapidly the water will evaporate. This causes the wet bulb to depress in temperature until a balance takes places between the cooling effect and the heat gain from the ambient air. A requirement to measure the wet bulb temperature is the air velocity across the bulb. This velocity must be at least 3 m/s (10 fps). Without this velocity, one will always tend to measure a higher humidity level than actual.

Figure 15.5-4 shows a portable psychrometer. This instrument consists of two thermometers (dry and wet) and a small fan. Before any measurement, the wick on the wet bulb must be saturated with distilled water. While the fan is operating, the wet bulb temperature will begin to depress until it stabilizes at its lowest point. The procedure may take from 1 to 2 minutes depending on the dryness of the air. For better accuracy, the wet bulb temperature should be read first. The instrument can be used for temperature measurements in the –7° to 43°C (19° to 109°F) range. A humidity indicator (Figure 15.5-5) is another device used in underground mines. The instrument is based on a thin polymer film sensor that changes its capacitance as it absorbs water molecules. When equipped with a Vaisala HMP41 probe, it can be used to measure relative humidity, absolute humidity, dry and wet bulb temperatures, and dew-point temperature. The operating range of the instrument is from –20° to 60°C (4° to 140°F).

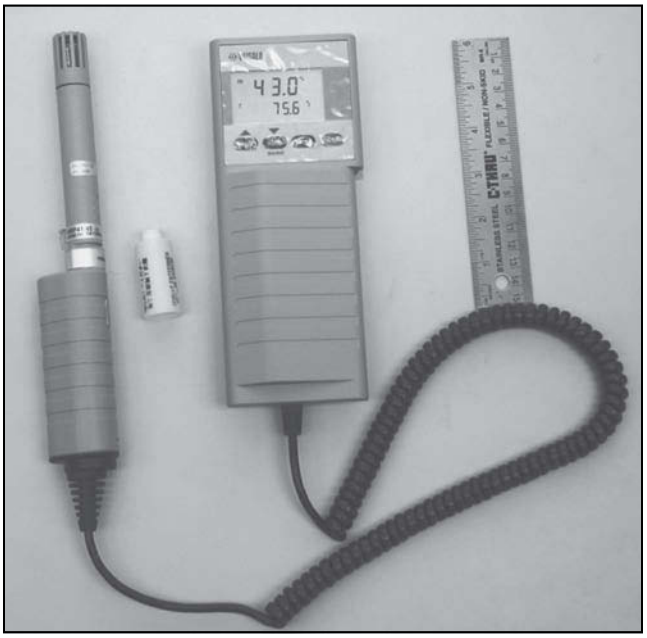

Figure 15.5-5 Digital humidity indicator

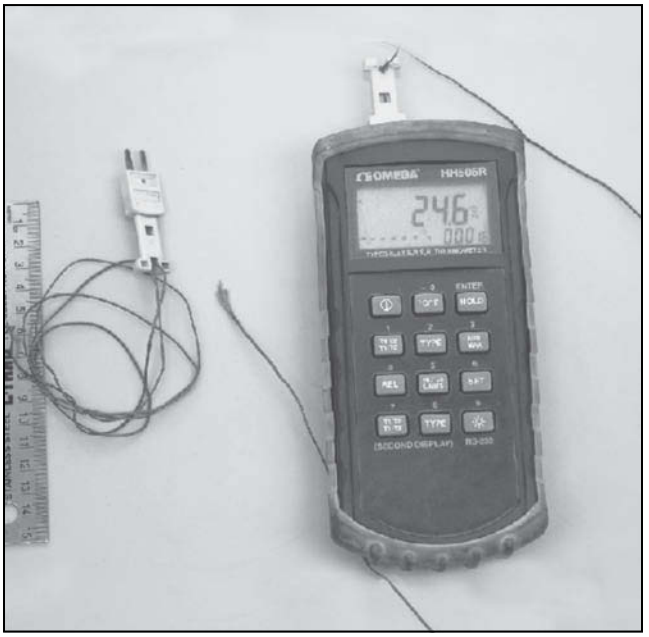

Figure 15.5-6 Thermocouple and digital thermometer

Rock Temperature Measurement

The rock temperature in a mine is usually measured by means of resistance thermometers and thermocouples. A resistance thermometer is constructed of a precious-metal conductor, such as platinum or silver, which exhibits increased resistance when heated. A thermocouple consists of insulated wire pairs with a junction point (bead) at one end and a male connector at the other. For underground applications, J-, K-, and T-type thermocouples are used. When a thermocouple is connected to a temperature indicator (reader), an analog or digital signal is obtained, making it suitable for temperature logging. Rock temperatures can be measured from boreholes that are drilled from underground openings or from the surface. In either case, it is good practice to allow the rock temperature to stabilize and eliminate the local heating and cooling effects. This is usually achieved 8 hours after the drilling is completed (Duckworth 1999). A plot of temperature verses depth is often used to determine the temperature distribution in the borehole and the virgin rock temperature (VRT). Figure 15.5-6 shows thermocouple wires and a digital thermometer. The fine wire thermocouples enable accurate temperature measurements without disturbing the base temperature of the body in which the installation is made. They are available in wire sizes ranging from 0.025 to 0.81 mm in diameter. The K-type thermocouple has an operating range of from –200° to 1,372°C (–328° to 2,502°F). The HH506R data logger (Omega Engineering) is a two-channel temperature-measuring device used with seven types of thermocouples. When recording mode is used, the instrument allows the user to store the maximum, minimum, and average temperatures during a 24-hour period.

HEAT SOURCES

Heat is emitted from various sources in underground mines, including autocompression, heat from wall rock, mining equipment, groundwater, oxidation of minerals, and metabolic heat. A study conducted on heat flow in seven underground mines in the United States has shown that wall rock, autocompression, and mining equipment account for about 80% of the total heat released. In shallow mines with depths of less than 1,000 m (3,280 ft), ventilation alone may be sufficient to remove the heat from the working sections. However, in deep mines with depths greater than 1,000 m (3,280 ft), the autocompression effect causes the wet bulb temperature to exceed the critical temperature of 28°C (82°F), and refrigeration becomes a necessity. The design of a refrigeration system requires a thorough evaluation of all sources of heat.

Heat from Rock

The heat flow from the rock depends on a number of variables, including the virgin rock temperature, rock type, size, shape, and depth of the openings and the presence of water on the rock surface. It also varies with the age of the opening. New and well-ventilated airways rapidly give off heat. After the airway has aged, the rock wall temperature will typically stabilize to within 2°C (3.6°F) of the dry bulb temperature. For rough estimates, Equation 15.5-10 can be used to approximate the radial heat flow, q, from the rock.

$$q = 2\pi\kappa L \frac{t_1 - t_2}{\ln(r_1/r_2)} \text{ W} \qquad (15.5\text{-}10)$$

where

κ = thermal conductivity, W/m °C
L = airway length, m
t_1 = rock wall temperature, °C
t_2 = virgin rock temperature, °C
r_1 = airway radius, m
r_2 = distance into the rock, m

Thermal conductivity is a measure of how well (or poorly) heat is conducted (or resisted) in a certain substance. It represents the temperature profile along each meter of drift length for a given heat flow. However, it does not measure how quickly the heat spreads along the drift. Thermal diffusivity is a measure of how quickly the heat spreads through the substance. Table 15.5-1 shows the thermal properties for

Table 15.5-1 Thermal properties of common substance

Substance	Conductivity, W/m °C	Specific Heat, kJ/kg °C	Diffusivity, $m^2/s\ 10^{-6}$
Water	0.60	4.19	0.14
Dry air	0.026	1.005	21.5
Coal	2.20	1.00	1.29
Copper	380	0.38	112
Gabbro	2.37	—	2.37
Granite	1.92	0.82	3.33
Pyritic shale	3.65	—	2.01
Quartz	5.50	0.88	2.32
Sandstone	1.97	0.71	1.68
Shale	2.39	—	0.90
Rhyolite	3.46	—	1.11
Gneiss	3.18	—	1.63
Concrete	1.20	0.88	0.59

Source: Adapted from ASHRAE 2007 and Brake 2008.

a number of substances determined from laboratory or field tests (ASHRAE 2007; Brake 2008). Temperatures t_1 and t_2 are rock temperatures measured at radii r_1 and r_2, respectively. For rectangular openings, r_1 is approximated by the hydraulic radius (= 2 × area/perimeter). Radius r_2 is the distance into the rock from the center of the opening. The virgin rock temperature t_2 is determined from a borehole that is at least 4 m (13 ft) long and drilled perpendicular to the longitudinal axis of the opening.

A pair of t_i and r_i measurements, together with the length of the opening and the thermal conductivity of the rock, is sufficient to determine the heat flow into an opening. However, to improve the accuracy of the estimates, it is recommended to take a series of measurements from various boreholes drilled radially from the airway.

Example 3. A 400-m-long drift that is 4 m in diameter (r_1 = 2 m) is driven in quartzite rock (Figure 15.5-7). The VRT at r_2 = 10 m is determined to be 50°C. If the rock wall temperature is 30°C, how much heat will flow into the section?

Solution. For κ = 5.5 W/m °C, $(t_1 - t_2)$ = 0°C and $\ln(r_1/r_2) = -1.61$, Equation 15.5-10 yields q = 172 kW. For a given q (measured directly), this approach can be used to determine the thermal conductivity of the rock.

Autocompression

Autocompression is the process in which a column of air is compressed and experiences a temperature increase as it enters a downcast shaft. In dry shafts, the compression occurs adiabatically. On average, the dry bulb temperature increases by 1°C (1.8°F) per 100 m (328 ft). This occurs even when there is no external heat added into the shaft or external work done on the air. The wet bulb temperature also increases with depth, but at a lower rate. Typically, this temperature increases by about 0.6°C (1.1°F) per 100 m (328 ft) when the surface wet bulb temperature is 6°C (43°F) and 0.4°C (0.7°F) per 100 m (328 ft) when the surface wet bulb is 25°C (77°F) (Brake 2008). In an upcast shaft, the air decompresses as it travels up the shaft, resulting in a drop of both dry and wet bulb temperatures, a reduction in air density, and a decrease of

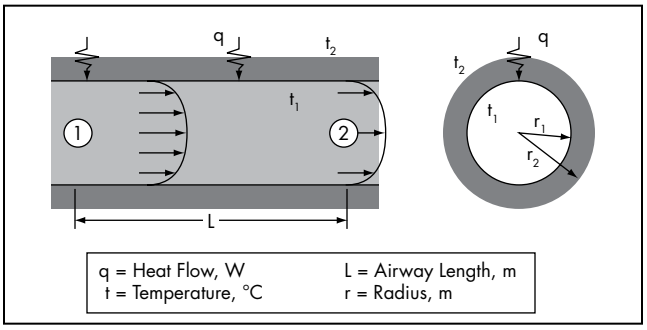

Figure 15.5-7 Heat flow from rock

atmospheric pressure. In locations with high humidity levels in the upcasting shafts and drifts, the decrease in temperature associated with decreasing pressure may result in the generation of fog as the conditions of saturation occur.

For a downcast shaft, the heat flow, q, can be estimated by

$$q = Q\frac{1}{V}(h_2 - h_1)\,\text{kW} \qquad (15.5\text{-}11)$$

where

Q = airflow rate, m^3/s
h_1 = enthalpy at state point 1 (shaft collar)
h_2 = enthalpy at state point 2 (shaft bottom)

Example 4. What is the heat load from autocompression when 100 m^3/s of dry air of t_{d1} = 30°C and t_{w1} = 20°C at sea level drops down a 1,500-m shaft?

Solution. Estimate the wet bulb temperature at the bottom of the 1,500-m shaft (t_{w2} = 26.8°C by interpolation); determine the specific volume of the air at shaft collar (V = 0.873 m^3/kg); and determine the enthalpies for t_{w1} and t_{w2} (h_1 = 57.2 kJ/kg and h_2 = 83.7 kJ/kg from Figure 15.5-1). Then, using Equation 15.5-11, q = 3,025 kW.

Electrical Equipment

Electrical motors, transformers, gearboxes, and other controls are not 100% efficient. Some of these inefficiencies are manifested in the form of sensible heat. All energy used in electrical equipment is transformed into two effects: work against gravity and heat. Conveyor belts, hoists, and pumps are examples where the electrical energy is transformed into potential energy and frictional heat. Other devices, such as rock breakers, fans, electric drills, and lights used on a horizontal plane, are examples where electrical energy is converted entirely into heat. Using Equation 15.5-12, for any given machine, the heat load, q, can be calculated as the difference in effective power and work done against gravity as follows:

$$q = PE - mgh\ \text{kW} \qquad (15.5\text{-}12)$$

where

P = input power, kW
E = total efficiency, decimal fraction
m = mass flow rate, kg/s
g = 9.81 m/s^2
h = elevation difference, m

Fans dissipate heat. However, this heat is detrimental only when the fan is located upstream of the main workings (either as blower or booster fans).

Example 5. A 1,500-m-long conveyor belt system transports ore at the rate of 720 t/h. The vertical lift is 280 m. The system consumes 2,500 kW of power at an efficiency of 85%. Determine the heat load along the belt line.

Solution. For an input power of 2,500 kW, an efficiency of 85%, m = 200 kg/s, and h = 280 m, Equation 15.5-12 yields q = 1,576 kW.

Diesel Engines

When diesel equipment is used in underground mines, in addition to smoke and fumes, a significant amount of heat is added to the air. The heat flow from a diesel engine is about 2.8 times the heat produced by an equivalent electric unit. About a third of this is added at the radiator, another third at the exhaust pipe in the form of smoke, and the remainder as useful work, which is finally also converted into heat. Each volume of fuel produces from three to ten volumes of water vapor. This results in increases of both latent and sensible heat of the air. The best way to determine the heat load is to estimate the fuel consumption, F, and the combustion efficiency, E. Using this information and the calorific value of the fuel (C = 34,000 kJ/L), the heat load, q, can be calculated using Equation 15.5-13.

$$q = FEC \tag{15.5-13}$$

Alternatively, it can be approximated by multiplying the effective engine power by 2.8 ($q = 3PE$).

Example 6. A 30-t truck (298 kW) is operated at 80% of its nameplate specifications in a development heading. How much heat does this engine produce when fully loaded?

Solution. From Equation 15.5-13, $q = 2.8 \times 298 \times 0.8 =$ 668 kW. This engine burns 668 kW of fuel to produce 298 kW of effective power.

Heat from Broken Rock

When freshly blasted rock is exposed to ventilation air and there is a temperature difference between them, there will be heat flow from the rock to the air. In most cases, the broken rock temperature will be less than the local VRT. However, the difference is small, and for rough estimations it can be ignored. Further, the rock temperature at the storage bin or exit point will be equal to the ambient air temperature. Based on these assumptions, the heat load from broken rock can be approximated using Equation 15.5-14 as follows:

$$q = mC_p(VRT - t_d)\ \text{kW} \tag{15.5-14}$$

where C_p is the specific heat of broken rock, kJ/kg°C.

Example 7. One hundred metric tons per hour of broken rock (granite) with a C_p = 0.82 kJ/kg°C is transported from a drawpoint where the rock temperature is 45°C to an ore bin where the rock has cooled down to 30°C. Estimate the heat transfer from the broken rock to the ventilation system.

Solution. For m = 27.78 kg/s and Δt = 15°C, Equation 15.5-14 yields q = 342 kW.

Heat from Groundwater

Mine water comes from two sources: natural fissures in the rock and human-induced sources from various applications, including water used for cooling. The fissure water has usually the same temperature as the VRT. However, the temperature of human-induced water can vary from below ambient temperature to more than 40°C (104°F). Ventilation air will pick up the heat from hot water in uncovered ditches. The heat flow from groundwater can be estimated by applying Equation 15.5-14, where the C_p(water) = 4.19 kJ/kg°C. Whenever possible, groundwater should be confined at the source and transported through pipelines or covered ditches.

Example 8. A mine produces 0.010 m^3/s of fissure water at the local VRT of 55°C. If the water exits the discharge system at 30°C, how much heat is added to the ventilation air?

Solution. For m = 10 kg/s and Δt = 25°C, q = 1,048 kW.

Other Sources of Heat

Other sources of heat include those from the oxidation of timber, sulfide ores, and carbon-based minerals. Oxidation of timber usually begins with the growth of bacteria in poorly ventilated areas (with less than 2% oxygen). Coal and pyritic sulfides will oxidize at normal ambient temperatures. The reaction is exothermic. If the heat is not removed, this can initiate a self-heating process and can develop into fires. Except for mines with extensive caved areas, this heat is usually swept out by ventilation and ignored in the estimation of the heat load.

Total Heat Load

For a given section, the heat load is determined as the sum of the heat loads from different sources. Once evaluated, this load is used to determine the ventilation or refrigeration requirements. The requirements are calculated by equating the wet bulb temperature at the exit of the section to the reject temperature. Psychrometric charts can be used to determine the size of fans and cooling devices.

Example 9. Air enters a section of a mine at t_d = 26°C, t_w = 20°C, and 101 kPa of absolute pressure. The heat load in the section is estimated at 3,000 kW. If the wet bulb temperature of the air leaving the section is not to exceed 28°C, what is the required quantity of air?

Solution. For V = 0.850 m^3/kg, h_1 = 57 kJ/kg, and h_2 = 89.5 kJ/kg, using Equation 15.5-11, q = 78.5 m^3/s.

MINE COOLING

When actual or projected heat loads exceed the ability of a mine's ventilation system to remove the heat, cooling methods must be considered. In principle, a mine cooling system is a heat-removal system. A substance such as air, water, or ice is sent into the mine at a low enthalpy state and removed at a higher one. Planning for existing or proposed mines generally follows the methods listed in this section (McPherson 1993; Howes and Hortin 2005).

Airflow Increase

It is generally less expensive to increase airflow than to install refrigeration. Primary fans can be replaced or sped up, booster fans can be installed, or new airways can be driven. However, for older mines, airflow increases are often impractical because of the cube relationship between fan power and airflow increase through a given resistance. Nor does increasing airflows help mines at or below the critical ventilation depth, which is the depth at which the intake shaft wet bulb temperature exceeds the design reject temperature.

Chilling the Service Water

This technique was developed in South Africa. All metal mines require service water to suppress dust whenever rocks are drilled or broken and to wash sidewalls and the face for ground support and geologic mapping. Chilled service water

is among the most flexible cooling methods available, because it is used where needed the most and then turned off and routed elsewhere. It intercepts rock heat before that heat enters the air. However, chilling the service water requires a refrigeration plant and insulated pipelines. Plate-and-frame evaporators can produce 1°C (34°F) water, whereas shell-and-tube heat exchangers are limited to about 3.3°C (38°F) because of potential tube rupturing. The effect can be wasted if chilled service water is used where cooling is not required. Chilled service water can be potable or nonpotable, but in any case it should be treated for microorganisms.

Bulk Cool Intake Air on Surface

This method is used at warm-climate mines to provide winter-like or better conditions year round. Surface refrigeration plants are almost always less expensive and easier to install and maintain than equivalent underground plants, are not limited in heat rejection, and are not subject to disruption following underground power outages. Ammonia machines can be used. Compressors are usually centrifugal or rotary screw. Multiple machines are often installed in parallel so that a single machine can be down for maintenance without disrupting cooling duty to any significant extent. Depending on conditions, evaporators and/or condensers on multiple machines can be installed in series to provide greater temperature difference (lift) to water temperatures. Mine refrigeration machines typically provide a lift of about 6° to 8°C (11° to 14°F). The lower positional efficiency and utilization over a year's time generally preclude surface bulk cooling from being used in cooler-climate mines.

Bulk Cool Air Underground

This practice has a higher positional efficiency and a higher utilization than do surface plants because it is closer to work areas. It also utilizes the full heat-removal potential of the ventilation system by rejecting heat to exhaust air via underground cooling towers. The refrigerant used must be nontoxic. Both centrifugal and rotary-screw compressors are used. As with surface plants, multiple machines are usually installed in parallel.

Installing Chillers

Also known as district cooling, midsize refrigeration machines of 350 to 1,250 kW(R) can chill water for a closed-loop system of cooling coils or spray chambers. These coils and chambers are located at the entrances of work areas. Coils can be located in a bank. Auxiliary fans draw air through the cooling units and blow it through a duct to work headings. Refrigeration machine condenser heat is preferably rejected to clean service water, if enough quantity is available. But heat is often rejected to mine sump water before being pumped out of the mine. Problems encountered with district cooling are coil-air side and condenser tube-water side fouling.

Spot Coolers

These units range from 70 to 350 kW(R) capacity. The units are portable and contain one or two direct-expansion cooling coils, one or two condensers, one or two compressors, and a fan. Cooled air is delivered through a duct to the heading. Condenser heat is usually rejected to the mine service water. This water typically discharges at temperatures between 35° and 45°C (95° and 113°F), and thus it should be piped to prevent it from contacting intake airflows. The service water flow rate is approximately 0.02 L/s per kW(R) of cooling at 21°C (70°F) water temperature, but can be less or more depending on temperature.

Spot coolers are popular with the work force. Although limited to moderate cooling duties, they are easily moved to positions close to advancing headings. Spot coolers cost more per unit of cooling but can be the only choice for development, exploration, or production workings on the periphery of operations. The service water system, mine dewatering system, and surface treatment or disposal system must be capable of handling the increased water flow required for condenser cooling. Some applications might employ air-cooled condensers. In the past, reciprocating compressors were used. More recently, scroll-type hermetic compressors have been employed because they are less expensive and can handle liquid slugging better than can reciprocating units. Larger spot coolers can use rotary-screw compressors. Current designs use non-ozone-depleting and non-global-warming refrigerants. As with water-cooling coils, direct expansion coils on spot coolers must be washed, the frequency depending on how much dusty air the unit receives.

Cooling Towers

Cooling towers utilize the full heat-removal capacity of a mine by rejecting refrigeration machine condenser heat to the exhaust air. Exhaust air typically exits the work areas at a temperature close to the design reject temperature, for instance, 28°C (82°F) wet bulb. A common misconception is that heat cannot be rejected to saturated air through evaporation, but the process in a cooling tower involves both sensible heating of the air by hot water followed by latent, or evaporative, cooling of the circulating condenser water. Latent heat is typically about 80% of total heat transfer. Water sprayed in the cooling tower is often about 45°C (113°F), which cools to about 35°C (95°F) before being sent back to the refrigeration room. Actual temperatures depend on the efficiency of heat transfer, both in tower and machine condensers, and on various design parameters, such as water flow rate and condensing temperature. Equation 15.5-15 calculates the total heat transfer on the water side, H_w, and Equation 15.5-16 calculates the total heat transfer on the air side, H_a, as follows:

$$H_w = M_w C_p \Delta t \text{ kW} \qquad (15.5\text{-}15)$$

where

M_w = mass flow of water, kg/s
C_p = specific heat of water, 4.18 kJ/kg°C
Δt = inlet water temperature minus the outlet water temperature, °C

$$H_a = M_a \Delta h \text{ kW} \qquad (15.5\text{-}16)$$

where

M_a = mass flow of air, kg/s
Δh = specific enthalpy of exit air minus the specific enthalpy of entering air, kJ/kg

Cooling tower analysis proceeds by equating H_w with H_a. Mines use the "factor-of-merit" method, developed in South Africa, for planning, designing, and analyzing cooling towers and spray chambers. The factor-of-merit for a direct-contact heat exchanger, such as a cooling tower or spray chamber, ranges between 0 and 1, where 0 implies no heat transfer takes place and 1 implies as much heat transfer as permitted by the second law of thermodynamics (Burrows 1982). In other words, the

fluid with the lower thermal capacity, either water or air, heats up or cools down to the entering temperature of the other fluid.

Normally the designer knows the exhaust air quantity and temperature available for the cooling tower through measurements or the mine plan. For a new mine, the tower entering air wet bulb temperature can be assumed to be about 1.5°C (2.7°F) lower than the design reject. The lower temperature is caused by leakage airflows entering exhaust. At most deep and hot mines, the air can be assumed to be saturated. Very roughly, 19.8 to 40.3 kW of heat can be rejected to 1 m³/s (2,100 cfm).

Cooling tower analysis is a complicated procedure. The designer must know or assume the heat to be rejected (the evaporator duty times the condenser heat-rejection factor), the entering air quantity and temperature, the tower factor-of-merit (from experience, based on accepted design criteria), and a first guess on the condenser water flow rate. Condenser water flow depends on the heat to be rejected and the refrigeration machine specifications. The exiting air temperature, the entering and exiting water temperatures, and the water makeup requirements can then be calculated via an iterative procedure. An example of cooling tower design for a 3.5-MW underground refrigeration plant is given in the 2007 ASHRAE applications handbook.

Large Spray Coolers

Large spray chambers are used to bulk-cool ventilating airflows that are used for mining operations. These chambers can be located on the surface at the intake shaft or underground. Chambers are usually two- or three-stage horizontal openings equipped with Vee Jet spray nozzles lining the chamber. Wave-fin mist eliminators at the exit keep water from blowing out of the chamber. More details are given in the 2007 ASHRAE applications handbook.

Small Spray Chambers

Small spray chambers are typically portable, enclosed, direct-contact heat exchangers for small duties 35 to 350 kW. An auxiliary fan draws or blows air through the chamber, which is then ducted to the work heading. Wave-fin or mesh-type mist eliminators keep sprayed water in the chamber. On the water side, about 0.018 L/s (2.85 gpm) per kW of chilled service water is required for operation. This water is dumped into the ditch and into the mine dewatering system. Or, in a closed loop system, the water is collected and pumped back to a district refrigeration machine. These chambers are efficient and inexpensive for small duties, especially those requiring auxiliary ventilation. Limited air scrubbing takes place. But they require the chilled water and mine dewatering infrastructure to support them.

Integrated Refrigeration Systems

Integrated or combination systems can cool both intake air and/or service water. The proportion depends on the season, with more bulk cooling in the summer and more water chilling in winter. If service water is recycled after being pumped out of the mine, it is often sent first to a precooling tower before being refrigerated. Recycling mine water may reduce treatment costs by reducing water that is rejected to surface drainage streams or ponds. Integrated systems come in a wide variety of cooling and energy recovery methods that utilize both surface and underground components. Most deep, hot mines employ some type of integrated refrigeration system.

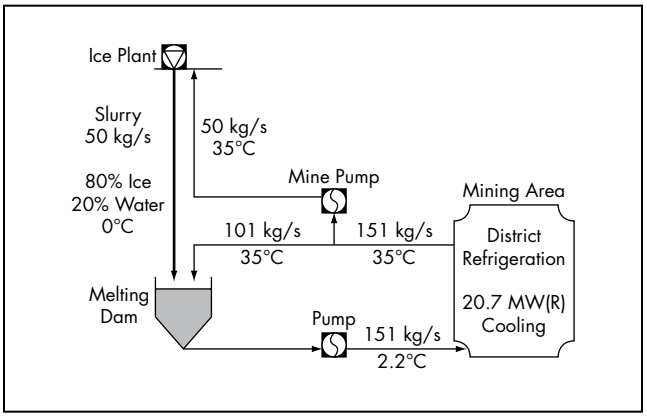

Figure 15.5-8 Basic ice cooling schematic with sample numbers

Ice Cooling

For deep, hot mines or mines already utilizing their full heat-removal capacity, ice cooling may be the answer. Ice can remove about 4.5 times the heat as an equivalent mass flow of chilled water. Ice is produced on the surface in chunk or slurry form and is sent underground to a melting dam, where the ice is melted by warm water returning from work areas. South African mines have been at the forefront of ice application. Problems with ice transport have been mostly solved. Currently, ice systems can compete on a cost basis with standard cooling techniques for deep mines. Figure 15.5-8 shows a basic ice cooling system.

Vests and Cabs

As mines become deeper, microclimate cooling should be considered for specific operations. Dry-ice (frozen carbon dioxide) or cold-pack cooling vests can be used by crews setting up ventilation in hot headings before permanent systems are in operation. These vests are heavy-duty "fire-fighter"-type jackets with internal pockets that are filled with ice slabs; the jacket is kept closed by a belt and/or straps, and the wearer is cooled as the ice melts. Vests are not popular with the work force—they are bulky and the cooling effect only lasts between 2 and 3 hours, then the vest must be recharged. Air-conditioned cabs on large load-haul-dump machines and trucks have proven themselves worthy of consideration. One of the biggest problems with diesel equipment is the heat produced. A diesel engine produces about 2.8 times the rated power in heat. Thus, a 100-kW loader operating at 80% utilization produces $100 \times 0.8 \times 2.8 = 224$ kW of heat. The design reject temperature can easily be exceeded in headings serviced by diesel vehicles. Air-conditioned cabs protect the operator from heat, noise, and dust. Although air-conditioned cabs are expensive, the cost is much less than trying to maintain the reject temperature in all headings serviced by diesel vehicles.

Energy Recovery

Most mines send water underground for various purposes, including wetting down muck piles and reducing dust. Hot mines also send down water solely for cooling. In deep, hot mines, water pressure must be periodically broken to prevent excessive hydrostatic heads in pipes. This is often accomplished by pressure-reducing valves or by using a cascading water-tank system. If service water flow is high enough,

thought should be given to a system that recovers the water's potential energy and converts it to useful work. A turbine—either a centrifugal pump designed to run in reverse or a Pelton wheel—can reduce the pressure and recover up to 80% of the energy required to pump the water back to the surface. Another benefit is preventing the conversion of water potential energy into heat; that is, 1°C (1.8°F) for every 427 m (1,400 ft) of drop. Other energy-recovery devices include the hydrochambers or hydrotransformers (popular in Europe). These are underground chambers equipped with two pumps in two separate circuits. The chambers are alternately filled with chilled water delivered from surface and hot water returned from the mine (McPherson 1993).

Controlled Recirculation

This technique is used with bulk air-cooling underground to reduce the fresh-air quantity needed to ventilate the mine. A portion of the mine exhaust air is cooled, scrubbed, and recirculated back to the workings. Advantages include higher air velocities in work areas; lower circuit fan pressure, because less air is drawn through the primary circuit; and a lower heat load due to autocompression. Autocompression can account for half the heat load at some mines. Controlled recirculation is usually applicable to deep, hot, mechanized mines, but because of the risk involved with recirculating air, it has not been used widely. Controlled recirculation systems must be monitored and controlled very carefully (Marks 1987). Fresh-air flow from the surface must be high enough to remove dust, blasting fumes, and diesel emissions. Controlled recirculation can be shut down during blasting.

Thermal Storage Systems

This innovative technique has been used to good effect in cold-climate mines. In winter, intake air is drawn through surface rubble piles or ice stopes where it is heated by the rock or by spraying water, which then freezes, releasing its latent heat into the air. In summer, the process reverses, with intake air being cooled by the rock rubble or melting ice (Stachulak 1989). This system is being successfully applied at Vale's Creighton mine in Ontario, Canada.

Maintenance

Mine cooling is not an install-and-forget system. Adequate maintenance must be planned from the start. Any cooling coil, direct expansion, or chilled water is subject to air side fouling. If at all possible, coils should be placed upstream of blasting. Coils receiving dusty and fume-laden air must be washed with a high-pressure spray (but not too high of a pressure or the fins will bend) at least every other day. Cooling coils should have a fin spacing no tighter than one fin per 4.2 mm (6 fins per inch) to limit fouling. If sump water is used for district refrigeration machine condenser cooling, the condenser tubes must be cleaned, either by an automatic reversing brush system with a flow diverter valve or by shutting the machine down periodically (depending on the water-fouling factor) and cleaning the tubes manually. Mines with extensive refrigeration systems (e.g., a large chiller plant or more than 10 spot coolers) should employ a mechanic specializing in refrigeration. This person can be assisted by apprentice mechanics. Another viable approach is to retain the services of factory mechanics or a local high-volume air conditioning and repair shop. Any such mechanics must be certified to handle refrigerants.

Selecting a Cooling System

Selecting a cooling system takes place after the mine cooling and ventilation requirements have been specified. The relationship between mine cooling and ventilation requires special attention, especially if mine exhaust air is expected to remove heat via underground cooling towers. Cost-benefit is the most common analytical technique. Each alternative requires certain expenditure and each provides a certain benefit. But just as important are hardware dependability, maintainability, dependency on outside factors, flexibility, safety, and technological level. An attempt must be made to quantify some of the more intangible aspects. Factors influencing selection of a mine cooling system include the following.

- **Seasonal surface ambient conditions.** As mentioned previously, warm climate mines tend to bulk-cool air on the surface close to the intake shaft.
- **Ore-body and mining methods.** The more massive the ore body, the more ideal bulk cooling becomes. Scattered stoping or continuously advancing headings lend themselves more to spot or district cooling. Large ore bodies amenable to bulk mining may use larger airflows and yet less air per ton of production.
- **Mining rate.** A fast mining rate prompts a high instantaneous heat load. But ironically, less total heat (and therefore lower costs) might be drawn from the wall rock due to stopes being quickly filled and sealed. One should leave as much heat in the wall rock as possible.
- **Size and condition of major airways.** In older mines beginning to experience heat problems, airflow increases might be prohibitively expensive due to small airways. Refrigeration might be needed earlier than at larger mines.
- **Heat sources.** The percentages of heat flow from various sources influences the selection of cooling methods. If autocompression is a major source, bulk cooling at the bottom of an intake shaft might be called for. If large quantities of heat come from diesel equipment, cabs might be appropriate. If more work takes place in the stopes or in the development and exploration headings than in the haulways, spot cooling might be best.
- **Costs.** Knowing the costs of labor, water, supplies, and power is critical for determining the optimum capital expenditure to control operating costs. For example, if power cost is high, a higher coefficient-of-performance system may be warranted.
- **Governmental regulation.** Some governments regulate heat stress. There are also laws prohibiting toxic refrigerants or combustible insulation underground. These factors can influence design of cooling systems.

VENTILATION AND REFRIGERATION PLANNING

Example 10 is presented to illustrate the various steps involved in developing a ventilation-refrigeration system for a hot deep mine. Decision parameters such as the critical depth, total heat load, and airflow requirements to create acceptable work conditions are highlighted. Once these parameters are made available, ventilation and climate simulators can be used to represent the mine openings and to predict the ventilation and air-cooling requirements.

CLIMSIM, a climatic simulator based on radial heat transfer from or to an airway, is used to predict the temperature and air-cooling profiles for a set of new workings, especially

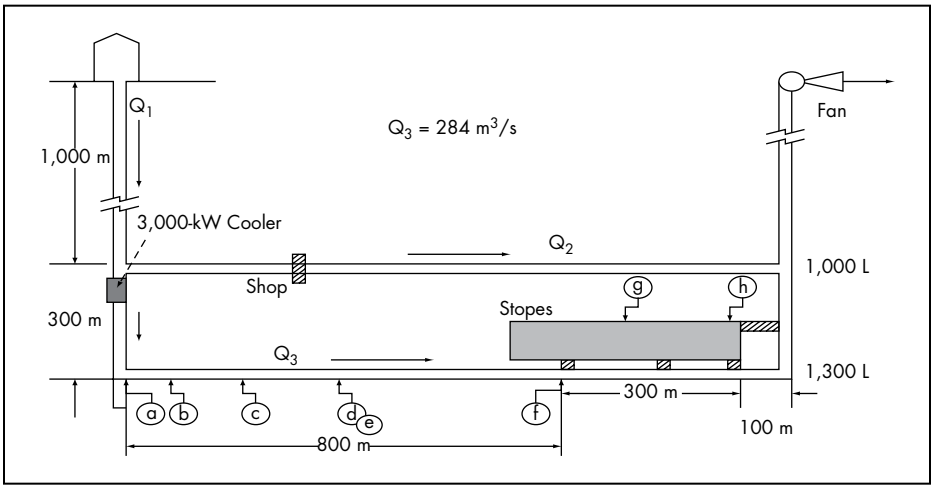

Figure 15.5-9 Mine ventilation schematic

for those subject to different types of heat loads (McPherson 1993). The profiles are then evaluated against preestablished standards, and the cooling requirements are determined. Wet bulb temperature and effective temperature are used as the target temperatures in the evaluation.

Example 10. A mining company extracts 1,200 t/d (1,320 stpd) of ore from an ore body located 1,000 m (3,280 ft) below the surface. Exploration work has shown that the ore body, a mineralized quartzite, extends to lower levels for at least 300 m (980 ft). This work has also shown a substantial increase in rock and groundwater temperatures with depth. Preliminary measurements have shown that, due to autocompression, the wet bulb temperature will increase by about 6°C (11°F) per 1,000 m (3,280 ft) of vertical depth and that the groundwater temperature will be 52°C (126°F) (VRT). The inflow of fissure water is estimated at 2.6 L/s (41 gpm). Currently, the company is preparing a prefeasibility study to deepen the mine to 1,300 m (4,265 ft) below the surface and to extract the remaining ore body at the rate of 1,500 t/d (1,650 stpd). The ore will be mined by conventional means of drilling and blasting. The required mining equipment includes seven jumbo drills (111 kW each), four production loaders (235 kW), and seven trucks (three 381 kW and four 135 kW), all diesel powered. In addition, the equipment includes a crusher-conveyor system (225 kW). The heat loads from the broken rock and groundwater are estimated at 352 and 262 kW, respectively. Figure 15.5-9 shows a schematic of the mine and the location of various heat sources. Table 15.5-2 summarizes the ventilation conditions that can be achieved with the current infrastructure, thermal properties of the rock, and heat loads for the resulting working areas. Based on this information, the problem is to determine the cooling requirement for this mine.

Solution. The problem was investigated using CLIMSIM for various heat load and ventilation conditions. During the analysis, two target temperatures were used: an average wet bulb temperature of less than 28°C (82°F) and a maximum wet bulb temperature of 32°C (90°F) at any working. When these targets were not met, the ventilation and cooling requirements were modified. Based on the psychrometric properties of the surface air, the depth of the openings, and an estimated VRT of 52°C (126°F), two scenarios were analyzed. The first simulated the mine before any air-cooling was installed and the second after an underground bulk air cooler was installed in the intake shaft.

Table 15.5-2 Airway, ventilation, and heat flow parameters for Example 10

Description	Parameter
Geometry of mine opening	
Length, m	1,200
Cross-sectional area, m^2	30.0
Perimeter, m	22.0
Airway friction factor, kg/m^3	0.04
Wetness factor	0.15
Ventilation at intake	
Airflow rate, m^3/s	284
Pressure, kPa	101.0*
Dry bulb temperature, °C	25*
Wet bulb temperature, °C	21*
Thermal properties (quartzite)	
Virgin rock temperature, °C	52.0
Geothermal step, m/°C	100
Thermal conductivity, W/m °C	5.50
Thermal diffusivity, $m^2\tau/s$	2.32
Heat sources†	
Ore bin, (x = 10 m), kW	352
Conveyor (x = 10 to 100 m), kW	100
Crusher (x = 100 m), kW	125
Drain water (x = 100 to 800 m), kW	262
Trucks (x = 100 to 800 m), kW	894
Loaders (x = 800 m), kW	940
Drills, controls (x = 1,000 m)	777
Booster fans (x = 1,100 m)	600

*Measured at intake shaft collar.
†x = Distance from intake.

For the first scenario, two sets of parameters were estimated: the required airflow rate to dilute the air contaminants and the heat generated at the workings. Based on the mining equipment, a flow requirement of 0.079-m^3/s (167 cfm) per kW of power, and a minimum quantity of 70-m^3/s (148,000 cfm) for two fixed facilities, the required airflow rate for the mine

Table 15.5-3 Airflow requirements for Example 10

Item	Utilization, %	Quantity, m^3/s
Loaders (4 × 235 kW)	80	59.4
30-t trucks (3 × 381 kW)	80	72.2
Other trucks (4 × 135 kW)	80	34.1
Jumbo drills (7 × 111 kW)	50	30.7
Crusher system (225 kW)	100	17.8
Underground shops	—	40.0
Other fixed facilities	—	30.0
Total quantity		284.2

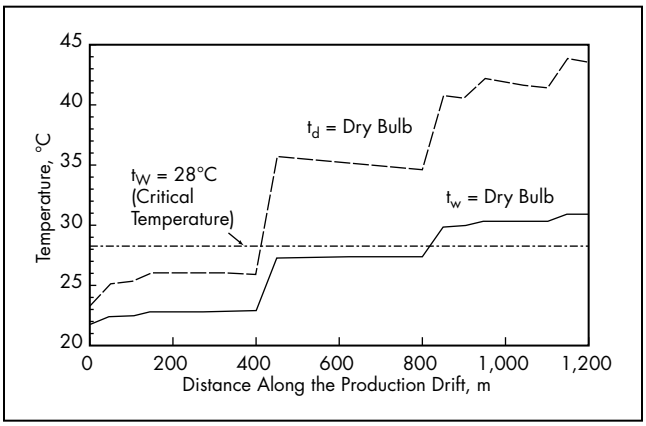

Figure 15.5-10 CLIMSIM output for Equation 15.5-10 (wet and dry bulb temperatures versus distance)

was estimated at 284 m^3/s (600,000 cfm) (Table 15.5-3). The heat loads and their distances from the intake shaft are those shown in Table 15.5-2 and Figure 15.5-9. The conveyor belt and the drainage water were represented as linear sources of heat. Once these values were input to the model and the simulator was run, the following results were generated: the wet bulb temperature at the bottom of the intake shaft was 26°C (79°F) and averaged 33.5°C (92.3°F) at the workings, and the dry bulb temperatures at active workings varied between 36° and 52°C (97° and 126°F). Both temperatures are above the acceptable target values, indicating that to maintain safe working conditions, the mine would require some form of cooling system.

For the second scenario, a 3,000-kW(R) refrigeration plant was installed in the intake shaft. Physically, this could be installed on the 1,000-m (3,280-ft) level, just upstream the intake shaft. Once this parameter was added to the model (as a negative heat source), the simulator generated the following results: the average wet bulb temperature would be equal to 26.5°C (79.7°F), with a maximum of 30°C (86°F) in the stopes; and the dry bulb temperature would average 33°C (91°F). These results show that the 3,000-kW plant would provide acceptable work conditions in the mine. Figure 15.5-10 shows two temperature profiles for the 1,200-m- (3,940-ft-) long production drift. The 3,000-kW refrigeration plant would reduce the wet bulb temperature at the bottom of the shaft to 22°C (72°F). This temperature would remain below 26°C (79°F) for 800 m (2,620 ft) where four 235-kW loaders are operated in four production stopes and two development headings. The heat and water vapor generated by these and other diesel units would increase the wet and dry bulb temperatures to 31° and 42°C (88° and 108°F), respectively.

This example shows the manner in which CLIMSIM can be used to formulate alternate solutions to heat flow problems and determine the capacity of the cooling system. It also shows the effect of autocompression in the ventilation air and allows the user to determine the critical depth, that is, the depth at which the mine would require some form of external cooling. In this example, such a depth is located at about 900 m (2,950 ft) below the surface.

CONCLUSIONS

In the United States, heat becomes an environmental concern in mines where workings are located at depths greater than 1,000 m (3,280 ft). At such depths, ventilation alone is not sufficient to control the heat load, and the mine must be supplemented by some form of air conditioning.

Since the introduction of the first heat stress index in 1923, more than 90 indices have been developed in various countries. In U.S. mines, heat stress is not regulated. Management must set and enforce the applicable limits. The most commonly used indices are

- Wet bulb temperature for continuous work: ≤27°C (80.6°F)
- Effective temperature for reduced workload: ≤28°C (82.4°F)
- Air velocity: ≥0.5 m/s (100 fpm)

In underground mines, heat is emitted from various sources, including autocompression, wall rock, mining equipment, groundwater, the oxidation of minerals, and metabolic heat. The estimation of the total heat load is crucial to the design of an air-cooling system. Once the individual heat loads are quantified, mine climate simulators such as CLIMSIM can be used to represent the mine openings and to predict the ventilation and air-cooling requirements.

Mine cooling is a heat-removal process in which a substance such as air, water, or ice is sent down the mine at a low enthalpy state and removed at a higher one. Depending on the amount of heat to be removed, several cooling methods can be used to create acceptable work conditions. These can range from upgrading the primary fans (increased ventilation) to cooling the mine air (refrigeration).

Ventilation is the least-expensive method to remove heat from mine workings. However, it has a limit—the critical depth. The critical depth is the depth at which the wet bulb temperature of the intake air exceeds the allowable wet bulb temperature.

Refrigeration plants used in hot mines range from spot coolers (for localized heat loads) to bulk air coolers (for widespread heat flow problems). Bulk air coolers can be installed on the surface, near the intake shaft, or underground, near the workings. Deciding at which stage a refrigeration plant is required is a difficult question to answer. Economics and site-specific conditions will dictate the optimal choice.

CHAPTER 15.6

Radiation Control

Derek B. Apel and Zaher Hashisho

RADIOACTIVE DECAY OF URANIUM SERIES

Uranium is a naturally occurring radioactive element. It is found in rocks, soils, rivers, and oceans, and traces can be found in food and in the human body. Uranium is a common substance that is found throughout the earth's crust. It is more common than all of the precious metals and is more common than many nonprecious metals. Uranium, for example, is 40 times more common than tin. More than 200 minerals contain uranium, of which uraninite is the most common. Uranium concentrations vary from substance to substance and place to place.

Uranium is the heaviest of the naturally occurring elements and is made up of a number of different forms known as isotopes. Natural uranium is primarily made up of two isotopes, ^{235}U and ^{238}U. About 99.3% of natural uranium is ^{238}U and approximately 0.7% is ^{235}U, the "fuel" component of natural uranium. Because it is present virtually everywhere, it contributes to what is called the natural background radiation. Almost every backyard contains traces of naturally occurring uranium.

Radon is derived from the radioactive decay of uranium to radium then radon (see Figure 15.6-1). During the decay process, the unstable elements emit radiation. In essence, three different types of radiation are emitted: alpha, beta, and gamma.

Alpha radiation occurs when an alpha particle (the nucleus of a helium atom, which contains two protons and two neutrons) is emitted from the atom's nucleus. An alpha particle carries a relative electrical charge of +2, and when this particle is emitted from an element, the atomic number of this element is reduced by 2 and its atomic mass is reduced by 4. Usually, alpha radiation is not able to penetrate clothing and human skin, but if the alpha-emitting material is inhaled, it will cause damage to the lung tissue.

In simple terms, the beta radiation occurs when an electron is ejected from the nucleus of the decaying element. Therefore, this radiation has a relative electrical charge of –1, which causes the decaying element to gain a positive charge. This is shown on the periodic table as an increase by 1 atomic number of the new element. Beta radiation may travel a couple of meters in the air and can penetrate human skin. If beta-emitting materials are left on the skin for a longer period of time, they will cause skin injury.

Like visible light, radio waves, and X-rays, gamma radiation is a type of electromagnetic radiation. Gamma radiation can travel for several meters in the air and several centimeters in human tissue. Gamma rays can penetrate most materials. Dense materials (e.g., lead) are needed for shielding against gamma radiation.

Radon is a colorless, odorless, tasteless, radioactive gas that generally lacks activity toward other chemical agents. However, radon occasionally forms clathrate compounds with some organic compounds, and it may form ionic or covalent bonds with highly reactive elements such as oxygen or fluorine. Radon is the heaviest noble gas and exhibits the highest boiling point, melting point, critical temperature, and critical pressure of all noble gases. Radon is highly soluble in nonpolar solvents and moderately soluble in cold water. Radon's isotopes, all of which are radioactive, include mass numbers ranging from 200 to 226. ^{222}Rn formed in the ^{238}U decay chain is the most important isotope because of its relatively long half-life of 3.82 days. The short half-life beta- and gamma-emitting decay products of ^{222}Rn achieve equilibrium with the parent isotope within several hours. The density of radon is 9.73 g/L, and it has solubility in water of 22.2 mL/100 mL at 20°C.

Units of Radiation

The activity (rate of decay) of ^{222}Rn is expressed in units called curies. The curie is based on the rate of decay of 1 g of ^{226}Ra or 3.7×10^{10} disintegrations per second. The International System of Units (SI) measure of activity is becquerels per cubic meter (Bq/m^3). One becquerel equals one disintegration per second. The radiation unit most widely used by the uranium industry is the working level (WL), which is based on the measurement of energy released by ^{222}Rn and its progeny.

One WL means that the ^{222}Rn and its progeny released in 1 L of air will emanate 1.3×10^5 million electron volts (MeV)

Derek B. Apel, Professor, School of Mining & Petroleum Engineering, University of Alberta, Edmonton, Alberta, Canada
Zaher Hashisho, Assistant Professor, Department of Civil & Environmental Engineering, University of Alberta, Edmonton, Alberta, Canada

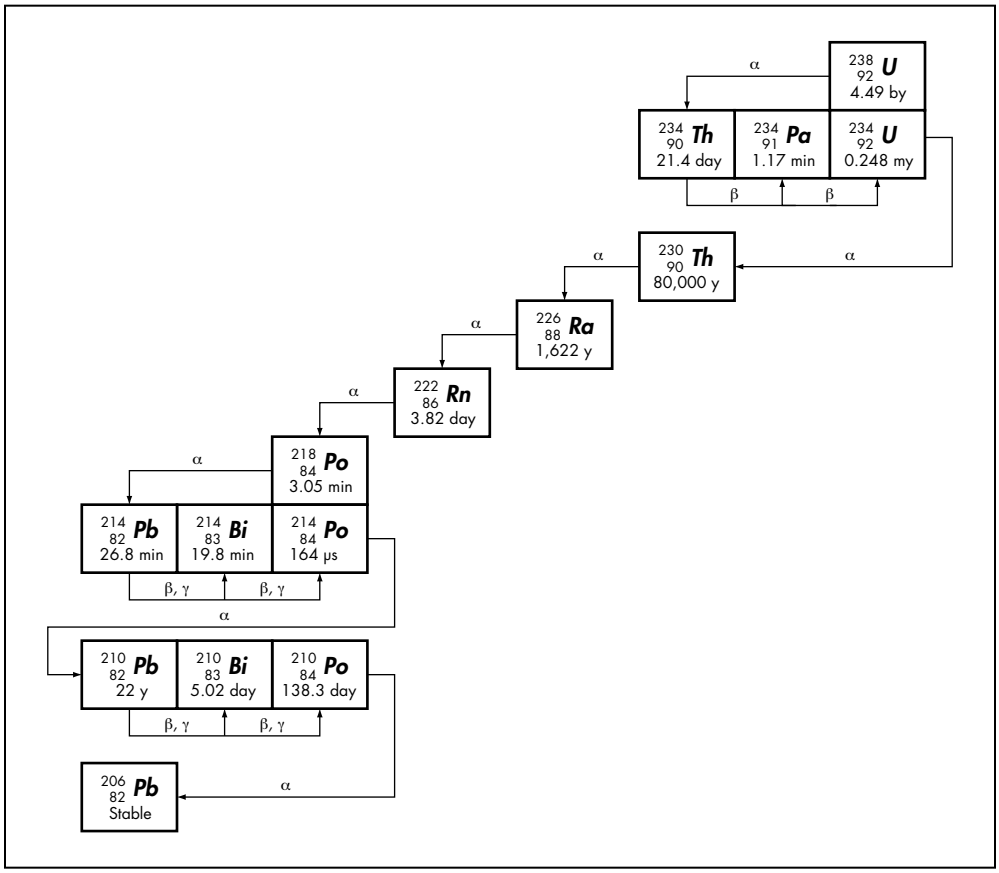

Figure 15.6-1 Uranium decay series (includes the half-life, atomic mass, atomic number, and emission type of each decay product)

of energy from alpha particles. The exposure to radiation at underground mines, which combines both exposure and time, is the working level month (WLM), which is defined as the exposure to one WL during 170 hours. For example, the WLM exposure for a miner who worked underground during a month for 120 hours and whose exposure was measured to be 0.9 WL has an exposure of 0.9 WL $\times$ 120 h/170 h = 0.64 WLM.

The joule-hours per cubic meter (Jh/m^3) is the SI unit of cumulative exposure to ^{222}Rn and its progeny. One WLM is equal to 3.5×10^{-3} Jh/m^3.

Occupational Exposure Limits

The exposure limit varies by regulating agency and type of worker. In the United States, the Mine Safety and Health Act regulates exposure to ^{222}Rn gas and ^{222}Rn progeny by underground miners. The act sets limits so that no employee can be exposed to air containing ^{222}Rn progeny in excess of 1.0 WL or 100 pCi/L (picocuries per liter) in active work areas. The act also limits annual exposure to ^{222}Rn progeny to less than four WLM per year (Field 1999).

EFFECT OF RADON PROGENY ON HUMAN HEALTH

The linkage between radon and the increased risk of cancer has been established throughout numerous studies (Frumpkin and Samet 2001). Even before the discovery of radon, many people blamed "mines air" for high mortality rates among underground miners. This was first described by Georgious Agricola (Agricola 1912) in his greatest work titled *De Re Metallica*, which was originally published in 1556. The study that most referenced in the literature linking radon exposure to lung cancer are findings summarized in a report titled *Health Effects of Exposure to Radon*, prepared by the National Research Council's Committee on the Biological Effects of Ionizing Radiation (BEIR) Report VI (NRC 1998). This report was based on data pooled from underground mines. The data show that of 60,000 miners who worked between 1941 and 1990 in different mines located in different countries, more than 2,600 developed lung cancer against only 750 cases based on background data. A study conducted by Kreuzer et al. (1999) reported that among 64,000 uranium miners in East Germany who worked a minimum of 180 days at these mines between 1946 and 1989, there were 1,436 deaths due to lung cancer.

The findings from these studies overwhelmingly show that radon progeny exposure causes lung cancer. Most of the radiation-hazard results from the inhalation of the short-lived radon progeny. Radon itself is of minor concern, because most of the inhaled radon is exhaled. Therefore, this is not radon itself but radon's progeny whose decay in lungs causes damage to the cells and DNA mutation that can lead to lung cancer. This was established by research conducted by Hursh et al. (1965). Additional work found that radon is removed from the body with a primary half-life of between 30 and 70 minutes (Crawford-Brown 1989).

EMANATION OF RADON AT UNDERGROUND MINES

The emanation of radon from uranium ore is the effect of radium decay. During this process, an alpha radiation is emitted from an atom of radium and its atomic mass is being reduced from 226 to 222. At the same time, the atomic mass drops from 88 to 86, and radium changes into radon. Radon can emanate to the mine atmosphere from the ore, rock walls, and mine water. The rate of radon emanation can be described as the number of radon atoms exhaled from a unit area of rock in a unit of time, and it is defined in units of picocuries per square centimeter per second (pCi/cm^2/s).

The emanation of radon from rock surfaces in underground mines (J) can be calculated (Bates and Edwards 1980) as follows:

$$J = C_\infty \sqrt{\lambda D \phi} \text{ pCi/cm}^2\text{/s} \quad (15.6\text{-}1)$$

where

C_∞ = radon concentration at infinite distance into rock, pCi/m^3
λ = radon decay constant (0.00755 disintegrations per atom or 2.1 $\times$ 10^{-6} Bq)
D = diffusion coefficient, m^2/s
ϕ = rock porosity (0.50 = 50% porosity)

If the emanation of radon from a unit volume of rock (B) is known, Equation 15.6-1 can be modified to the following form:

$$J = B\sqrt{\frac{D}{\lambda\phi}} \quad (15.6\text{-}2)$$

where B is sometimes called the emanating power, pCi/cm^3/s.

The random movement of the radon gas atoms mixed in the air results in a net migration of the radon gas toward the direction of its decreasing concentration in the air. This phenomenon is called molecular or atom diffusion.

Table 15.6-1 shows examples of various media and their coefficients of diffusion. The table illustrates that the coefficient of diffusion decreases with the density of the material.

Table 15.6-1 Coefficient of diffusion for radon in various materials

Material	Coefficient of Diffusion D, m^2/s
Dense rock	0.05 × 10^{-6}
Rock with porosity of 6.2%	0.2 × 10^{-6}
Rock with porosity of 12.5%	0.5 × 10^{-6}
Rock with porosity of 25%	3.0 × 10^{-6}

Water	1.13 × 10^{-8}

CONTROLLING RADON PROGENIES AT UNDERGROUND URANIUM MINES

The control of radon progenies at underground uranium mines should commence with the process of selecting the mining method, controlling water inflows, and designing a flexible ventilation system. In addition, each mine has to establish safety operating procedures specific for each operating mine. The latter is extremely important, as even the best ventilation system can malfunction because of a power outage, human error, or other unforeseen circumstances. When designing ventilation systems for underground uranium mines, deposits can be divided into two groups: low-grade deposits, usually ranging from 0.1% to 2% U_3O_8 (triuranium octoxide), and high-grade deposits, where the grade can exceed 20% U_3O_8.

Ventilation Systems

In the case of high-grade deposits, the radon emanation rate from the ore would make it practically impossible to dilute the radon daughters using flush-through ventilation, and in these cases the ore is mined using remote mining methods (e.g., raise boring or mining using water jets) while a minimum pillar thickness of 5 m of an inert rock is kept between the ore and the miners (Figure 15.6-2; Apel 2000).

Production areas where the emanation of radon is high can be ventilated using both flush-through ventilation and a secondary ventilation system that is used to capture radon at its source and then exhaust it to the restricted entry return air drifts. The new development headings shall be ventilated using a combination of positive and negative pressure ducting. The positive pressure ducting is used to flush the air at the heading, whereas the negative pressure rigid ducts are used to transfer the radon-contaminated air to the exhaust air drifts or shafts (see Figure 15.6-3).

All inactive areas must be sealed off by ventilation bulkheads, and the bulkheads should be periodically checked for radon leaks. In cases where a complete seal cannot be established by the ventilation bulkheads, it should be connected to the low-pressure negative ventilation system.

Experiments conducted in mines in the United States showed a reduction of radon concentration by using positive blowing versus the exhaust systems of up to 20% (Schroeder and Evans 1969; Franklin 1981). However, these experiments were conducted in relativly shallow mines, and it may not be feasible to achieve any decrease of radon production in deep mines where rock-in-situ stresses are much higher.

Water Control

Radon is soluble in water and is also readily released from it. Therefore, by limiting water inflows into mine openings, radon emanation into the mine air will be reduced. Controlling the water inflows can be achieved by using grout curtains ahead of the development or using ground freezing (Apel and Szmigiel 2006). The solubility of radon decreases with an increase in water temperature (e.g., 510, 230, and 169 cm^3/kg at 0°C, 20°C, and 30°C, respectively) (NRC 1998). Because not all the radon leaves water immediately after entering the underground openings, all the water sumps must be ventilated using negative pressure ventilation. The removal of radon from water can be done through aeration. Aeration simply forces radon from the water to the air and can be very effective. According to Dixon et al. (1991) and Kinner et al. (1993), bubble-plate aeration and diffused bubble aeration as point-of-entry units are capable of achieving removal efficiencies in excess of 99% at loading

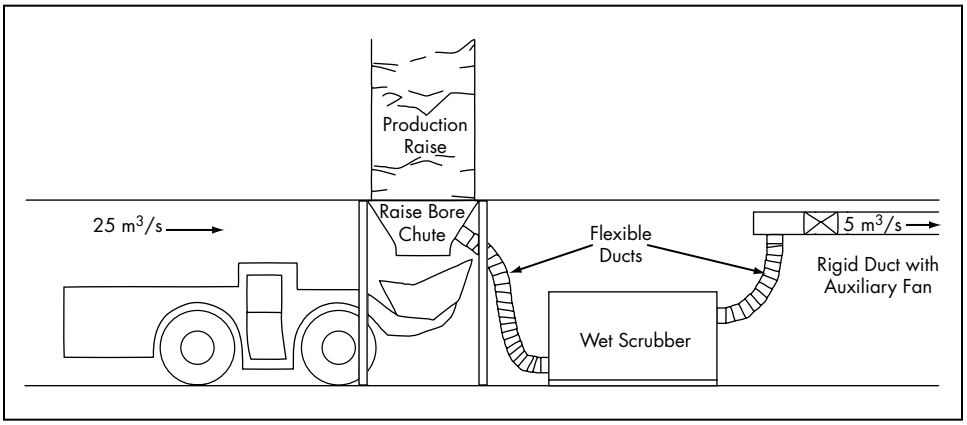

Figure 15.6-2 Ventilation setup for the raise-boring mining method

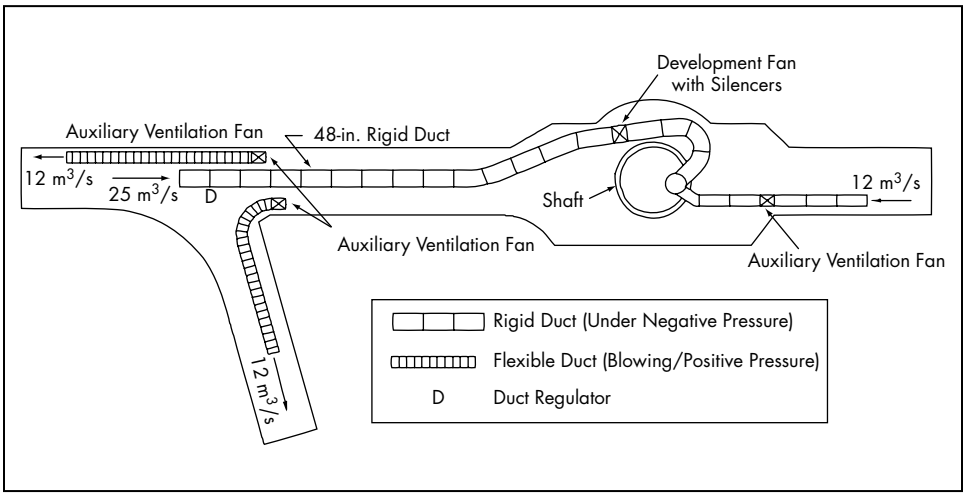

Figure 15.6-3 Ventilation setup during the development stage at a uranium mine

rates of 185 Bq/L or more, whereas the simple spray-jet aeration technique only removes between 50% and 75% of the radon.

Dust Control

Dust control is extremely important at uranium mines because radon progenies can get electrostatically attached to tiny particulates, such as dust, in air. If these particulates get inhaled, they will start decaying and releasing damaging alpha and beta particles. How much radon progenies get attached to the dust depends on factors such as the size and concentration of the airborne particles. The size and density of a particle determine whether or not the particle will reach the lung tissue. Particles with diameters of 10 μm are generally filtered by the nose and saliva during breathing and, therefore, should not reach the lungs. However, particles that range in diameters of from 2 to 10 μm have a good chance of being deposited in the bronchial region (Hinds 1999).

Obviously, selection of the mining method will impact how much dust will be created, but facts such as allowing longer periods after the blasts for dust to settle or spraying the muck with water after the blast will also limit the amount of air-bound dust created. Using personal protective equipment, such as an air respirator, is probably the best way to limit exposure to dust at uranium mines.

RADIATION MONITORING

Exposure of workers to radiation at underground mines can be controlled by adjusting the ventilation. The level of radiation at underground mines can change with further development of underground workings or changes in the uranium-ore production rates. Therefore, monitoring of radiation is very important in reducing the exposure of workers. Monitoring techniques at underground mines can be classified based on their ability to measure radon or its progeny. They can also be classified based on the measurement time frame into grab sampling, integrated sampling, or continuous monitoring and sampling. Radiation monitoring is not only limited to monitoring radon and its progeny, but it also includes monitoring of gamma-ray radiation.

Grab Sampling

Grab sampling consists of collecting samples over a short period of time, ranging from minutes to hours.

Radon Sampling with Scintillation Cells

A scintillation cell, such as the Lucas chamber, consists of a flask coated with silver-activated zinc sulfide on the inner surfaces, except for a clear window on one side to allow photons produced from alpha disintegrations to be counted. Sample air

is admitted to the evacuated cell, which is typically 100 mL to 2 L in size (Sengupta 1989). Usually, the air sample is left to age for 4 hours to allow for equilibrium between radon and its progeny. Radon concentration is proportional to the photon count obtained with a photomultiplier tube. Correction factors are used to account for the decay during the time between sampling and counting and for decay during counting (McDermott and Ness 2004). Scintillation cells offer a reliable technique for radon sampling. For short counting periods, a sensitivity of 5 to 10 pCi/L is attained, whereas the limit sensitivity can reach 0.1 pCi/L for long counting periods (≥100 minutes) (Sengupta 1989).

Radon Progeny Sampling

Kusnetz method. The Kusnetz (1956) method involves drawing a known volume of air (100 to 250 L) through an air filter using a vacuum pump during a short time frame, typically 5 minutes (McDermott and Ness 2004). Airborne radon progeny attached to dust particles are collected on the surface of the filter. The decay of these progeny results in emission of alpha particles. The alpha particles are counted over a typical duration of 5 minutes after a delay period of 40 to 90 minutes. The delay time is the time in minutes from the end of sampling to the middle of counting. For a given delay time, t_k, an appropriate Kusnetz conversion factor, K, can be calculated using the following equations (CNSC 2003):

$$K = 230 - 2t_k \quad \text{for } 40 \le t_k \le 70 \tag{15.6-3}$$

$$K = 195 - 1.5t_k \text{ for } 70 \le t_k \le 90 \tag{15.6-4}$$

Knowing the volume of sampled air and the alpha particles count, radon progeny concentration can be determined as WL. The original method assumes perfect equilibrium, which results in greater than a ±25% error (Vutukuri and Lama 1986). Modifications of the Kusnetz method compensate for the assumption of equilibrium by taking alpha-activity count at several occasions during the growth of the progeny activity and making corrections for nonequilibrium (Vutukuri and Lama 1986).

The original Kusnetz method measures alpha particle activity with a rate meter, resulting in a practical lower limit of measurement of 0.3 WL. In the modified Kusnetz method, a scaler is used instead of the rate meter, resulting in a 10-times improvement in the sensitivity (Sengupta 1989).

The concentration in working levels, WL, can be obtained with the following equation(DCEP 2008):

$$\text{WL} = \frac{C_S - C_B}{E \times K \times V \times t_c} \tag{15.6-5}$$

where

WL = concentration in working levels
C_S and C_B = gross and background alpha counts, respectively, recorded over the interval t_c
E = efficiency of equipment detection, fraction
K = factor to convert from counts per minute to working level
V = volume of air sampled, L
t_c = counting time, minutes

For the Kusnetz method, K is the Kusnetz conversion factor determined from Equations 15.6-3 and 15.6-4.

The right side of Equation 15.6-5 can be multiplied by a correction factor to compensate for the absorption of radon progeny on the sampling filter. This factor will probably be less than 0.02 for a cellulose ester filter, but it may exceed 0.1 for a glass-fiber filter (CNSC 2003).

A disadvantage of the Kusnetz method is that it is not suitable for atmospheres containing both ^{222}Rn and ^{220}Rn progeny, because the delay period allows for the ingrowth of ^{220}Rn progeny, which will contribute to the gross alpha count (DCEP 2008). In Canada, the Canadian Nuclear Safety Commission inspectors in underground mines rely on the modified Kusnetz method for sampling, counting, and computational procedures (CNSC 2003).

Modified Tsivoglou method. The modified Tsivoglou method is very similar to the Kusnetz method, except that the filter is counted three times after collection to measure the concentration of the individual radon daughters. Filter counting occurs at the following intervals after completion of sampling: 2 to 5, 6 to 20, and 21 to 30 minutes (McDermott and Ness 2004).

Based on a half-life for ^{218}Po of 3.04 minutes, the concentration of each of the radon decay products, that is, ^{218}Po, ^{214}Pb, and ^{214}Po, can be determined using the following calculations:

$$C_1 = \frac{1}{FE}\begin{pmatrix} 0.16921\ G1 - 0.08213\ G2 \\ +0.07765\ G3 - 0.5608\ R \end{pmatrix} \tag{15.6-6}$$

$$C_2 = \frac{1}{FE}\begin{pmatrix} 0.001108\ G1 - 0.02052\ G2 \\ +0.04904\ G3 - 0.1577\ R \end{pmatrix} \tag{15.6-7}$$

$$C_3 = \frac{1}{FE}\begin{pmatrix} -0.02236\ G1 + 0.03310\ G2 \\ -0.03765\ G3 - 0.05720\ R \end{pmatrix} \tag{15.6-8}$$

where

C_1, C_2, and C_3 = concentrations of ^{218}Po, ^{214}Pb, and ^{214}Po, respectively, pCi/L
F = sampling airflow rate, L/min
E = counting efficiency, counts per minute/disintegrations per minute
$G1$, $G2$, and $G3$ = gross alpha counts at the 1st, 2nd, and 3rd intervals, respectively
R = background counting rate (counts per minute)

The working level can be expressed using the following equation:

$$\text{WL} = 10^{-3}\ (1.028C_1 + 5.07C_2 + 3.728C_3) \tag{15.6-9}$$

Using an alpha-scintillation scaler instead of a rate meter results in a 10-times improvement in the sensitivity (Sengupta 1989).

Rolle method. The Rolle method is used for the determination of ^{222}Rn progeny concentration (DCEP 2008). This method is similar to the original Kusnetz method, except that the timing for filter counting after sample collection is different. In the Rolle method, the delay period is 5 to 10 minutes, allowing for faster measurement compared to the Kusnetz method. In addition, the short delay time minimizes the error in the radon progeny ratio allowing better measurement of the concentration of ^{222}Rn progeny (Sengupta 1989). The working level of ^{222}Rn progeny can be calculated using Equation

Table 15.6-2 Conversion factor for Rolle method

Sampling Time, minutes	Delay Time, minutes	Counting Time, minutes	Conversion Factor	Error, %
4	6.46	5	213	12
5	6.06	5	213	11
10	4.35	5	213	11
15	1.36	10	212	10
20	2.12	5	210	10

15.6-5 (i.e., the same equation used for the Kusnetz method) but with a conversion factor selected from Table 15.6-2 (DCEP 2008).

Rock method. The Rock method is mainly used for the determination of ^{220}Rn progeny concentration because of the extended delay time allowing for the ingrowth of ^{220}Rn progeny. The method is similar to the Kusnetz method, but the delay period is typically between 5 and 17 hours. An advantage of this method is that the long delay period allows sampling of remote locations and sending the samples for laboratory analysis. The concentration of ^{220}Rn progeny can be calculated using Equation 15.6-5, but with the conversion factor selected from Table 15.6-3 (DCEP 2008).

Cote method. The Cote method allows for the determination of the concentration of ^{220}Rn and ^{222}Rn progeny based on the selection of the delay period for the alpha count. The method consists of 10-minute dust sampling followed by several 15-minute alpha counts. The first count, conducted 1.2 minutes after the completion of sampling, is used to obtain the concentration of ^{222}Rn progeny, because the contribution of ^{220}Rn progeny is negligible at this time. A conversion factor of 218 is used in Equation 15.6-5 to obtain the WL concentration of ^{222}Rn progeny. The second count, conducted 155 minutes after sampling, provides the combined contribution of ^{222}Rn and ^{220}Rn progeny using a conversion factor of 14.1 in Equation 15.6-5. The final count, conducted 225 minutes after sampling, is used to obtain the ^{220}Rn progeny contribution using a conversion factor of 14.2 in Equation 15.6-5. A disadvantage of the Cote method is the need for a counting instrument to be placed on or very close to the sampling location (DCEP 2008).

Table 15.6-3 Conversion factor Rock method

Time After Sampling, hours	Conversion Factor
5	13.2
7	11.3
9	9.8
11	8.6
13	7.5
15	6.7
16	6.3

Integrated Sampling

Integrated sampling provides a single concentration value averaged over the duration of the sampling time, which can ranges from days to weeks, months, or up to a year.

Radon Sampling

Activated carbon canisters. Adsorption on activated carbon allows integrative sampling of radon gas over a period of up to 7 days. Because the adsorbed radon undergoes radioactive decays during the sampling period, this method does not uniformly integrate radon concentrations. Sampling can be active using a pump, or passive based on diffusion (Katz 1977; McDermott and Ness 2004). After sampling, the activated carbon is analyzed using a sodium iodide gamma-scintillation detector to count the gamma rays between 0.25 and 0.61 MeV emitted by the radon decay products on the activated carbon (Katz 1977; McDermott and Ness 2004). Alternatively, radon can be desorbed from the activated carbon and transferred to a counting cell for alpha counting (Katz 1977). For gamma counting of a diffusion-based activated carbon monitor, the lower limit of detection ranges from 0.1 to 0.2 pCi/L of radon for a sampling time of 4 days (George 1990). Radon sampling with activated carbon canisters is a simple and low-cost method. However, the results can be sensitive to humidity and temperature. Desiccant can be used to avoid interference from adsorption of water vapor.

Alpha track detectors. Alpha track detectors provide an integrated concentration of radon over the exposure period, which ranges from few months to a year. The detector consists of a plastic film, such as cellulose nitrate (LR-115, manufactured by Kodak-Pathé) or allyl diglycol carbonate (CR-39) films (Alter and Fleischer 1981). The films are enclosed in a container that allows only radon to diffuse through and prevent the penetration of radon progeny. Alpha particles emitted by the radon and its progeny in the container strike the detector and produce submicroscopic damage tracks. Following exposure, the detectors are treated with a caustic solution to visualize the damage tracks for manual counting with a microscope or automated counting with an optical counting system. Radon concentration is proportional to the net areal density of tracks per unit time. The advantages of alpha track detectors are their simplicity, cost-effectiveness, and the lack of need for external power sources. Their main disadvantage is the dependence of results on the type of film used. However, the variability in the results can be decreased by counting more tracks over a larger area of the detector (McDermott and Ness 2004).

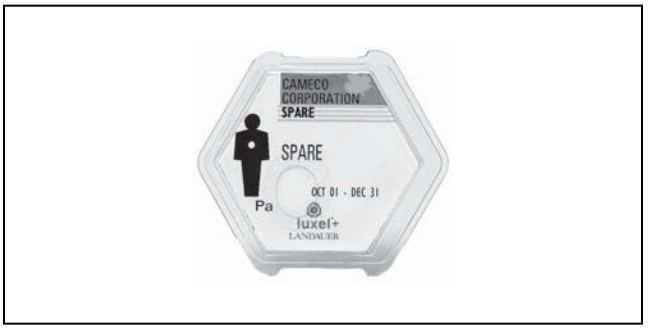
Radon Progeny Sampling

Thermoluminescent dosimeter (TLD). TLD-based systems integrate radon progeny concentration over sampling periods ranging from few days to a few weeks. The system contains a detector assembly through which sample air is drawn. The detector assembly includes a filter and two TLDs. One TLD is used for measuring alpha particles emitted from radon progeny collected on the filter. The other TLD is shielded from the alpha particles emitted from the filter and is used for measuring background gamma radiation (Vutukuri and Lama 1986; McDermott and Ness 2004). Alpha particles emitted from the decay of the radon progeny are registered on a luminescent material such as calcium fluoride dysprosium or

lithium fluoride. Following sampling, the detector assembly is sent for analysis using a TLD reader. Light emitted from the TLD as a result of heating in the TLD reader is detected with a photomultiplier tube and is proportional to the radon progeny collected on the filter paper during sampling (George 1990). A TLD is accurate and suitable for long sampling periods; however, they suffer from their relatively high cost and clogging of filters (Vutukuri and Lama 1986). Instead of TLDs, optically stimulated luminescence (OSL) dosimeters are used for measuring exposure of mine workers to radiation. OSL dosimeters use luminescent material such as Al_2O_3:C that responds to gamma radiation (Figure 15.6-4). The OSL dosimeter is typically exposed for several months before it is analyzed. Unlike the case of TLDs, the readout method for OSL dosimeters is all optical, eliminating the need for heating of the samples. OSL dosimeters also provide a high-sensitivity, fast-readout process, as well as the possibility of multiple readings (McKeever 2001).

Electret detector and alpha track detector systems. A filter-based system similar to the one used with a TLD system can be used with other types of detectors, such as an alpha track detector or an electret detector. An electret is an electrostatically charged disk positioned in an ion chamber. Alpha particles generated from the decay of radon progeny collected on the filter result in negatively charged ions that are collected on a positively charged electret, resulting in a reduction in its surface voltage. Radon progeny concentration is proportional to the voltage reduction (McDermott and Ness 2004). Short-term electrets integrate measurements up to 7 days. Long-term electrets are less sensitive but integrate measurements for 1 to 12 months. The lower limit of detection for a short-term electret is 0.2 pCi/L of radon for a 3-day exposure (George 1990).

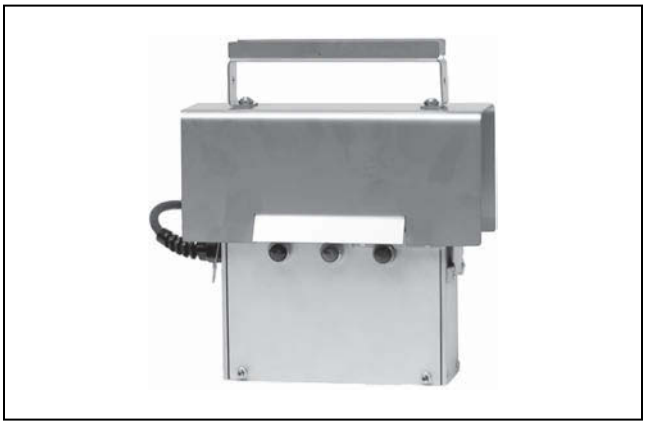
Continuous Monitors



In continuous monitoring, sampling and analysis occur simultaneously and continuously.

Scintillation Cell

A variation of the scintillation cell used for grab sampling of radon can be used for continuous radon monitoring. One configuration consists of a flow-through scintillation cell in which air is continuously pumped through for a few minutes. Alpha particles from the decay of radon gas are counted as the gas is swept through. Another configuration consists of a periodic-fill cell, into which air is pumped once during each preselected time interval, and the alpha particles are counted in each interval. Passive scintillation cells in which radon diffuses through a filter area allow passive continuous monitoring of radon after a short diffusion time lag with a lower limit of detection of about 1 pCi/L for a 1-hour counting (George 1990; McDermott and Ness 2004).



Diffusion-Based Ionization Chamber

A diffusion-based ionization chamber allows radon gas to diffuse into the chamber while radon progeny are removed electrostatically. As is the case with a passive scintillation chamber, there is a short time lag with this method. Inside the ionization chamber, the emitted alpha particles from radon decay generate bursts of ions that are recorded by an electrometer. The lower limit of detection is about 0.5 pCi/L for a 1-hour counting (George 1990).

Figure 15.6-5 A Continuous working-level monitor intended for operation as a station monitor

Continuous Radon Progeny Monitors

Continuous radon progeny monitors use filters to collect radon progeny and an alpha detector to measure alpha particles generated from the decay of the radon progeny. Hence, they are similar to integrated radon progeny samplers, except that automated sampling of air is done on a continuous basis and alpha counting is integrated over short-time intervals ranging form several minutes to an hour (George 1990). Gross alpha counting is also used to provide WL radon progeny. One commonly used system, alphanuclear prism, has four alpha-energy counting windows that indicate WL concentrations of <0.1 WL, 0.1 to 0.25 WL, 0.25 to 0.5 WL, 0.5 to 1 WL, and >1 WL (Figure 15.6-5).

CHAPTER 15.7

Noise Hazards and Controls

Gary E. Walter

INTRODUCTION

Noise is an inherent health hazard in the mining industry. The mining process is highly mechanized from the earliest ore removal to final processing, and heavy equipment is essential at virtually every stage of operation. Exposure to noise is a concern for workers who drive mechanized equipment as well as those who operate or work near stationary equipment such as haulage belts or crushing equipment. Exposure to noise levels above regulatory or recommended limits can result in hearing loss that adversely affects the daily lives of workers and negatively impacts society as workers so affected access health care services.

Worker exposure to noise is regulated by many government agencies. In the United States, these agencies include the Mine Safety and Health Administration (MSHA) and the Occupational Safety and Health Administration (OSHA). In the United Kingdom, the regulatory agency for worker health and safety is the Health and Safety Executive (HSE). The European Union (EU) has also enacted a directive on noise that must be implemented by member countries. Another significant contributor to the assessment of risk and establishment of industrial hygiene standards in the United States is the American Conference of Governmental Industrial Hygienists (ACGIH), which is not a government agency but rather a professional society that publishes recommendations for exposures to various hazardous agents to workers.

It is important to emphasize that most hearing loss is preventable. Prevention can be achieved by eliminating noise sources, substituting quieter equipment, installing appropriate engineering controls, implementing administrative controls, using personal protective equipment, and adopting effective hearing-conservation programs. Regulations in many parts of the world require noise-control and hearing-conservation programs. Many of these regulations were recently updated to reflect new information regarding the levels of noise that can cause hearing loss. This has resulted in reduced permissible exposure levels and enhanced requirements to conduct risk assessments and implement control measures.

DEFINITIONS

Action level (AL)—The level, established by regulation, at which action must be taken to protect the hearing of workers exposed to noise. The action required is country-specific.

- **Action level** (MSHA)—The 8-hour time-weighted average sound level (TWA_8) sound level of 85 dBA, or equivalently a dose of 50%, integrating all sound levels from 80 to ≥130 dBA (A-weighted). (Note: An A-weighted setting measures sound similarly to the way the human ear responds to sound. A C-weighted setting measures sound in a flat or linear response.)
- **Lower exposure action value** (HSE)—The lower of the two levels of daily or weekly personal noise exposure or of peak sound pressure that, if reached or exceeded, requires specified action to be taken to reduce risk; that is, a daily or weekly personal noise exposure of 80 dBA.
- **Upper exposure action value** (HSE)—The higher of the two levels of daily or weekly personal noise exposure or of peak sound pressure that, if reached or exceeded, requires specified action to be taken to reduce risk; that is, a daily or weekly personal noise exposure of 85 dBA.

Criterion level—The sound level that, if constantly applied for 8 hours, results in a dose of 100% of that permitted by regulation.

dB—The unit of measure for sound pressure, defined in two ways:

1. For sound-pressure levels measured by sound level meter (SLM), the decibel is 20 times the common logarithm of the ratio of the measured sound pressure to the standard reference sound pressure of 20 μPa, which is the threshold of normal hearing sensitivity at 1,000 Hz.
2. For hearing-threshold levels measured by audiometer, the decibel is the difference between audiometric zero (reference pressure equal to 0 hearing-threshold level) and the threshold of hearing of the individual being tested at each test frequency.

Gary E. Walter, Principal Consultant, Primo Safety and Health Services, LLC, Wilmington, Delaware, USA

dBA—The level of noise, measured by SLM or dosimeter, A-weighted to represent the way the ear processes sound.

Dosimeter—A personal monitoring device that integrates noise exposure. Dosimeters must be set to match the criterion, threshold, and exchange rate established by the relevant regulation.

Exchange rate—The amount of increase in sound level, in decibels, that would require halving of the allowable exposure time to maintain the same noise dose. The MSHA and OSHA exchange rates are both 5 dB (which the American Industrial Hygiene Association recommends lowering to 3 dB). The EU and HSE exchange rates are both 3 dB. The ACGIH threshold-limit value (TLV) exchange rate is also 3 dB.

Noise dose—The integrated noise exposure that reaches a worker's ear, measured by personal noise dosimeter, including all sound that is >80 dBA. The permissible exposure limit or the recommended criteria is exceeded when this value is >100%.

Permissible exposure limit (PEL)—The noise-exposure limit that must not be exceeded, established by government regulation. The MSHA PEL is 90 dBA.

Sound level meter—An instrument designed to react to noise much as does the human ear in order to measure and compare against appropriate noise standards.

Threshold—The cutoff level of sound used to measure and calculate noise dose. Sound below this level is considered zero in noise–dose calculations.

Threshold-limit value (ceiling), or TLV—An exposure that should not be exceeded, even instantaneously.

Threshold-limit value (time-weighted average) for physical agents—The time-weighted average exposure for an 8-hour workday and a 40-hour workweek.

NOISE REGULATIONS AND EXPOSURE LIMITS

Noise-exposure regulations vary by country, resulting in the existence of differing exposure limits, measurement procedures, compliance activities, and required controls. In the United States, workplace noise-exposure standards are governed by MSHA and OSHA. Whether a mine operation is regulated by these two entities determines which regulations the operator must meet. Some operations may be covered by both agencies for different parts of the operation. In general, most mine operations are regulated by MSHA. Some states have additional noise regulations. Environmental or community noise requirements established by the U.S. Environmental Protection Agency or by state and local governments may also affect operations near residential or public areas. The MSHA (2006) regulation for noise in mines is in the Code of Federal Regulations (CFR) as Title 30, Part 62, *Occupational Noise Exposure*. For OSHA-covered operations, the OSHA (2004a, 2004b) regulations are in the CFR as Title 29, Part 1910.95, *Occupational Noise Exposure* and *Methods for Estimating the Adequacy of Hearing Protector Attenuation*.

The European Union adopted Directive 2003/10/EC, *Minimum Health and Safety Requirements Regarding the Exposure of Workers to the Risks Arising from Physical Agents (Noise),* for application throughout Europe. Each member country must adopt this directive at a minimum but may adopt more stringent regulations. An example of a country adopting more stringent regulations is the United Kingdom, where the HSE issued *Control of Noise at Work Regulations 2005*, which applies to all U.K. industry sectors, including mining.

The ACGIH has for longer than 50 years adopted TLVs for chemical substances and physical agents including noise (ACGIH 2006). ACGIH members are industrial hygienists or other occupational health and safety professionals dedicated to promoting workplace health and safety. The ACGIH publishes guidelines regarding safe levels of exposure to chemical and physical agents found in the workplace. In many parts of the world where no regulations exist, ACGIH TLVs have become the standard reference for the protection of worker health.

Although present-day international standards for measuring noise and hearing are generally in agreement, there is some difference of opinion regarding what level of noise adversely affects human health. As a result, there are different acceptable levels of allowable exposure for workers and some differences in the actual application for regulatory standards. The following are MSHA, EU, HSE, and ACGIH standards for TWA_8 exposure (MSHA 2006; EU 2003; HSE 2005; ACGIH 2009).

- MSHA standards
  - AL: 85 dBA (50% dose); all sound >80 dBA is included
  - PEL: 90 dBA (100% dose); only sound >90 dBA is included
  - Threshold: AL is 80 dBA; PEL is 90 dBA
  - Exchange (doubling) rate: 5 dBA
- EU and HSE standards
  - Lower AL: 80 dBA
  - Upper AL: 85 dBA
  - PEL: 87 dBA
  - Threshold: 80 dBA
  - Exchange (doubling) rate: 3 dBA
- ACGIH recommendations
  - TLV: 85 dBA
  - Threshold: 80 dBA
  - Exchange (doubling) rate: 3 dBA

Note: A modern personal noise dosimeter can record and calculate both AL and PEL levels.

Using the EU (HSE) upper AL limit of 85 dBA and exchange (doubling) rate of 3 dB as the reference for worker exposure, the amount of time permitted at various noise levels can be calculated by adding 3 dBA to the 85 dBA limit and cutting the time in half from the permitted 8 hours. Table 15.7-1 shows the amount of time at various noise levels that is equivalent to 85 dBA for the time shown.

Table 15.7-2 shows the same information when the MSHA limits are used as the reference for worker exposure. The times are different partly because ACGIH uses the more conservative 3-dB exchange (doubling) rate whereas the MSHA standard uses 5 dB. The data in these tables can be used to calculate worker noise exposure using the formula given in Equation 15.7-1.

INSTRUMENTATION AND SURVEY TECHNIQUES

Noise levels must be measured before any control measures are undertaken. It is important to document worker exposures in order to meet regulatory requirements and make informed decisions about implementing hearing-conservation programs for exposed workers. These measurements are the basis for most decisions regarding the application of engineering controls and assist in determining the most effective control measures. Measurement of worker exposures as part of a risk-assessment process can help prioritize the application of engineering controls so that the greatest number of affected employees can be protected through implementation

*At no time shall any excursion exceed 115 dBA. For any value, the reference duration T in hours is computed by $T = 8/2^{(L-90)/5}$ where L is the measured A-weighted, slow-response sound pressure level.

of engineered solutions or administrative or other control procedures. A good basic reference for understanding the measurement of noise is the *Handbook of Noise Measurement* (Peterson 1980).

Three types of instruments are used for measuring noise: the SLM, personal noise dosimeter, and octave band analyzer. Each has a specific purpose. Any instrument used for the measurement of noise must meet minimum standards to ensure accuracy. Figure 15.7-1 shows an SLM being used to measure noise levels near a haul truck. Figure 15.7-2 shows a miner wearing a newer personal noise dosimeter.

In the United States, SLMs must meet the standards set forth in American National Standards Institute (ANSI) S1.4-1983. Personal noise dosimeters must meet the standards set forth in ANSI S1.25-1991. In other parts of the world, international standard ISO 1999:1990 is the generally recognized standard for measurement of noise. In underground mines where explosive gases or atmospheres may be present,

Courtesy of Quest Technologies, a 3M company.
Figure 15.7-1 Sound level meter in use near a haul truck

electrical instruments must be rated intrinsically safe for use in explosive atmospheres. In the United States, MSHA maintains a list of permissible instruments and other equipment.

The SLM is the most commonly used instrument for identifying both stationary and mobile noise sources that may contribute to worker exposure. Most have both A-weighted and C-weighted settings. Readings are often used to assess machinery or community noise and to evaluate the attenuation of hearing protectors for use in high-noise environments.

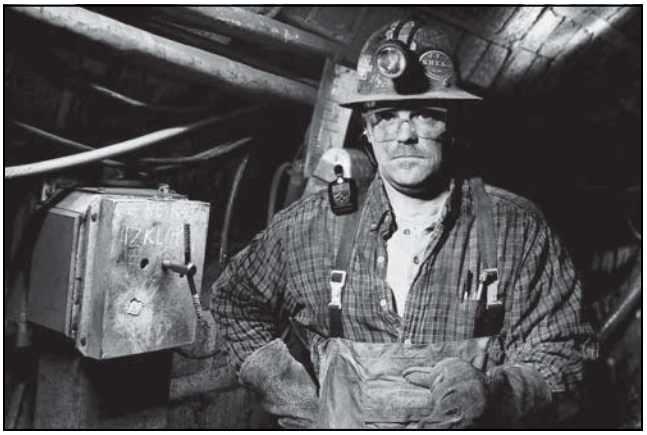
A basic noise survey conducted with an SLM helps identify potential noise sources, determine sound levels in areas where workers may be exposed, and determine whether workers may be exposed to hazardous levels of noise. The entire area should be surveyed to identify all stationary sources so these sources and associated noise levels can be documented on a mine map or other plan. Mobile equipment must be measured while in service. SLM readings can help identify potential sources that require additional monitoring, often with more sophisticated equipment.

Although the noise dose that a worker receives can be calculated using SLM readings, in practice this is difficult to do with sufficient accuracy to determine compliance with regulations or standards. To use SLM readings, a worker must be followed throughout the work period to identify each source of noise, measure each source's noise level, and determine how much time the worker is exposed to each noise source and level. The worker's noise exposure is

$$\text{dose } (\%) = 100(C_1/T_1 + C_2/T_2 \ldots C_n/T_n) \qquad (15.7\text{-}1)$$

where C is the total duration of noise exposure at a specific noise level and T is the total duration of noise exposure permitted at that level. If the sum of the fractions exceeds 100, then the combined exposure exceeds the PEL if comparing against a regulatory limit or the TLV if comparing against the ACGIH recommended limit.

The personal noise dosimeter overcomes some of the disadvantages of the SLM. It is worn by the worker throughout the day and records all sounds exceeding the regulatory or recommended limit. At the end of the work shift, the dosimeter gives a readout of the equivalent dose in dBA or percentage of allowed exposure. Most contemporary dosimeters have software for downloading the collected data for individual time periods recorded, often for periods as short as 1 minute. The data can be printed out in table or graph form. Comparison of this data with observations about the work performed throughout the day can reveal which tasks or noise sources contributed to the overall exposure, allowing prioritization of noise sources for further study or engineering control.



The octave band analyzer is a more sophisticated SLM. It is more accurate and has the asset of filters that measure noise at different frequencies. Table 15.7-3 lists the octave frequency bands that are commonly used for determining the frequency distribution of noise. Use of an octave band analyzer to obtain the frequency distribution of sound is important when designing engineering controls to reduce noise levels. As with other sound-measuring instruments, an octave band filter set and integrating SLM must meet specific standards (ANSI S1.43-1997 (R2002), ANSI S1.11-2004). Different frequencies may require different strategies for reducing worker exposure to noise. The information gained from this analyzer can also be used to calculate the protection factors of hearing-protective devices.

In general, noise surveys are of two types: (1) a health survey, to determine whether workers are exposed to noise levels above regulatory or recommended limits; and (2) an engineering survey, to identify sources of noise that contribute to worker exposure.

Health surveys, as noted previously, can be accomplished using either an SLM or a personal noise dosimeter. In conducting a health survey, it is important to ensure that an adequate number of workers are sampled so as to obtain a representative assessment of noise exposure. The best approach is to divide workers into homogeneous exposure groups (HEGs), each containing workers assigned similar tasks and thus expected to experience similar levels of exposure to noise. In deciding which workers to include in each HEG, the following must be considered: fluctuations in noise level, fluctuations due to working activities (variations in operating conditions, shutdowns, productions schedules), and variations in task performance among workers.

A number of samples for the same worker or multiple workers performing the same tasks over several different work periods is usually necessary to ensure that worker exposure is correctly measured. The number of samples required is based on statistical evaluation of the HEG and the variability of the noise levels. Six measurements for each HEG should be considered the minimum for a representative and statistically significant assessment. Samples should be as close to full-shift as possible and distributed over different days and shifts.

Software tools are available that can assist in obtaining statistically valid samples. After basic screening has been performed and potential workers and tasks that may be above regulatory or recommended limits have been identified, such tools can help determine whether the data is sufficient to determine compliance and the need for engineering controls. If in doubt, a competent, trained individual can be consulted to assist in the evaluation of worker exposure.

Engineering surveys can be accomplished using an SLM or an octave band analyzer. The latter identifies specific frequencies that contribute to the total noise arising from individual noise sources. The engineering control solution often depends on the frequencies measured. Materials specified for controlling noise at the source must be matched to the frequency of the noise generated by the source.

It is important to remember that the decibel scale is logarithmic, so one cannot simply add decibel values when combining values from multiple noise sources. Two noises of exactly the same level, measured independently of one another, have a combined noise level that is 3 dBA higher than the individual values. The greater the difference between two individual noise sources, the lower the combined noise level.

Table 15.7-4 shows a simple way to determine combined noise levels. If more than two sources contribute to the overall noise level, then this process should be repeated iteratively to calculate the combined noise level. The *OSHA Technical Manual* (1999) contains a good description of this technique. When dealing with multiple noise sources, the best approach is to determine which source generates the most noise, and this source should be the first priority in deciding where to apply engineering controls.

Table 15.7-4 Adding decibels for two noise sources (in decibels)

Difference in dB Values	Add to Higher Level
0–1	3
2–3	2
4–9	1
≥10	0

Whether a survey is for health or engineering purposes, it is essential to document survey results so that one can understand the sources of noise and ensure that data conforms to regulatory requirements. Documentation must be kept in a form suitable for comparison with future survey results. Such comparisons are useful in evaluating engineering controls and equipment performance over time. In survey documentation, the following information should be recorded:

- Date and time
- Instrumentation details (model, serial number, settings, calibration)
- Workplace descriptions
- Task descriptions
- Unusual conditions

BASIC NOISE-CONTROL CONCEPTS

Noise control is complicated at best. The preferred method for reducing noise is to control it at the source so that it does not create an exposure hazard for workers. Mining operations present difficult challenges for the application of engineering controls, including underground equipment operation, special considerations for environment/climate, and type and age of equipment.

When obtaining new or replacement equipment, appropriate language must be included in the contract or purchase order ensuring that the purchased equipment will generate the lowest noise level that is technically feasible. Obtaining new equipment with noise-control features included reduces the need to retrofit controls in the work environment. The manufacturer is in the best position to reduce noise at the source by means of improved design and integration of noise controls.

As most mining equipment has a relatively long service life, noise controls may need to be added to current equipment to reduce exposure risk. Three basic types of control can be considered:

1. Substitution
2. Modification of the noise source
3. Modification of the sound wave

Substitution is a long-term effort to replace existing equipment or processes with alternatives that generate less noise. Although substitution may ultimately reduce noise levels, replacement schedules for most equipment in mining operations are too long to accommodate near-term improvements. Substitution should always be considered, but the need to protect workers and meet regulations means that alternative controls must be implemented sooner.

Modification of the noise source usually involves changing the way equipment works so as to reduce noise levels. Although some changes can be made to mobile equipment, changes may be more effective when made to stationary equipment such as screening and crushing equipment, motors, pumps, dryers, and air compressors. Typical control measures for stationary equipment include installation of isolation dampers and vibration-damping materials for vibrating equipment or surfaces, and use of exhaust mufflers and rerouting of intake/exhaust points on pneumatic equipment. Additional measures include improved bracing, increased stiffness, or application of damping materials to vibrating surfaces.

Modification of the sound wave is frequently the easiest method to implement. This can be accomplished by confining sound waves in acoustical enclosures, absorbing sound waves within a room or space, and absorbing sound along its transmission path. Effective enclosure design involves many factors, including the following:

- Selection of construction materials for the enclosure wall
- Selection of acoustical linings based on the frequency distribution of the noise
- Sealing of enclosure joints
- Mounting of the enclosure so as to minimize vibration
- Addition of access panels (doors) for maintenance and other operational needs
- Consideration of the effect that the enclosure design will have on the operating equipment
- Ventilation by means of inlets/outlets designed to prevent the escape of noise

It is important to focus on controlling the frequencies that most adversely affect human hearing in the speech range. Those frequencies are 500, 1,000, 2,000, 3,000, 4,000, and 6,000 Hz. The higher frequencies are usually easier to control.

If full enclosure is not possible, partial enclosures, noise barriers, or shields that separate the noise from the worker should be considered to reduce noise levels. Barriers are most effective for high- or medium-frequency noise. Barriers should be as high as practical and as close to the noise source as possible.

Ventilation ducts and conveyor systems can be important transmitters of noise. Ducts can be lined to attenuate sound traveling through them. Similarly, noise in conveyor systems can be attenuated by selection of appropriate lining materials or application of vibration-damping materials.

In addition to enclosing the noise source, it is also possible to reduce worker exposure to noise by enclosing the worker. This option is particularly effective for mobile-equipment operators. Many manufacturers offer original-equipment enclosures that reduce noise as well as minimize exposure to airborne contaminants and temperature extremes. Enclosed sound-reducing stationary-equipment control rooms can minimize worker exposure to noise at fixed locations. These enclosures can also serve as quiet areas where other workers can gain relief from noise during their work shifts.

It is important to consider the flammability of materials selected for engineering controls in mining operations. In the United States, MSHA references ASTM International's ASTM E162-87 in its regulations for product flammability in underground mines. Understanding the flammability of acoustical materials selected is particularly important where burning, welding, or other hot work is done in the vicinity of the selected materials.

More specific information regarding the design and construction of noise controls in mining is available from a variety of sources. In the United States, MSHA has a number of publications providing detailed guidance on applying engineering controls in mining operations (MSHA 1999a, 1999b, 1999c), many of which are available on the MSHA Web site at www.msha.gov. The U.S. National Institute for Occupational Safety

and Health (NIOSH) has specific programs for mining that are available on their Web site at www.cdc.gov/niosh/mining, including an area devoted to noise. The U.K. HSE lists case studies and sound solutions on their Web site at www.hse.gov.uk. Other countries may have similar information available. These resources can provide up-to-date information concerning control of noise in the mining industry.

Administrative controls are changes in work schedule or operations that reduce worker exposure to noise. Administrative controls should be used as adjuncts to—and not in lieu of—engineering controls. They may also have a place in minimizing worker exposure to noise while engineering controls are being designed and installed. As noise dose is a function of both noise level and duration of exposure, work can be organized into tasks that involve worker exposure to noise for only limited amounts of time during the work shift such that the noise dose remains below the regulatory or recommended limit. The balance of the work shift would include tasks where the noise is below the level that would contribute to the overall noise dose. Such rotational work schedules must be carefully designed so that worker exposures remain below acceptable levels. Other administrative controls could include remote operation of equipment or provision of quiet areas where employees can gain relief from noise. Improved maintenance of equipment and engineering controls can help to keep noise levels at the lowest level. In practice, however, administrative controls are of limited use because workers may not be allowed or able to switch among jobs, or work schedules can become too complicated to manage.

VIBRATION

Minimizing vibration, especially induced vibration, can contribute significantly to noise reduction. Many sources of noise that affect worker hearing are related to the vibration of equipment or surfaces. Vibration can be caused by a number of types of action, including rotation and reciprocation of devices. Examples of devices that tend to vibrate include compressors, pumps, fans, electric motors, pulleys, transfer belts, bin surfaces, gasoline and diesel engines, screening devices, and many more too numerous to mention. Vibration can result directly when rotating-equipment parts are unbalanced, misaligned, loose, or eccentric, or indirectly when induced in another piece of equipment.

The measurement and control of vibration serves two purposes: (1) prevention of premature wear and failure due to structural damage; and (2) reduction of noise levels. Measurement of vibration requires specialized equipment and experience in data interpretation. Many preventive-maintenance programs make use of vibration analysis to predict maintenance scheduling and equipment replacement.

Health effects beyond those related to hearing are also related to vibration. These additional effects are broadly considered to be ergonomics or human-factors issues related to whole-body vibration from activities such as operating mobile or stationary equipment. Both acute and chronic effects are of concern. Possible acute effects include loss of control of vibrating equipment due to mechanically induced decoupling from the hand. Possible chronic effects relate to the link between whole-body vibration and musculoskeletal problems including back pain and degenerative spinal disk disease.

The ACGIH, in its TLV recommendations and documentation, includes a TLV for whole-body vibration (ACGIH 2001). Whole-body vibration hazards and controls are not covered in this chapter but should be considered when vibration related to noise control is evaluated.

Vibration is controlled principally by reducing the mechanical disturbance that causes the vibration, isolating the disturbance from a radiating surface, and reducing the response of the radiating surface by applying damping or stiffening materials. Techniques such as balancing rotating equipment and installing isolation dampers may be obvious from initial evaluation. Increased maintenance to ensure that all equipment operates as designed and to observe early changes that may indicate increased vibration can help minimize vibration. Vibration control can be an iterative process involving incremental improvements as vibrating components are identified and managed.

PERSONAL PROTECTION

Even with the design and installation of engineering controls in mining operations, workers are still likely to be exposed to levels of noise that exceed regulatory or recommended limits. Even at levels below regulatory limits, noise-induced hearing loss can still occur. Most noise regulations established in recent years incorporate the concept of an action level. An action level is lower than the regulatory limit allowed for work-shift exposure, but still at a level where some hearing loss can occur. At this level, most regulations require that a number of measures be taken to monitor worker hearing and ensure that additional protective measures are implemented.

Most government regulations regarding noise in the workplace now require implementation of hearing-conservation programs for workers exposed above the action level. A hearing-conservation program should contain the following elements:

- Periodic assessment of worker exposure to noise (risk assessment)
- Health surveillance including audiometric testing
- Training
- Hearing protection

Periodic assessment of worker exposure to noise provides information about the continued effectiveness of installed engineering controls. Engineering controls over time may become damaged or require other maintenance to retain maximum effectiveness. Exposure data taken over time can also reveal changes in equipment noise levels caused by wear and tear. Continued compliance with regulatory or recommended exposure limits can be confirmed through periodic monitoring, and corrective actions can be taken as necessary. Worker use of engineering controls and hearing protection can be reinforced during periodic exposure assessments.

Health surveillance of workers exposed to high noise levels can identify workers with early signs of hearing loss so that further preventive measures can be taken. Usually health surveillance is conducted under the guidance of a physician who ensures that worker hearing is tested using approved audiometric test equipment and procedures and that test results are compared to normal hearing levels. If hearing loss is detected, additional testing can be undertaken and a specialist can be consulted to confirm the test results. If hearing loss is confirmed, the risk assessment should be reviewed and appropriate intervention taken for workers with confirmed hearing loss. The assessment should also explore whether workers have significant exposure to noise from activities outside of their employment.

Training, instruction, and information are key components to a successful hearing-conservation program. Most workers who understand the risks will take precautionary measures designed to prevent hearing loss. Information on the following subjects should be covered at a level at which the workers can understand:

- Nature of the hazards from exposure to noise
- Exposure limits compared to the exposure levels measured
- Risk assessment results
- Engineering controls in place
- Health surveillance program, including audiometric testing
- Purpose and value of wearing hearing protectors
- Types of hearing protection provided
- Government regulations as required

Computer software simulators have recently demonstrated the effects of noise-induced hearing loss. Use of these tools in training efforts can clearly demonstrate the effects of overexposure to noise. NIOSH has developed a hearing-loss simulator called HLSim, available from their Web site at www.cdc.gov/niosh/mining/products. The simulator demonstrates normal hearing and presents examples showing the effect of hearing loss on the ability to understand speech.

Hearing protection is critical for the prevention of worker hearing loss and is the last defense against the risks of noise. However, when properly selected and worn, hearing protectors are very effective in preventing hearing loss. Various types of protector are widely available, including ear plugs, ear caps, and ear muffs. The appropriate type for a particular situation depends on the level and frequency of noise measured during the risk assessment. In rare cases, double protection may be required. In the United States, MSHA has established a dual hearing-protection level of 105 dBA or greater for an 8-hour work shift. If necessary, a combination of ear plugs and ear muffs can provide added protection for very high noise exposure. Training programs should cover the various types of protector selected, the effectiveness of each type, and how to wear the protector properly.

Most hearing protectors have a noise-reduction rating (NRR) that indicates relative effectiveness. The NRR must be used with adjustment to compensate for variations in actual use. Several methods exist for calculating the adequacy of a protector. The easiest is to start with the NRR for a specific protector and calculate the attenuation value according to an approved method. NIOSH has published three methods for determining protector adequacy that vary by type of noise measurement data used (NIOSH 1975). OSHA has published a modified method for calculating adequacy based on the NRR value (OSHA 2004a, 2004b). Any of these methods can help ensure that the noise reaching the worker's ear has been reduced to protective levels.

SUMMARY

Noise exposure in mining operations remains a hazard, and continued diligence is required to protect worker hearing. Regulations to reduce the acceptable levels of exposure permitted for workers require the use of the following hierarchy of controls to reduce risk:

- Elimination
- Substitution
- Engineering controls
- Administrative controls
- Personal protective equipment

The controls at the top of this list are potentially more effective and protective than those at the bottom of the list, and result in the implementation of inherently safer systems that depend less on individual action. Thus, in the design of new processes and equipment, elimination and substitution, although the most difficult to implement, have the best chance for success. Administrative controls and personal protective equipment should be reserved for existing situations while engineering controls designed to remove the hazard are investigated and installed. If engineering controls do not reduce risk to acceptable levels, administrative controls and personal protective equipment may, by default, become long-term solutions.

The engineer plays an important role in the design and installation of engineering controls to reduce noise levels as much as reasonably achievable with the ultimate goal of eliminating noise as a risk in the work environment. There is broad recognition that this goal can be difficult to achieve. Understanding the risks of noise exposure and the importance of designing equipment and processes to minimize noise can help protect workers and minimize risk.

PART 16

Environmental Issues

CHAPTER 16.1

Site Environmental Considerations

Michael G. Nelson

INTRODUCTION

Activities associated with mining have direct and lasting effects on both the physical and the human environments. The social, economic, and political effects in the latter category are often considered sustainability issues and are discussed briefly in this chapter. Also in the latter category are issues of worker health and safety, which are discussed in Part 15 of this handbook.

Mining includes the following activities, all of which have distinct impacts on the environment:

- **Exploration.** Economic deposits are identified and their characteristics are determined to allow recovery.
- **Development.** Preparations are made for mining.
- **Extraction.** Valuable material is removed for sale or processing.
- **Reclamation.** Disturbances caused by any of the preceding activities are corrected or ameliorated.
- **Closure.** Activity ceases and the area is abandoned or returned to another use.

This chapter will address the environmental considerations incumbent in the development and extraction in some detail, including the permitting process required (in almost all jurisdictions) before mining activities begin.

Environmental regulations vary among the countries of the world. Most large mining companies endeavor to follow uniform practices at all their mines, regardless of location, and have publicly committed to follow well-articulated standards of sustainability, such as those described under "Sustainable Practices" in this chapter. However, because of the variations in regulations, it is difficult to give a detailed description of environmental requirements and practices that applies worldwide. Thus, the focus of this chapter is to give a general description of environmentally sound practices and procedures. Some of the most important are illustrated by specific examples. The first example shows the approach to environmental risk assessment taken by CODELCO (Corporación Nacional del Cobre de Chile), the national copper corporation of Chile, as part of its environmental management plan under the International Organization for Standardization (ISO) Standard 14001. The second example gives a description of surface coal mining regulations in the United States, probably some of the most detailed and specific regulations in existence. The third example describes the permitting and approval process for the Safford mine, located in a historic mining area in southern Arizona (United States), and includes descriptions of the public input to this process. The fourth example describes a successful approach to early involvement of local communities in mine planning and permitting at the Diavik diamond mine, which operates in a pristine northern environment where no mining had previously occurred.

HISTORIC MINING PRACTICES

In the recent past, mining was done with little knowledge of its effects on the environment and, from a modern perspective, with little concern for the effects that were known. The consequences of this approach often resulted in significant damage to the natural environment, including (but not limited to)

- Unreclaimed mine pits, shafts, tunnels, and waste piles that may result in landslides and large amounts of blowing dust;
- Surface and groundwater that may be contaminated by solid particulates and chemical contaminants released by active and abandoned workings, or by waste piles;
- Abandoned pits, shafts, and tunnels that may create potential falling hazards to humans, livestock, and wildlife;
- Similarly, release of particulates and chemical contaminants from mine workings or waste and spoil piles that may cause direct injury to or damage the health of humans or animals;
- Erosion, with its consequent loss of soil and vegetation in and around unreclaimed workings, that may be a significant problem; and
- Underground workings, current or abandoned, that may cause surface subsidence, which can result in damaged surface structures, and in fissures or escarpments that are hazardous to humans and animals (Craig et al. 2001).

Examples of these kinds of mining-induced damages are readily found in any historic mining district. In fact, water

Michael G. Nelson, Department Chair, Mining Engineering, College of Mines & Earth Sciences, University of Utah, Salt Lake City, Utah, USA

contamination and abandoned waste piles left by ancient Roman mining activity in Spain resulted in rediscovery of the ore body on which Rio Tinto, one of the largest mining companies in the world, was founded (Raymond 1986).

In most cases, the environmental damage caused by mining was not well understood. There were some notable exceptions, such as the lawsuit in 1884 by downstream farmers against mining companies in California's "Mother Lode" district. By that time (well after the initial gold rush of 1849) those companies used a method called hydraulicking, in which entire hillsides were washed away with a powerful stream of water so the gold-bearing gravels could be processed. The resulting debris clogged streams and rivers and flooded meadows and fields, causing serious damage to agriculture (Hill et al. 2001). Other early environmental lawsuits related to the mining industry were directed at smelter operators by farmers who alleged that smelter gases were damaging their crops. Such suits were filed in England in 1865 (Brubaker 1995), and in the United States in Kansas in the 1880s (Junge and Bean 2006) and in Utah in 1903 (Lamborn and Peterson 1985). While these lawsuits may have been driven more by economic concerns than by a pure concern for the environment in the abstract, they certainly addressed what today would be considered environmental issues.

The public's expectations of the mining industry began to change in the 1950s, and by the end of the 1970s, governments in developed countries had enacted broad environmental laws that had direct bearing on all industrial activities, including mining (Kaas and Parr 1992). Although environmental standards still vary among countries, almost all major mining companies now state as policy that they will operate all their mines, regardless of location, to first-world standards of environmental protection and worker health and safety.

SUSTAINABLE PRACTICES

Leading mining companies have recently formulated, and pledged to follow, standards and principles for sustainable development of mineral resources worldwide. While not all of these principles relate directly to environmental practices, they represent a significant change in approach for the mining industry as a whole, a change that has already affected environmental practices in the industry. For that reason, the principles of sustainable development (as applied to mineral extraction) are discussed here.

In 1999, nine of the largest mining companies decided to embark on a new initiative intended to achieve a serious change in the way industry approached today's problems. They called this the Global Mining Initiative. It included a program of internal reform, a review of the various associations the companies belonged to, and a rigorous study of the societal issues they had to face. As a result, the International Institute for Environment and Development was commissioned to undertake the Mining, Minerals and Sustainable Development (MMSD) project.

Between 2000 and 2002, the MMSD project identified critical issues associated with development of mineral resources in four "spheres":

Economic sphere

- Maximize human well-being.
- Ensure efficient use of all resources, natural and otherwise, by maximizing rents.
- Seek to identify and internalize environmental and social costs.
- Maintain and enhance the conditions for viable enterprise.

Social sphere

- Ensure a fair distribution of the costs and benefits of development for all those alive today.
- Respect and reinforce the fundamental rights of human beings, including civil and political liberties, cultural autonomy, social and economic freedoms, and personal security.
- Seek to sustain improvements over time; ensure that depletion of natural resources will not deprive future generations through replacement with other forms of capital.

Environmental sphere

- Promote responsible stewardship of natural resources and the environment, including remediation of past damage.
- Minimize waste and environmental damage along the whole of the supply chain.
- Exercise prudence where impacts are unknown or uncertain.
- Operate within ecological limits and protect critical natural capital.

Governance sphere

- Support representative democracy, including participatory decision making.
- Encourage free enterprise within a system of clear and fair rules and incentives.
- Avoid excessive concentration of power through appropriate checks and balances.
- Ensure transparency through providing all stakeholders with access to relevant and accurate information.
- Ensure accountability for decisions and actions, which are based on comprehensive and reliable analysis.
- Encourage cooperation in order to build trust and shared goals and values.
- Ensure that decisions are made at the appropriate level, adhering to the principle of subsidiarity where possible.

In 2001, the board of the metals industry's representative organization, the International Council on Metals and the Environment agreed to broaden the group's mandate and transform itself into the International Council on Mining and Metals (ICMM).

In 2002, ICMM member companies signed the Toronto Declaration committing ICMM to continue the work started by the MMSD project and engage in constructive dialogue with key stakeholders, and in 2003, the International Council on Mining and Metals committed corporate members to implement and measure their performance against the ten principles shown in Table 16.1-1 (ICMM 2006).

Initially there was considerable debate in the mining community regarding the concepts of sustainability as applied to mineral extraction (NWMA 2002). Some argued that, because mineral resources are by nature finite, mineral extraction can never be truly sustainable. However, these concepts have in general been adopted by most of the mining industry, and they influence corporate practices in all areas of mining activity.

Table 16.1-1 ICMM's ten principles

1. **Implement and maintain ethical business practices and sound systems of corporate governance.**
   - Develop and implement company statements of ethical business principles, and practices that management is committed to enforcing.
   - Implement policies and practices that seek to prevent bribery and corruption.
   - Comply with or exceed the requirements of host-country laws and regulations.
   - Work with governments, industry and other stakeholders to achieve appropriate and effective public policy, laws, regulations and procedures that facilitate the mining, minerals and metals sector's contribution to sustainable development within national sustainable development strategies.
2. **Integrate sustainable development considerations within the corporate decision-making process.**
   - Integrate sustainable development principles into company policies and practices.
   - Plan, design, operate and close operations in a manner that enhances sustainable development.
   - Implement good practice and innovate to improve social, environmental and economic performance while enhancing shareholder value.
   - Encourage customers, business partners and suppliers of goods and services to adopt principles and practices that are comparable to our own.
   - Provide sustainable development training to ensure adequate competency at all levels among our own employees and those of contractors.
   - Support public policies and practices that foster open and competitive markets.
3. **Uphold fundamental human rights and respect cultures, customs and values in dealings with employees and others who are affected by our activities.**
   - Ensure fair remuneration and work conditions for all employees and do not use forced, compulsory or child labor.
   - Provide for the constructive engagement of employees on matters of mutual concern.
   - Implement policies and practices designed to eliminate harassment and unfair discrimination in all aspects of our activities.
   - Ensure that all relevant staff, including security personnel, are provided with appropriate cultural and human rights training and guidance.
   - Minimize involuntary resettlement, and compensate fairly for adverse effects on the community where they cannot be avoided.
   - Respect the culture and heritage of local communities, including indigenous peoples.
4. **Implement risk management strategies based on valid data and sound science.**
   - Consult with interested and affected parties in the identification, assessment and management of all significant social, health, safety, environmental and economic impacts associated with our activities.
   - Ensure regular review and updating of risk management systems.
   - Inform potentially affected parties of significant risks from mining, minerals and metals operations and of the measures that will be taken to manage the potential risks effectively.
   - Develop, maintain and test effective emergency response procedures in collaboration with potentially affected parties.
5. **Seek continual improvement of our health and safety performance.**
   - Implement a management system focused on continual improvement of all aspects of operations that could have a significant impact on the health and safety of our own employees, those of contractors and the communities where we operate.
   - Take all practical and reasonable measures to eliminate workplace fatalities, injuries and diseases among our own employees and those of contractors.
   - Provide all employees with health and safety training, and require employees of contractors to have undergone such training.
   - Implement regular health surveillance and risk-based monitoring of employees.
   - Rehabilitate and reintegrate employees into operations following illness or injury, where feasible.
6. **Seek continual improvement of our environmental performance.**
   - Assess the positive and negative, the direct and indirect, and the cumulative environmental impacts of new projects—from exploration through closure.
   - Implement an environmental management system focused on continual improvement to review, prevent, mitigate or ameliorate adverse environmental impacts.
   - Rehabilitate land disturbed or occupied by operations in accordance with appropriate post-mining land uses.
   - Provide for safe storage and disposal of residual wastes and process residues.
   - Design and plan all operations so that adequate resources are available to meet the closure requirements of all operations.
7. **Contribute to conservation of biodiversity and integrated approaches to land use planning.**
   - Respect legally designated protected areas.
   - Disseminate scientific data on and promote practices and experiences in biodiversity assessment and management.
   - Support the development and implementation of scientifically sound, inclusive and transparent procedures for integrated approaches to land use planning, biodiversity, conservation and mining.
8. **Facilitate and encourage responsible product design, use, reuse, recycling and disposal of our products.**
   - Advance understanding of the properties of metals and minerals and their life-cycle effects on human health and the environment.
   - Conduct or support research and innovation that promotes the use of products and technologies that are safe and efficient in their use of energy, natural resources and other materials.
   - Develop and promote the concept of integrated materials management throughout the metals and minerals value chain.
   - Provide regulators and other stakeholders with scientifically sound data and analysis regarding our products and operations as a basis for regulatory decisions.
   - Support the development of scientifically sound policies, regulations, product standards and material choice decisions that encourage the safe use of mineral and metal products.
9. **Contribute to the social, economic and institutional development of the communities in which we operate.**
   - Engage at the earliest practical stage with likely affected parties to discuss and respond to issues and conflicts concerning the management of social impacts.
   - Ensure that appropriate systems are in place for ongoing interaction with affected parties, making sure that minorities and other marginalized groups have equitable and culturally appropriate means of engagement.
   - Contribute to community development from project development through closure in collaboration with host communities and their representatives.
   - Encourage partnerships with governments and non-governmental organizations to ensure that programs (such as community health, education, local business development) are well designed and effectively delivered.
   - Enhance social and economic development by seeking opportunities to address poverty.
10. **Implement effective and transparent engagement, communication and independently verified reporting arrangements with our stakeholders.**
    - Report on our economic, social and environmental performance and contribution to sustainable development.
    - Provide information that is timely, accurate and relevant.
    - Engage with and respond to stakeholders through open consultation processes.

Table 16.1-2 ISO 14001 standards

Systemic requirements
- a. Establish, document, implement, maintain, and continually improve an environmental management system in accordance with the standard.

Policy requirements
- a. Establish, define, document, implement, maintain, and communicate the organization's environmental policy.

Planning requirements
- a. Establish, implement, document, and maintain procedures to identify the environmental aspects of all activities, products, and services.
- b. Establish, implement, and maintain procedures to identify and clarify the legal and other requirements that apply to the organization's environmental aspects.
- c. Establish, implement, and maintain environmental objectives and targets.
- d. Establish, implement, and maintain programs to achieve environmental objectives and targets.

Operational requirements
- a. Personnel and resources
  - i. Provide the resources needed to establish, implement, maintain, and improve the environmental management system.
  - ii. Define, document, and communicate environmental management roles, responsibilities, and authorities.
  - iii. Appoint someone to assume the role of management representative.
- b. Training
  - i. Ensure competency of those who perform tasks that could have a significant environmental impact by identifying training needs, delivering training programs, and maintaining records of training activities.
  - ii. Establish, implement, and maintain a procedure to make people aware of the organization's environmental management system.
- c. Communication
  - i. Establish, implement, and maintain procedures to control the organization's internal and external environmental communications.
  - ii. Document the organization's environmental policy, objectives, and targets, and the main parts of its environmental management system.
  - iii. Describe how the parts of the organization's environmental management system interact.
- d. Documents
  - i. Control all environmental management documents and records required by the ISO 14001:2004 standard.
  - ii. Establish, document, implement, and maintain procedures to manage and control operational situations that could have significant environmental impacts.
  - iii. Establish, document, implement, and maintain procedures to control significant environmental aspects of goods and services provided by suppliers and contractors.
- e. Emergency situations
  - i. Establish, implement, and maintain procedures for potential emergency situations and accidents that could have an impact on the environment.
  - ii. Establish, implement, and maintain procedures to respond to actual emergency situations and accidents that have an impact on the environment.
  - iii. Test environmental emergency response procedures.
  - iv. Respond to actual environmental emergencies and accidents.
  - v. Prevent or mitigate the adverse environmental impacts that emergencies and accidents can and do cause.
  - vi. Review and revise environmental emergency preparedness and response procedures.

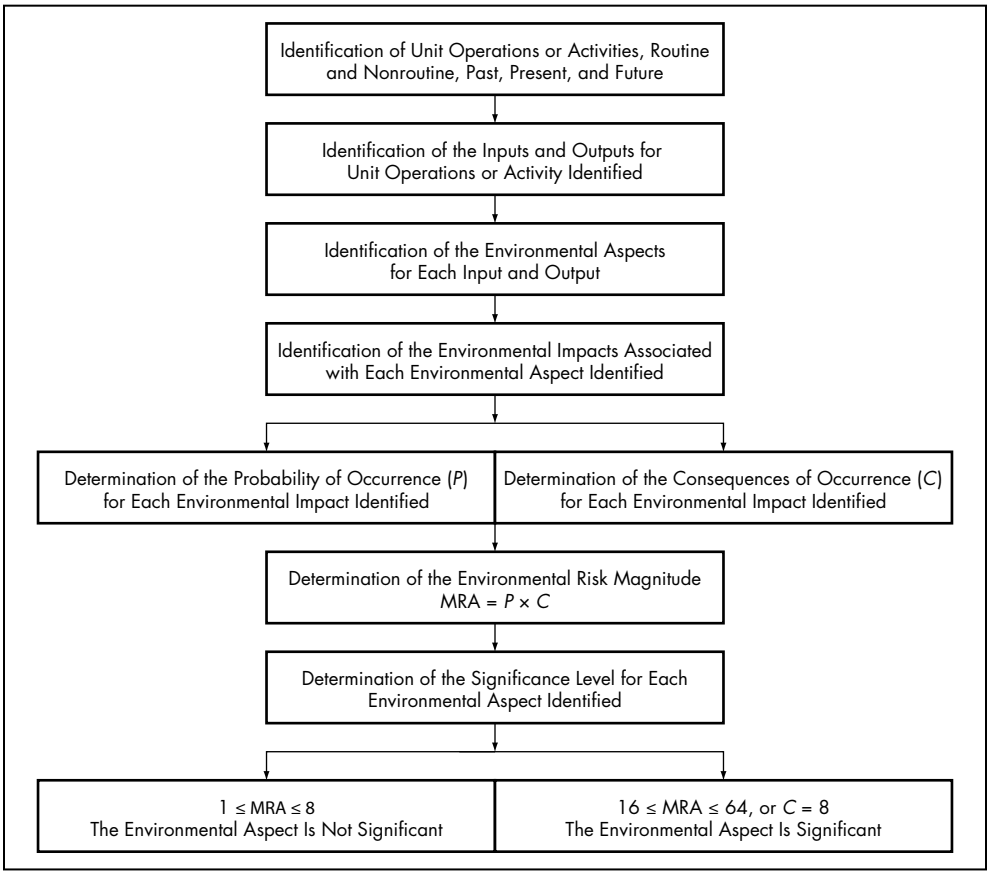
Compliance requirements
- a. Measurement and monitoring
  - i. Establish, implement, and maintain procedures to monitor and measure the operational characteristics that could have a significant impact on the environment.
  - ii. Use and maintain calibrated or verified environmental monitoring and measuring equipment.
  - iii. Keep a record of environmental monitoring and measuring activities.
- b. Documentation
  - i. Establish, implement, and maintain a procedure to periodically evaluate how well the organization complies with all relevant legal and other environmental requirements.
  - ii. Record the results of the organization's legal and other environmental compliance evaluations.
- c. Dealing with nonconformities
  - i. Establish, implement, and maintain nonconformance management procedures.
  - ii. Change documents when nonconformities make it necessary.
- d. Controlling records
  - i. Establish environmental records for the organization.
  - ii. Establish, implement, and maintain procedures to control the organization's environmental records.
- e. Internal audits
  - i. Establish, implement, and maintain an environmental management audit program and procedures.
  - ii. Conduct internal audits of environmental management system.
  - iii. Report internal audit results to management.
- f. Environmental management reviews.
  - i. Review the suitability, adequacy, and effectiveness of the environmental management system.
  - ii. Assess whether or not the organization's environmental management system, policy, objectives, or targets should be changed.
  - iii. Keep a record of all environmental reviews.

ENVIRONMENTAL MANAGEMENT SYSTEMS

ISO 14001, issued in 2004, provides standards by which a community or organization may put in place and implement a series of practices and procedures that, when taken together, result in an environmental management system (EMS).

An EMS is one part of an organization's larger management system. The EMS is used to establish an environmental policy and to manage the environmental aspects of the organization's activities, products, and services. A management system is a network of interrelated elements that include responsibilities, authorities, relationships, functions, processes, procedures, practices, and resources. A management system uses these elements to establish policies and objectives and to develop ways of applying these policies and achieving these objectives.

ISO 14001 is a detailed document comprising many pages. It describes systemic, policy, planning, operational, and compliance requirements. Table 16.1-2 outlines those requirements.



ISO 14001 is not a technical standard and thus does not in any way replace technical requirements embodied in statutes or regulations. It also does not set prescribed standards of performance for organizations. However, ISO certification or equivalent has become a critical component to acceptance by environmental agencies, nongovernmental organizations, and funding organizations.

The following example shows how a large mining company (CODELCO) complies with part of ISO 14001.

Example 1. Identification and Evaluation of Environmental Consequences

CODELCO adopted a sustainable development policy in June 2003 (CODELCO 2009). In December 2006, the company issued the Corporate Directive for Identification of Environmental Aspects and Evaluation of the Risk of Their Impacts (CODELCO 2006), providing a detailed and systematic method for assessing environmental risk, which is applied to all projects and activities in the corporation. The directive includes the following steps:

1. Identification of unit operations or activities, routine and nonroutine, past, present, and future.

Courtesy of CODELCO.

Figure 16.1-1 Process for identifying significant environmental aspects

2. Identification of all the inputs and outputs for each unit operation or identified activity.
3. Identification of the environmental aspects associated with the inputs and outputs of each unit operation or identified activity.
4. Identification of the potential associated environmental impacts of each identified environmental aspect.
5. Evaluation of the environmental risk, as determined by the probability of occurrence of each potential identified impact, as a function of its frequency, and the consequences of that impact on the environment, as a function of its reversibility and extent.
6. Determination of the magnitude of environmental risk (MRA, for the Spanish *magnitud del riesgo ambiental*), according to the probability and consequences, for each potential impact identified.
7. Determination of the degree of significance of each environmental aspect, according to the value of the MRA for that aspect.

The directive follows ISO 14001:2004 and distinguishes between environmental aspects and environmental impacts. An environmental aspect is an element of the activities, products, or services of one organization that can interact with the environment; environmental impact is any change in the environment, whether adverse or beneficial, wholly or partially resulting from environmental aspects of an organization.

The process begins with generation of the process map for each level in a given work center, using the environmental impacts as the main elements. This allows the direction of the process and any associated equipment to achieve common objectives aligned with the corporate standards. Here, the term *process* includes any activity of production, service, or administration and is defined as a sequence of activities that effect the transformation of certain inputs, with the use of certain resources, labor, goods, and services, to satisfy those who receive or use the process output. A process map is defined as a diagrammatic representation of a process in the abstract, showing connections among constituent activities and flows of material, energy, or information, and designed to facilitate understanding and analysis of the processes. Figure 16.1-1 shows a process map for the identification of significant environmental aspects.

In the identification of unit operations and activities, when there are areas or activities that are not defined within a specific organizational unit or may be subject to overlapping jurisdictions, the environmental management representative in charge of environmental affairs, together with the leaders of those areas or activities, define the allocation of responsibility for assessment of environmental risk.

In the identification of inputs and outputs, the responsible personnel examine each unit operation or activity (routine and nonroutine, past, present, and future). They identify all the inputs, including raw materials, resources, consumables, intermediate or recycled products, energy, services, and in general everything that the unit operation or activity receives from the preceding unit operation. Similarly, they identify all

Table 16.1-3 Evaluation criteria for the probability of occurrence of an environmental impact

	Criterion: Occurrence of the Impact, as a Function of Its Frequency	Value
Probability (*P*)	The impact always occurs in association with a given activity, or the impact happens often or frequently.	High (8)
	The impact is expected to occur sometimes, or the impact is known to have occurred on some occasions.	Medium (4)
	The impact is expected to occur on one occasion, or the impact is known to have occurred on one occasion.	Low (2)
	Occurrence of the impact is highly unlikely, or the impact has never occurred.	Negligible (1)

Courtesy of CODELCO.

Table 16.1-4 Evaluation criteria for consequences of the occurrence of an environmental impact

	Criterion: Description of the Impact Based on Its Reversibility and Extent	Value
Consequence (*C*)	The alteration of the original environmental conditions is considered irrecoverable, or the extension of the impact exceeds the limits for the area of direct and indirect influence of the project activity, or it significantly alters environmental conditions, and it cannot be attenuated.	High (8)
	The alteration of the original environmental conditions is considered to be 50%–90% recoverable, or the extent of the impact does not exceed the limit of the area of direct and indirect influence of the project of activity, or the impact significantly alters or has the potential to alter environmental conditions, but the effects can be mitigated by 50%–90%.	Medium (4)
	The alteration of the original environmental conditions is expected to be minor or transitory, or the possible alteration can, with appropriate control measures, be transitory or reduced to minor levels, or the environmental impacts occur only within the company property.	Low (2)
	The alterations in the original condition will not result in any noticeable changes to the environment, or it will be possible to minimize any alterations so they will be imperceptible, or controlled completely.	Negligible (1)

Courtesy of CODELCO.

Table 16.1-5 Values for environmental risk magnitude

		Consequences (*C*)			
	MRA	Negligible (1)	Low (2)	Medium (4)	High (8)
Probability (*P*)	Negligible (1)	1	2	4	8
	Low (2)	2	4	8	16
	Medium (4)	4	8	16	32
	High (8)	8	16	32	64

Courtesy of CODELCO.

Table 16.1-6 Significance criteria for environmental aspects

MRA = *P* × *C*	Classification of Environmental Impact	Significance of Environmental Aspect Leading to Environmental Impact
1–8	Insignificant	Insignificant
16–64	Significant	Significant
Consequence 8	Significant	Significant

Courtesy of CODELCO.

the outputs, including products sent to market, intermediate products, services to third parties, wastes and residues, and in general everything that the unit operation or activity delivers to subsequent unit operations or activities. The output of one unit operation or activity may often be the input to the next operation. In such cases, the line executive and the environmental management coordinators of both areas must define which operation is responsible for the identification of environmental aspects and the potential environmental impacts associated with this process flow, including the discharge, transport, required surge storage, and so on.

When identifying the environmental aspects, it is important to consider that different aspects can be associated with each operation or activity, not just for those performing the immediate task but for third parties. An example is the incorrect execution of a maintenance task, which may have effects on both the maintenance worker and on those who use the equipment after maintenance. The identification of these environmental aspects should consider (1) activities of all personnel who have access to the workplace, including contractors, suppliers, and visitors; (2) work in areas provided by the company and by third parties; and (3) activities that interact with other resources or protected areas, including tourist attractions, landscapes, or archaeological, anthropological, historical, or cultural heritage sites.

The probability of occurrence of an environmental impact, *P*, is evaluated according to Table 16.1-3, and the consequences of an environmental impact are evaluated according to Table 16.1-4. Next, for each identified environmental impact, the corresponding value in Table 16.1-5 is calculated as the product of the probability and the consequence for that impact.

Finally, the significance of the environmental aspects that give rise to each environmental impact is determined from Table 16.1-6. There are two conditions under which an environmental aspect is classified as significant: when the MRA is 16 or higher, or when the consequences of an associated environmental impact are high.

Figure 16.1-2 shows an example of a worksheet used to assess environmental risk by CODELCO's vice president of corporate projects, Office of Sustainable Development (E. Córdova, personal communication). The first column of the worksheet is prepared by listing every function or activity associated with a given project, in this case, the development of the Pilar Norte (the North Pillar) sector of the El Teniente deposit. The second column is completed with the environmental aspects and affected areas for each function or activity as identified by project personnel.

The sheet, with its first two columns completed, is circulated to experts within the company, each of whom assigns a value of 1, 2, 4, or 8 to the probability and the consequence of each environmental aspect in the second column. This procedure is similar to that used for hazard identification and risk assessment in the workplace (Chapanis 1986; Colling 1990). The product of the probability and the consequence agreed on for each aspect determines whether the aspect is significant or insignificant, according to the procedures and criteria described previously. Aspects with significant environmental aspects are addressed as priorities in project planning and management.

Function or Activity	Environmental Aspect	Affected Area	Probability	Consequence	Magnitude	Classification
Operation of diesel equipment	Particulate emissions	Work area	8	1	8	Not significant
	Gas emissions	Work area	8	1	8	Not significant
	Fuel consumption	Work area	8	1	8	Not significant
Handling hazardous materials	Potential for spills	Ground & air/Work area	4	4	**16**	**Significant**
	Generation of hazardous solid residues	Work area	8	2	**16**	**Significant**
	Welding gas discharge	Work area	8	1	8	Not significant
Equipment maintenance and repair	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Potential for spills of hazardous materials	Ground & air/Work area	4	4	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	4	No Significant
Installation of workplace utilities and structures	Generation of non-process wastewater	Agua o Suelo	1	4	4	Not significant
	Generation of trash and other wastes	Work area	4	1	4	Not significant
	Generation of any solid residues	Work area	4	2	8	Not significant
	Potable water consumption	Natural resources	4	1	4	Not significant
Civil, mechanical, and electrical area control rooms; emergency drifts; main electrical room; transformer room; air shaft connections at level; extraction drift connections at level; hydraulic breaker foundations and control rooms; fan rooms	Welding gas discharge	Work area	4	1	4	Not significant
	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	4	Not significant
	Water consumption	Natural resources	8	1	8	Not significant
	Potential for spills of hazardous materials	Ground & air/Work area	4	4	**16**	**Significant**
Electical cables, cableways, and lights	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	4	Not significant
Installation and assembly of ventilation doors	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	4	Not significant
	Water consumption	Natural resources	8	1	8	Not significant
	Potential for spills of non-hazardous materials	Ground & air/Work area	4	4	**16**	**Significant**
Installation of compressed air system	Generation of hazardous solid residues	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	4	Not significant
Foundations and other concrete structures for hydraulic breakers	Generation of any solid residues	Work area	8	2	16	Significant
	Electrical energy consumption	Natural resources	4	1	**4**	**Not significant**
	Water consumption	Natural resources	8	1	**8**	**Not significant**
	Potential for spills of non-hazardous materials	Ground & air/Work area	4	4	16	Significant
Installation of hydraulic breakers with hydraulic power systems and control panels	Generation of any solid residues	Work area	8	2	16	Significant
	Electrical energy consumption	Natural resources	4	1	**4**	**Not significant**
	Water consumption	Natural resources	8	1	**8**	**Not significant**
	Potential for spills of hazardous materials	Ground & air/Work area	4	4	16	Significant
Installation of fire prevention system	Potential for spills of non-hazardous materials	Work area	4	2	**8**	Not significant
	Electrical energy consumption	Natural resources	4	1	**4**	Not significant
	Water consumption	Natural resources	8	1	**8**	Not significant
Installation of industrial water system	Emission of welding gases	Work area	4	1	**4**	Not significant
	Potential for spills of non-hazardous materials	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	**4**	Not significant
Installation of water system for fire control	Welding gas discharge	Work area	4	1	**4**	Not significant
	Potential for spills of non-hazardous materials	Work area	4	2	**8**	Not significant
	Electrical energy consumption	Natural resources	4	1	**4**	Not significant
Installation of hydraulic power system	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Potential for spills of hazardous materials	Ground & air/Work area	4	4	**16**	**Significant**
Installation of ventilation fans	Potential for spills of non-hazardous materials	Work area	4	2	**8**	Not significant
Installation of steel arch-type roof supports	Potential for spills of non-hazardous materials	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	**4**	Not significant
Modification and reconditioning of equipment washdown areas	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	**4**	Not significant
	Water consumption	Natural resources	8	1	**8**	Not significant
	Potential for spills of hazardous materials	Ground & air/Work area	4	4	**16**	**Significant**
Construction of civil and electrical maintenance shops	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	**4**	Not significant
	Potential for spills of hazardous materials	Ground & air/Work area	4	4	**16**	**Significant**
Installation of bridge crane	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	**4**	Not significant
	Potential for spills of hazardous materials	Ground & air/Work area	4	4	**16**	**Significant**
Installation of water treatment (de-acidification) plant	Emission of welding gases	Work area	4	1	**4**	Not significant
	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Ground & air/Work area	4	1	**4**	Not significant
	Water consumption	Work area	8	1	**8**	Not significant
	Potential for spills of hazardous materials	Work area	4	4	**16**	**Significant**
Installation of air compressors and lubrication systems	Generation of any solid residues	Work area	8	2	**16**	**Significant**
	Electrical energy consumption	Natural resources	4	1	**4**	Not significant
	Potential for spills of hazardous materials	Work area	4	4	**16**	**Significant**

Figure 16.1-2 Identifying and evaluating environmental effects of projects

ENVIRONMENTAL REPORTING

The conveyance of information is critical at all phases of a mining project. All of the people and institutions with an interest in how the project is conducted should be well informed of the ongoing plans for and progress with the project. MMSD addressed the issue of access to information in a report titled *Breaking New Ground* (MMSD 2002):

Information flow is essential in a sustainable stakeholder society. Information comes in different forms and is of variable quality. Information about a company and its operations is used by a range of actors, such as communities, investors, employees, lenders, suppliers, and customers, often through appropriate accounting and reporting procedures

based on defined indicators and measurement techniques. Within the industry, information is used by management to monitor performance efficiency and the impacts of operations. At the exploration phase, accurate geoscientific data and maps are crucial.

The working group that prepared *Breaking New Ground* held a workshop in 2001 in Vancouver. The workshop provided the opportunity to discuss the information used in preparing the report and examine how that information was viewed and handled by the mining industry. It was concluded that information often fails to flow to communities in a timely and transparent fashion, that disclosure practices often fall short of current best practice, and that one-size-fits-all systems of public reporting or a global reporting standard would be an extremely difficult initiative to develop. The distinct nature of specific mines, projects, companies, locations, and communities means that a different mix of indicators, metrics, and evaluations is needed. One effective way of scoping the need for information around any project is to ask the community what they need to know in considering project proposals.

The ISO 14001 standard includes disclosure as an outcome of the environmental auditing and management systems. The standard mainly addresses internal environmental management systems. Certain items within the standard refer in general terms to external communications as part of an organization's EMSs.

There are also voluntary initiatives to standardize the way corporations convey information. Most closely examined by the MMSD was the Global Reporting Initiative (GRI). It was convened in 1997 by the Coalition for Environmentally Responsible Economies "to make sustainability reporting as routine and credible as financial reporting in terms of comparability, rigour and verifiability" through "designing, disseminating and promoting standardized reporting practices, core measurements and customized sector specific measurements." The GRI Sustainability Reporting Guidelines suggest that reports include a CEO statement; key indicators; a profile of the reporting entity; policies, organization, and management systems; management performance; operational and product performance; and a sustainability overview (GRI 2009).

SOUND ENVIRONMENTAL PRACTICES

Past publications have provided detailed descriptions of environmental regulations and permitting procedures for a given location—often the United States. In this chapter, a more general approach is taken by describing the principles of sound environmental practice, which can and should be applied in any political jurisdiction. However, some examples of regulations and accepted practice are given for illustrative purposes.

Before discussing the individual activities involved in mining, it is important to point out that, in general, mining activities should be conducted with the future in mind. This will not only minimize the environmental effects of each activity, but will also result in significant cost savings. This approach will lead to some considerations that are very broad and apply to almost all projects. For example,

- Government officials and all residents in the area of the proposed mine should be well informed of and directly involved in all project plans from the beginning. Such involvement will help address the concerns of local people as they occur and may well obviate formal objections when permit applications are filed; and
- The overall mine plan should include consideration of the requirements of reclamation and restoration. Placement of waste piles, tailings ponds, and similar materials should be carefully planned to minimize rehandling of material.

At the same time, other considerations will be specific to a given project. For example,

- Design and location of roads developed for exploration should consider future needs for mining and processing. This will minimize unnecessary road building and decrease effects on the local ecosystem; and
- When containment ponds are required for drilling fluids or cuttings, consideration should be given to the future use of those ponds for tailings impoundment, storm water catchment, or settling ponds.

The mining operation should be thoroughly planned, in consultation with government agencies and people living in the region. Historic, cultural, and biological resources should be identified, and plans made for their protection. This is especially important in areas where indigenous people have little exposure to the technologies used in mining. Mining companies should take the appropriate steps to ensure that the indigenous people understand the mining plans. The indigenous peoples' values and land-use practices must be understood, and steps must be taken to protect them. In some locations, this will necessitate the involvement of anthropologists, sociologists, and other experts. It may also require a planning and approval process that differs from those to which the company is accustomed. For example, some indigenous peoples make decisions by group consensus, necessitating large community meetings that may last for several days.

Mine Development

Development is the preparation of the facilities, equipment, and infrastructure required for extraction of the valuable mineral material. It includes land acquisition, equipment selection and specification, infrastructure and surface facilities design and construction, environmental planning and permitting, and initial mine planning.

Hunt (1992) provided a useful checklist for mine development projects in the form of a questionnaire (see Table 16.1-7). While some aspects of this list are specific to operations in the United States, its breadth and detail make it a worthwhile resource for almost any mining project. It includes considerations for projects in areas where no mining has occurred, for projects in previously mined areas, and for expansion projects at operating mines.

Infrastructure and Surface Facilities Design and Construction

Infrastructure and surface facilities may include all of the following:

- Roads and railroads
- Power plants, electric power lines, and substations
- Fuel supply lines and tank farms
- Dams, diversions, reservoirs, groundwater well fields, water supply lines, water tanks, and water treatment plants
- Sewage lines and sewage treatment plants
- Maintenance shops
- Storage sheds and warehouses
- Office buildings, parking lots, shower facilities, and changehouses

- Worker accommodations (housing, cafeteria, infirmary, and recreation facilities)
- Houses for pumps, fans, and hoists
- Waste piles and impoundments
- Ponds for catchment of surface and groundwater, and mine drainage
- Industrial and household waste landfills

Six general environmental considerations apply to the design and construction of surface facilities and infrastructure:

1. Select locations of surface structures and infrastructure to minimize the effects of their construction and use on surface water, groundwater, plant and animal ecosystems, and nearby human habitation. Surface structures and infrastructure include roads, railroads, and power lines, for example.
2. Remove and store topsoil for future use from areas that will be later reclaimed.
3. Control runoff so that water exiting the boundaries of the permitted mine site is captured and treated as required to meet applicable discharge standards. Many jurisdictions permit mines as zero-discharge facilities, meaning that all water or solid waste is contained within the permitted mine area.
4. Protect surface water and wetlands. Because these features may exist directly over mineral reserves, their relocation may be necessary.
5. Revegetate disturbed areas. Recontour the land to a defined standard and revegetate with an approved mix of seeds and plantings.
6. Control emissions of dust and noise to meet the requirements of local regulations and the reasonable expectations of persons living nearby. In particular, if explosives are used, control air blast and ground vibration as required.

Specific considerations for some surface facilities or infrastructure include

- Maintenance shops should be designed to avoid contamination of soil and water by spilled fuel and lubricants;
- Surface facilities should be designed to minimize energy consumption, using solar water heating and alternative electric power generation wherever possible; and
- Surface facilities should also be designed architecturally to harmonize with the natural surroundings in the locale.

Environmental Planning and Permitting

The forward-thinking approach mentioned earlier is especially important in environmental planning and permitting. In the permitting process, careful planning is imperative, so that information is gathered efficiently, the applications submitted to regulators meet all requirements, including timely submission, and mine planning costs are minimized by avoiding redesign required after agency review. As pointed out by Hunt (1992), "One of the most serious deficiencies encountered by many operators in the permitting process is to fail to adequately plan the time required to collect baseline data and to provide for public and agency review of applications." Hunt goes on to list the major tasks and activities required during early phases of environmental planning:

- Identification of the regulatory agencies that will be responsible for permitting the proposed mining operation
- Acquisition of all necessary permitting forms and copies of applicable regulations
- Identification of possible legal or technical restrictions that may make approval difficult or require special attention in the permitting process
- Identification of environmental resources information that will be required and the development of a plan and schedule for collection of the required data

Development of a comprehensive permit plan during the initial stages of mine development is critical. The plan should identify predecessor information that must be generated at each stage in the permitting, thereby identifying critical path issues and potential bottlenecks. A Gantt chart is often used for this purpose. For example, if the groundwater discharge permit for the tailing impoundment takes 2 years, and the design must be submitted with the application, the mine may need to move the "design tailing impoundment" task up on the schedule. It is recommended that an environmental permitting specialist be tasked with preparing the comprehensive permit plan.

After preliminary planning, permit applications must be completed. Many jurisdictions require a detailed environmental audit, which is then described in a report, often called an environmental impact statement, or EIS. Depending on local regulations, the EIS may be issued for public review and comment. Topics covered in an EIS usually include the following 19 areas:

1. Permits required and permitting status
2. Ownership of surface and mineral rights
3. Ownership of the company or companies that will be operating the mine, including contractors
4. Previous history of the entities described in Item 3
5. Information on archaeological, historical, and cultural resources within the planned mine site and adjacent areas
6. Hydrology of the mine site and adjacent areas, including the presence of potential pollutants and plans for dealing with them
7. Potential for dust and air pollution, and plans for mitigation
8. Plans for use and control of explosives
9. Plans for disposal of mine waste, including methods for controlling dust generation, slope stability, and seepage of contaminated water
10. Plans for impoundments, and methods for preventing failure or overtopping
11. Plans for construction of backfilled areas during mining, and for backfilling of mine excavations when mining is finished, including methods for preventing slides or other instability
12. Potential for surface subsidence, both immediate and long term, and proposed methods of preventing subsidence or compensating for its negative effects
13. Potential for fires in mine workings, at outcrops, and in spoil piles, and methods for prevention and control of such fires
14. Planned use of injection wells or other underground pumping of fluids
15. Information on previous mine workings, plans for reclaiming previous workings, and description of how the planned workings will interact with previous workings
16. Socioeconomic impact analysis
17. Visual impact analysis
18. Noise impact analysis
19. Biological assessment and impact analysis

Table 16.1-7 Environmental audit checklist

Category	Checklist Items
Permits	☐ Provide a list of all permits existing, applied for, and in preparation for the mine. Indicate the current status of each permit. ☐ If the mine has National Pollutant Discharge Elimination System permits, air permits, waste permits, water withdrawal permits, or other permits, include a listing of each applicable permit. ☐ Are any additional permits required for the facility but not already obtained? ☐ Were any citizen protests or comments filed on any of the permits? If so, describe the issues raised. ☐ What is the status of the bond on each permit? Indicate the amount of bonding liability under each permit.
Surface and mineral rights information	☐ Is the surface property owned or controlled by the mining company? ☐ Does the mine have a specific written agreement with each surface owner pertaining to and providing applicable rights to the surface? ☐ If the mine is an underground mine, do the surface rights specifically include language that says the company has the right to subside? ☐ Has the mine ever received any complaints from a surface owner or any of the surrounding landowners? Indicate the nature of any complaint received. ☐ With respect to mineral rights, has there ever been a claim made suggesting that the mining company does not have complete and full mineral rights? ☐ Have any other entities been granted access rights to the property that may conflict with the rights to extract the mineral (e.g., oil wells, pipelines, utility easements, etc.)?
Ownership and violation information	☐ Is the mine permit held by any company not owned and controlled 100% by the operator? ☐ Is the mine permit being held by an independent contractor? ☐ Is the mine operation being conducted by any company not owned and controlled 100% by the permittee? ☐ Is the mine being operated by an independent contractor? Give a a brief summary of applicable relation. ☐ If the mine is permitted by or being operated by an independent contractor, has a review been completed of the contractor's violation history with regard to any other mines potentially affiliated with the contractor? ☐ If the mine is permitted by or being operated by an entity only partially owned, has a review been completed of the contractor's violation history with regard to any other mines potentially affiliated with the other parties? ☐ How is the relationship between mine personnel and the mine inspectors (excellent, good, poor)? If poor, please describe the problems encountered. ☐ Have there been any citizen complaints filed on the mine? If so, please describe the complaints filed.
Information on archaeological sites, cemeteries, etc.	☐ Within the permit area and adjacent areas, including the area over existing, past, and proposed underground workings, does the mine contain any of the following features? • Are there any federal lands? Indicate the type of federal land involved. • Is there any archaeological or historical site that has been previously identified? Indicate the type of site involved. • Are there public roads where there is not a specific written approval for mining through or under the public road by the agency that has jurisdiction over the road? • Are there occupied dwellings where there is not a specific written waiver from the owner of the occupied dwelling? • Are there any public buildings, schools, churches, community, or institutional buildings? • Are there any public parks? • Are there any public or private cemeteries?
Hydrology	☐ Has the mine obtained all necessary water discharge permits? ☐ Is the mineral being mined associated with potential pollutants, such as high-sulfur-bearing strata? ☐ Has the mine ever experienced any difficulties with poor-quality mine drainage? Briefly describe the situation encountered. ☐ Does any of the mine water need to be treated to meet effluent limitations or other applicable standards? ☐ Has any poor-quality mine drainage been observed on any part of the permit area, in any of the surrounding areas, whether associated with the mine or not? ☐ Have any of the surrounding landowners or occupants ever complained about loss of water or the mine contaminating their water supplies? ☐ Is the water used by surrounding landowners of poor quality? For example, is the water discolored, does it have a bad odor or bad taste, or are there other problems with water quality in the area? ☐ Has the mine ever had any complaints about the water level in streams increasing or decreasing, or the fish population in streams increasing or decreasing? ☐ Are there any in-stream treatment facilities or in-stream sediment ponds associated with the mine? ☐ Are there any wetland areas, wet areas with cattails, or similar aquatic vegetation that could be considered wetlands, within the vicinity of the mine?
Air pollution	☐ Has the mine obtained all the necessary quality permits? ☐ Have there been complaints about dust or air quality discharges from the mine? ☐ Are mine haul trucks covered with tarps to minimize dust and to prevent material from falling off? ☐ Is there a program for controlling dust and air pollution from the mine?
Explosives	☐ Has the mine had any complaints from landowners pertaining to blasting or the use of explosives? ☐ Is the mine access limited because of topographic conditions, or is it possible for local people to obtain unauthorized access to the mine site? ☐ If it is possible for unauthorized persons to obtain access to the site, what measures are currently taken to control this access? ☐ Are any personnel other than trained mine personnel allowed within the mine pit or the mine property in an area that may ever be subject to blasting?

(continues)

Table 16.1-7 Environmental audit checklist (continued)

Category	Checklist Items
Waste disposal	☐ Does the operation include a facility for the disposal of mine waste? ☐ Have there ever been any discolored or bad-quality water seeps from the waste pile? ☐ Does the groundwater indicate any levels of pollution from the waste pile? ☐ What is the worst-case chemical analysis for the waste material being disposed of at the mine? ☐ Have there ever been any signs of slumping or instability of the waste pile? ☐ Does the waste pile have any public roads, homes, occupied dwellings, or other structures downstream that could be affected by failure? ☐ Is the waste pile routinely inspected and certified by a professional engineer to verify that it is being built in accordance with the approved plan? ☐ Are there any abandoned mine waste piles within the vicinity of the mine, including the area overlying underground workings? ☐ Do any of the abandoned mine waste piles show any signs of instability or poor mine drainage? ☐ Does the disposal of any domestic or other nonmine waste occur within the property boundaries, including the disposal of garbage by mine or nonmine personnel? ☐ Has a survey been done to determine whether there is any nonmine waste on the property? Are there any abandoned nonmine waste piles within the mine property? ☐ What does the mine do with trash from the mine?
Impoundments	☐ Are there any large impoundments within the vicinity of the mine or included in the mine permit? ☐ Are there any public roads, facilities, dwellings, or other such facilities downstream of an impoundment that could be affected by the impoundment's failure? If so, briefly describe. ☐ Are all impoundments routinely inspected and certified by a professional engineer to verify that they are being built in accordance with the approved plans? ☐ Have any of the impoundments ever experienced overtopping?
Backfilling and slides	☐ Has the mine ever experienced a slide or instability of backfilled material or of outslope material? ☐ Does the mine have an excess spoil fill? Does the mine have a durable rock fill? Were any of the fills constructed in a location where there was a stream or running water prior to mining? ☐ If the mine is a surface mine, what is the maximum size pit and the size of the total pit currently open for the mine? How many cubic meters (cubic yards) of material would be required if the mine was closed today and the pit had to be backfilled? ☐ What is the maximum amount of highwall currently open on the operation, including total length and height? How many cubic yards (cubic meters) of material would be required if the mine was closed today and the highwall had to be completely eliminated?
Subsidence	☐ Does the mine include longwall or pillar removal mining? ☐ Has the mine ever identified any substance subsidence? ☐ Have there ever been any complaints by surface owners about surface subsidence? ☐ Does the mine have any significant problems with roof or floor control?
Mine fires	☐ Have there ever been any mine fires, including outcrop fires, identified on the mine property?
Underground injections	☐ Does the mine have any injection wells or pump any fluids or other material of any type underground? ☐ If the mine is an underground mine, has an evaluation ever been completed to determine what will occur after the mine is closed and the mine workings become flooded? If yes, briefly describe the resulting conclusion.
Previously mined areas	☐ Does the area affected by the mine include a previously mined area? ☐ Are there any of the following problems on the previously mined area? • Bad water drainage? • Unstable spoil? • Spoil on the outslope? • Refuse material on the outslope? • Unreclaimed areas where revegetation will be difficult? • Unreclaimed highwall?
Miscellaneous	☐ How close is the nearest house? ☐ Have there been complaints about the use of roads in the area? ☐ Has the mine ever received a closure or cessation order? ☐ Are there cleaning or other chemical solvents located at the mine? Have all necessary forms been filled out and provided in regard to "right to know" requirements for chemical exposure? ☐ Have all transformers or other electrical equipment been checked for polychlorinated biphenyl contamination? ☐ Is oil or fuel stored on the property? What types of facilities are provided for oil or fuel storage? Are there any underground storage tanks? Have all such tanks been tested? ☐ Are there any oil or gas wells, or similar facilities on the property that could conflict with mining?

Source: Hunt 1992.

Some countries require one comprehensive permit that addresses all environmental aspects, but some countries, such as the United States, require many individual permits covering myriad aspects. The following example illustrates the planning and permitting process for a surface coal mine in the United States.

Example 2. Premine Planning and Permitting for Surface Coal Mines in the United States

Table 16.1-8 describes reclamation requirements for surface coal mining based on requirements given in the Surface Mining Control and Reclamation Act (SMCRA) of 1977. Under SMCRA, specific requirements are given for obtaining a mining permit, and formal documents must be filed (CFR 2009).

A large amount of information is required for preparation of the reclamation and operations plan. Table 16.1-9 summarizes those requirements.

Government Agency Review of Permit Applications

The processing of a permit application begins with the submission of a completed application for a new permit, permit revision, or permit renewal to the regulatory authority and ends with the final decision to approve or deny the application. Agency review begins when the applicant officially files the permit application. For most permits, after the agency determines the application is complete, they begin the formal review process, notify affected parties, and begin a public comment period. In most cases, members of the public will be able to both submit written comments and request a hearing on the merits of the particular application. If the permit is granted, the operator may be required to post a bond. Upon approval of the bond, mining operations may commence.

Most agencies will conduct a detailed technical review of each application received to ensure that all applicable regulatory requirements are met. As part of this technical review, the applicant is notified of any deficiencies identified in the application as submitted and provided an opportunity to respond to the agency comments and to correct deficiencies. Failure to provide an adequate response or to correct any permit deficiency could result in denial of the application.

The time required for agency reviews will range from a few months to 2–3 years. This time can be even longer in areas where opposition to a project is well coordinated and well funded. The permitting for the Safford mine in Arizona, described in detail in this section, took 13 years. Thus it is extremely important that permit applications be prepared with great care and reviewed meticulously to minimize delays by the agencies.

In some countries, efforts have been made to speed up the permit review process. For example, in Chile, when environmental regulations were promulgated in 1994, specific approval times were specified. The maximum time for approval of an Environmental Impact Declaration is 90 days, not including the days required for response to questions from regulatory agencies. For the more complex environmental impact study, which requires establishment of baseline standards and community participation, the maximum is 180 days (República de Chile 2002).

Example 3. Freeport-McMoRan's Safford Mine

Exploration of the Dos Pobres/San Juan area of the Safford Mining District began in about 1940. The district is in Graham County, Arizona, about 12.9 km (8 miles) north of Safford. It comprises four porphyry copper deposits—Dos Pobres, San Juan, Lone Star, and Sanchez—located along the southwestern slope of the Gila Mountains north of the Gila River.

The Phelps Dodge Corporation (PD; now a part of Freeport-McMoRan) acquired an interest in the property in 1957 and began underground development in 1968. Underground activity stopped in 1982, and by 1992 interest had shifted to the oxide mineralization in the area. By 1994, PD owned most of these mineral deposits, but some extended onto public lands administered by the U.S. Bureau of Land Management (BLM). The portions of the deposits on BLM land were controlled by PD through mining claims filed under the U.S. General Mining Law of 1872 (Cooper 2008).

In an effort to consolidate its holdings in the Safford Mining District, PD proposed a land exchange to the BLM, in which PD would acquire public lands (referred to as the selected lands) within and adjacent to its existing private property in the mining district in trade for other lands (the offered lands) in Arizona currently owned by PD. Both parties signed an Agreement to Initiate (ATI), which began formal consideration of the land exchange.

The administration of public lands in the United States is often controversial, especially in the western states. In most areas, groups of citizens have organized to oppose almost any development on those lands. These groups are often supported by large, well-funded environmental organizations, such as the Sierra Club. Before making a decision about the land exchange, the BLM decided to prepare an EIS to comply with provisions of the U.S. National Environmental Policy Act (NEPA). After the parties agreed to formally consider a land exchange, public scoping took place in late fall of 1994 and baseline studies commenced.

Under the U.S. Clean Water Act, the U.S. Army Corps of Engineers (ACE) issues permits for the discharge of dredged or fill material into the navigable waters at specified disposal sites. Review of these permits usually requires several months after notice and the opportunity for public hearings. In late 1995, ACE stated that it would likely require an EIS as part of its environmental review for a Section 404 permit to implement the foreseeable mining uses if the land exchange was authorized. At about the same time, PD accelerated the planning and development schedules for the Dos Pobres/San Juan project.

PD submitted a mining plan of operations (MPO) in May 1996, which allowed the BLM, ACE, and EPA (U.S. Environmental Protection Agency), as cooperating agencies, to consolidate their respective environmental reviews for the proposed mining activities. The MPO alternative provided agency employees and the general public with more information regarding the potential effects of the foreseeable mining uses of the selected lands and also conformed to regulations of the Council on Environmental Quality and the guidelines published in *NEPA's Forty Most Asked Questions* (NEPA 2009).

In response to PD's submittal of an MPO, the BLM determined that the EIS should reflect the fact that an MPO was now the proposed action and made the land exchange proposal one alternative to the MPO. The BLM also involved ACE and EPA as cooperating agencies in the EIS process. The BLM then reinitiated the scoping process begun earlier because submittal of the MPO represented a significant change in scope from the original land exchange proposal. In December 1997, The U.S. Bureau of Indian Affairs (BIA) became a cooperating

Table 16.1-8 SMCRA reclamation requirements

Requirement	Description
Operations plan	• The type and method of coal mining, procedures, and proposed engineering techniques; anticipated annual and total production of coal, by tonnage; and the major equipment to be used for all aspects of those operations • The construction, modification, use, maintenance, and removal of the following facilities: retention dams, embankments, and other impoundments; overburden and topsoil handling and storage areas and structures; coal removal, handling, storage, cleaning, and transportation areas and structures; spoil, coal processing waste, and noncoal waste removal, handling, storage, transportation, and disposal areas and structures; mine facilities; and water and air • Existing structures proposed to be used in connection with or to facilitate the surface coal mining and reclamation operation • Blasting practices and blast monitoring system
Maps	Locations of • Lands proposed to be affected throughout the operation and any change in a facility or feature to be caused by the proposed operations • Buildings, utility corridors, and facilities to be used • The area of land to be affected within the proposed permit area, according to the sequence of mining and reclamation • Each area of land for which a performance bond or other equivalent guarantee will be posted • Each coal storage, cleaning, and loading area • Each topsoil, spoil, coal waste, and noncoal waste storage area • Each water diversion, collection, conveyance, treatment, storage, and discharge facility to be used • Each air pollution collection and control facility • Each source of waste and each waste disposal facility relating to coal processing or pollution control • Each facility to be used to protect and enhance fish and wildlife and related environmental values • Each explosives storage and handling facility • Each sedimentation pond, permanent water impoundment, coal processing waste bank, and coal processing waste dam and embankment, and fill area for the disposal of excess spoil
Air pollution control plan	Description of fugitive dust control practices and a monitoring program to provide sufficient data to evaluate the effectiveness of the fugitive dust control practices proposed to comply with federal and state air quality standards
Fish and wildlife information	All listed or endangered species, and all unusual habitats; protective measures to be undertaken during mining and reclamation; and plans for habitat enhancement
Reclamation plan	• A detailed timetable for the completion of each major step in the reclamation plan • A detailed estimate of the cost of reclamation of the proposed operations required to be covered by a performance bond, with supporting calculations for the estimates • A plan for backfilling, soil stabilization, compacting, and grading, with contour maps or cross sections that show the anticipated final surface configuration of the proposed permit area • A plan for removal, storage, and redistribution of topsoil, subsoil, and other material • A demonstration of the suitability of topsoil substitutes or supplements, based on analysis of the thickness of soil horizons, total depth, texture, percentage of coarse fragments, pH, and areal extent of the different kinds of soils • A plan for revegetation including, but not limited to, descriptions of the revegetation schedule; the species and amounts per acre of seeds and seedlings to be used; methods to be used in planting and seeding, mulching techniques, and irrigation (if appropriate); pest and disease control measures, if any; measures proposed to be used to determine the success of revegetation; a soil testing plan for evaluation of the topsoil results; and the handling and reclamation procedures related to revegetation • A description of the measures to be used to maximize the use and conservation of the coal resource • A description of measures to be employed to ensure that all debris, acid-forming and toxic-forming materials, and materials constituting a fire hazard are disposed of properly, and a description of the contingency plans that have been developed to preclude sustained combustion of such materials • A description, including appropriate cross sections and maps, of the measures to be used to seal or manage mine openings, and to plug, case, or manage exploration holes, other boreholes, wells, and other openings within the proposed permit area • A description of steps to be taken to comply with the requirements of the Clean Air Act, the Clean Water Act, and other applicable air and water quality laws and regulations, and health and safety standards • Description of the land use within the proposed mining area before mining, and of the proposed land use after mining and reclamation are complete • A general plan and a detailed design plan for each proposed siltation structure, water impoundment, and coal processing waste bank, dam, or embankment within the proposed permit area, and of the plans for removing each such structure
Hydrology	• Sampling and analysis methodology • Baseline information • Groundwater information, including the location and ownership for the permit and adjacent areas of existing wells, springs, and other groundwater resources; seasonal quality and quantity of groundwater and usage. Water quality descriptions shall include, at a minimum, total dissolved solids or specific conductance, pH, total iron, and total manganese. • Surface water information, including the name, location, ownership, and description of all surface water bodies such as streams, lakes, and impoundments; the location of any discharge into any surface water body in the proposed permit and adjacent areas; and information on surface water quality and quantity sufficient to demonstrate seasonal variation and water usage • Baseline cumulative impact area information • Alternative water source information • Probable hydrologic consequences determination • Cumulative hydrologic impact assessment • Hydrologic reclamation plan • Groundwater monitoring plan • Surface water monitoring plan

(continues)

Table 16.1-8 SMCRA reclamation requirements (continued)

Requirement	Description
Geology	• Sufficient detail to assist in determining the probable hydrologic consequences of the operation on the quality and quantity of surface and groundwater in the permit and adjacent areas, including the extent to which surface water and groundwater monitoring is necessary; all potentially acid- or toxic-forming strata down to and including the stratum immediately below the lowest coal seam to be mined; and whether reclamation can be accomplished and whether the proposed operation has been designed to prevent material damage to the hydrologic balance outside the permit area, including, at a minimum, the following: A description of the geology of the proposed permit and adjacent areas down to and including the deeper of either the stratum immediately below the lowest coal seam to be mined or any aquifer below the lowest coal seam to be mined that may be adversely impacted by mining. The description shall include the areal and structural geology of the permit and adjacent areas, and other parameters that influence the required reclamation and the occurrence, availability, movement, quantity, and quality of potentially impacted surface and groundwaters. • Analyses of samples collected from test borings, drill cores, or fresh, unweathered, uncontaminated samples from rock outcrops from the permit area, down to and including the deeper of either the stratum immediately below the lowest coal seam to be mined or any aquifer below the lowest seam to be mined that may be adversely impacted by mining. The analyses shall result in the following: (a) logs showing the lithologic characteristics including physical properties and thickness of each stratum and location of groundwater where occurring; (b) chemical analyses identifying these strata that may contain acid- or toxic-forming or alkalinity-producing materials and to determine their content, except that the regulatory authority may find that the analysis for alkalinity-producing materials is unnecessary; and (c) chemical analyses of the coal seam for acid- or toxic-forming materials, including the total sulfur and pyritic sulfur, except that the regulatory authority may find that the analysis of pyritic sulfur content is unnecessary.
Diversions	Stream channel and other diversions to be constructed within the proposed permit area, including maps and cross sections
Protection of area	Measures that will be taken to protect any publicly owned parks and historic places within the proposed permit area
Public and private interests	Description, including appropriate maps and cross sections, of measures that will be taken to ensure that the interests of the public and landowners affected are protected if during mining the operator undertakes the relocation or use of public roads
Disposal	Description, including appropriate maps and cross-sectional drawings, of methods for disposal of excess spoil, including the proposed disposal site, the design of the spoil disposal structures, the removal, if appropriate, of the site and structures, and any requisite geotechnical investigation
Roads	Description, including plans and drawings, for each road to be constructed, used, or maintained within the proposed permit area

agency in the preparation of this EIS, specifically to contribute its expertise in the areas of Indian trust resources and tribal consultation. Protection of groundwater resources was of particular interest to the Indian (indigenous) people in the project area.

In September 1998, the draft EIS was published. It was more than 400 pages long (not including seven appendices), and included 108 tables and 73 figures. It addressed the scoping issues shown in Table 16.1-10. The EIS also identified the laws, regulations, and other government actions applicable to the project, including nine federal acts, five federal executive orders, six federal land-use or management plans, and twelve state and local laws.

A groundwater model and the Model, Monitor, and Mitigate program for groundwater protection were prepared. Both documents were reviewed at length by the BLM's hydrologist, the BIA, and a consultant retained by the BIA. However, the agencies disagreed on these and other issues, and the BIA withdrew as a cooperator in June 2000, without facilitating consultations with Indian tribes regarding potential impacts to trust resources. In April 2001, BLM reinitiated direct consultations with the Gila River Indian Community and the San Carlos Apache Tribe, which continued throughout the preparation and evaluation of the EIS.

Publication of the draft EIS was followed by a 60-day public comment period that was extended twice, and during which public and tribal open house meetings were held in four locations. Notices were published in the *Federal Register* and in the *Eastern Arizona Courier.*

The draft EIS informed readers that the 60-day comment period would end on November 25, 1998. During this period, BLM received three requests by electronic or regular mail for an extension of the comment period. BLM notified these three requesters via electronic mail and the public at large by a notice published in the *Federal Register* on November 30, 1998, that the comment period was being extended until December 18, 1998. The public was notified of a second extension of the comment period until January 29, 1999, through a notice printed in the *Federal Register* on December 18, 1998. Thus, the public comment period lasted a total of 127 days.

Three public open house meetings lasting 4 hours each were held at BLM field offices in Safford, Tucson, and Phoenix on, respectively, October 27, 28, and 29, 1998. Representatives from the BLM, ACE, and EPA were present in each meeting. A total of 212 members of the public attended the three meetings. A tribal open house meeting was held on December 4, 1998, on the San Carlos Apache reservation and was attended by 23 persons representing the tribe. Graphic depictions of the mine layout and selected and offered lands, a summary of the impacts of the project, and self-addressed comment sheets were available to the public at these meetings.

Within the comment period, BLM received 269 letters on the draft EIS including two letters originally sent to ACE. Of the total, 127 letters were from private individuals and 142 were from persons representing organizations, groups, businesses, or agencies. The BLM identified 650 comments in these letters.

All comments made in the letters were addressed by BLM. Those comments, and the responses to them, were

organized into 14 categories. Discussion of the categories and the responses to the letters required 95 pages in the EIS. A review of that material showed that those letters came from the following sources:

- Fifteen from other government agencies, requesting clarification or further response to specific issues
- Seven from individuals, objecting to specific aspects of the project or to the project in general
- Five from nongovernmental organizations, objecting to specific aspects of the project or to the project in general
- Five from Indian tribes or related organizations, objecting to specific aspects of the project or to the project in general
- One from an Indian tribe stating no objection to the project
- One from PD, requesting clarification or further response to specific issues

The remaining 235 letters expressed support for the project or for the proposed land exchange.

In addition to the 269 letters received during the comment period, 24 letters were received after the close of the extended comment period on January 29, 1999. These letters are not included in the official administrative record for this project; however, all were read by BLM and analyzed for comments. The BLM determined that all the issues and comments raised in the late letters had already been raised by other commenters and were being considered in the preparation of the final EIS.

In August 2001, PD submitted an updated MPO that addressed several concerns raised during the draft EIS public comment period. Specifically, PD modified the crushing, pretreatment, and material handling elements of the MPO to reduce impacts and increase the efficiencies of the ore production processes. As a result of PD's continuing optimization efforts, the projected water usage, truck haulage and associated air emissions, tank storage, and sulfuric acid truck deliveries were meaningfully reduced.

In July 2004, the BLM issued a Record of Decision (ROD) in favor of the land exchange, allowing the project to move forward (BLM 2004). In August the San Carlos Apache Tribe and Western Mining Action Project (WMAP) claimed that the land exchange between BLM and PD did not benefit the public interest and should not take place, and both parties filed protests to the ROD. WMAP claimed that BLM failed to meet its responsibility to ensure that springs and water holes will not be dewatered, instead saying, "Groundwater pumping and aquifer drawdown from the proposed mine will significantly reduce and/or eliminate a number of springs and water holes in the area" (Jones 2004a). The same groups also questioned the validity of PD's mining claims on selected lands

in the Gila Mountains, saying the validity of the claims was assumed by BLM when it prepared the EIS and the ROD. The WMAP protest accused BLM of basing the EIS and ROD on the assumption that the mine was going to be built "without determining if the projects would comply with federal law" (Jones 2004b).

By September, BLM had responded to the protests and allowed the ROD to stand. PD proceeded to file for air quality and aquifer protection permits and began the final feasibility study for the project (Stockton 2005). The feasibility study was completed in 2006. Construction at the site began in June of 2007, and the first cathode copper was produced on December 31, 2007 (Cooper 2008).

Public Participation in the Review of Permits

The environmental regulations in most jurisdictions provide an opportunity for public participation in the permitting process. Notice of the submittal of the permit application is usually advertised locally, with information provided on the schedule for public comment, the availability of the application for public review, and the location where comments may be submitted and hearings requested.

Interested persons or organizations, particularly those who may be adversely affected by a proposed mine, have the right to submit comments and objections to the issuance of the permit during the public comment period. Requests for hearings or conferences on the application must also be submitted within the time provided for public comment. In most jurisdictions, affected persons who file comments on the application, and the applicant if the permit is denied, may appeal the agency's decision through an administrative or judicial hearing. In an administrative hearing, evidence will be accepted, and the administrative law judge or review panel will render a decision to uphold or overrule the agency determination. Additional appeals from a final administrative decision can be brought to appropriate state or federal courts if desired by an adversely affected party.

Recently, there has been an increase in opposition to mining projects in developing countries, from individuals and environmental organizations in developed countries. These organizations are well funded and expert in using legal maneuvering to delay or prevent projects they oppose. Legal delays are but one tactic used to prevent development projects (Olpin 1991).

One example of these organizations is Earthworks, which is "a non-profit organization dedicated to protecting communities and the environment from the destructive impacts of mineral development, in the U.S. and worldwide" (Earthworks 2009). Earthworks is the sponsor of the No Dirty Gold campaign, which has organized opposition to mines proposed in Canada, Costa Rica, Ghana, Papua New Guinea, Peru, Romania, and the United States (No Dirty Gold 2009). The No Dirty Gold campaign has been particularly effective in persuading prominent retail jewelers to pledge not to use gold produced from mines that the campaign judges to be noncompliant with its "Golden Rules," which are as follows:

1. Respect basic human rights outlined in international conventions and law.
2. Obtain the free, prior, and informed consent of affected communities.
3. Respect workers' rights and labor standards, including safe working conditions.
4. Ensure that operations are not located in areas of armed or militarized conflict.
5. Ensure that projects do not force communities off their lands.
6. Ensure that projects are not located in protected areas, fragile ecosystems, or other areas of high conservation or ecological value.
7. Refrain from dumping mine wastes into the ocean, rivers, lakes, or streams.
8. Ensure that projects do not contaminate water, soil, or air with sulfuric acid drainage or other toxic chemicals.
9. Cover all costs of closing down and cleaning up mine sites.
10. Fully disclose information about social and environmental effects of projects.
11. Allow independent verification of the above (No Dirty Gold 2009).

Clearly, these rules are quite similar to the principles of sustainability adopted by ICMM. However, some of the rules are particularly difficult for mine operators. For example, Rules 4, 5, and 6 offer no consideration of the fact that ore deposits are located without respect to political conditions, protected areas, or human communities. Similarly, the independent verification in Rule 11 may be difficult to attain. Career environmentalists are often mistrustful of

government agencies and mining company personnel, so "independent verification" implies inspection and approval by someone selected by the environmental organizations. Unfortunately, these organizations do not get increased financial support by giving approval to mining and other resource development projects; quite the contrary, a mining company may be reluctant to allow "independent verification" of this type.

The direct involvement of organizations like Earthworks, Greenpeace, Oxfam, and others in the permitting process makes it even more important for mining companies to form good relationships with local people and governments well before permit applications are filed. An excellent example of a project where this was done successfully is the Diavik diamond mine, described in the following example.

Example 4. Diavik Diamond Mines Inc.

The Diavik diamond mine operates in the Northwest Territories of Canada, one of the most untouched and ecologically sensitive environments in the world. The mine is surrounded by tundra and is home to bears, wolverines, and migrating caribou. The water of nearby Lac de Gras is exceptionally pure and hosts many species of fish and birds.

Development of the Diavik mine required about 10 years. The first claims were staked in 1991 and 1992. Sampling and exploration continued, and Diavik Diamond Mines Inc. was formed in 1996. In 1997, baseline environmental studies were completed. As required by Canadian law, a project description was submitted in March 1998, and the environmental assessment report followed in September of the same year. Regulatory and financial approvals were given in 1998 and production began in 2003.

In planning the mine, Diavik consulted extensively with local communities about its operation and effects. Diavik is committed to providing training, employment, and business opportunities to residents in local communities of the Northwest Territories and the West Kitikmeot region of Nunavut, ensuring that it leaves a legacy of economically and socially stable local communities in the region. The process followed in developing agreements with indigenous peoples is described by Prest (2002):

> At the start, we developed a shared vision with our communities with regards to project development. As part of that vision, right from the beginning we integrated social and environmental dimensions into our project plans.
>
> We had regular meetings with our all neighboring aboriginal and other communities. We incorporated traditional knowledge learned from community elders and members. We are proud to say that information learned from our aboriginal communities has definitely led to a better designed project.
>
> As a third step in the engagement process, we entered into a number of formal agreements for the project. There are three legs to this framework, the Environmental Agreement, the Socio-Economic Monitoring Agreement, and, separate Participation Agreements with each of our five aboriginal groups.
>
> [Diavik's] Participation Agreements are legally binding, private contracts which contain mutually beneficial provisions for both the company and individual aboriginal communities. Parts of these agreements address shared responsibility for training, employment and business participation.

The negotiations with indigenous communities were conducted according to the traditions of those communities. Diavik's representatives met with each community and discussed all the issues until a consensus was reached. Reportedly, this sometimes took several days (R. Davey, personal communication).

Diavik's commitment to community development and investment is evident in the Diavik Socio-Economic Monitoring Agreement (SEMA), which was formalized in 1999 between Diavik Diamond Mines Inc. and the Government of Northwest Territories. The agreement was ratified by local indigenous communities and outlines Diavik's commitment to provide training, employment, and business opportunities to northerners and, more specifically, indigenous northerners. Diavik individualized these commitments through participation agreements negotiated with each of the same five aboriginal groups (Diavik 2009b):

1. Tlicho Government
2. Yellowknives Dene First Nation
3. North Slave Metis Alliance
4. Kitikmeot Inuit Association
5. Lutsel K'e Dene First Nation

Commitments under SEMA are reported publicly twice a year. Diavik has consistently exceeded expectations outlined in SEMA:

- Diavik committed to supporting a 40% northern work force during construction. At its conclusion, Diavik had reached 44% northern employment.
- Diavik committed to reaching levels of northern purchasing of 38% during construction. At its conclusion, Diavik had actually reached 74%, representing about Can$900 million (US$853 million) in contracts with northern companies, of which approximately $600 million was with indigenous companies.
- During operations, Diavik had committed to purchasing 70% of its annual requirements for goods and services from northern companies.
- For operations, Diavik committed to 66% northern employment and 40% indigenous employment for its operations. In 2007, Diavik's work force averaged 785 people, 67% of whom were northern, with one-half being indigenous.

The mine meets its environmental protection commitments through a comprehensive management system. This system is ISO 14001:2004 certified and is responsible for managing environmental protection activities, ensuring that all employees are properly trained, anticipating and avoiding environmental problems, ensuring regulatory compliance and due diligence, and ensuring consistency with the corporate environmental policy of the company (Diavik 2009a).

Diavik has several active programs that contribute to environmental protection and sustainable development values. In some cases, the measures taken in these programs go beyond the strict legal requirements that apply to the project area. The programs include the following:

- **Caribou management.** A small portion of the Bathurst caribou herd passes through the Lac de Gras region during

spring and fall migrations. To protect caribou passing near the mine, haul roads display advisory signs to ensure that caribou and other wildlife have the right of way. Diavik annually monitors the caribou within the region, with the assistance of elders from local indigenous communities.

- **Water quality management.** During early meetings with local communities, the indigenous people emphasized the importance of preserving water quality in the lakes and drainage. Diavik constructed an extensive water collection system to help protect the surrounding lake waters. Sumps, pipe networks, storage ponds, and reservoirs collect runoff water, which is used in processing and can then be treated before release to the environment. In addition, the Aquatic Effects Monitoring Program ensures that lake water is regularly sampled and analyzed at set locations over the complete range of depth, in all seasons of the year.
- **Fish habitat.** The mine constructed rock-fill dikes to access the three ore bodies under the lake, so that mining operations occupy less than 0.5% of the area of Lac de Gras. However, even this small area removed some fish habitat, so Diavik constructed a coarse rock-fill area on the outside of one dike to provide new fish habitat. During mining, rock shoals are constructed inside the dike area; when the mine closes, these will become fish habitat. The area behind the dikes will be flooded, the dikes will be breached to locate islands, and the area returned as part of Lac de Gras. Thus there will be no net loss of fish habitat, as required by Canadian fisheries regulations.
- **Progressive reclamation.** The progressive reclamation practiced at Diavik uses knowledge gained through community consultation to prepare the mine site for eventual closure. Some examples include the contouring of country rock piles to create smooth hills that allow caribou safe access, and the creation of new fish habitat. Revegetation studies and waste rock management projects are also being conducted.
- **Closure security.** Diavik is committed to complete closure of the mine site. It has committed a substantial amount of financial security to guarantee full closure when mining ceases, as established in the environmental agreement. The value of this security is revised regularly to adjust for the projected environmental liability and its associated cost of closure versus efforts the company has made to progressively reclaim the site.
- **Sustainable development research.** Diavik is cooperating with Canadian universities and researchers in numerous scientific studies of the environment and geology at the mine site. Recent studies have included research into effects of mine blasts on fish, evaluations of potential plant species for reclamation, and monitoring of dust distribution using lichen as a bioindicator. The results of these research projects are published regularly and are available on the Internet (Diavik 2009b). Research results are routinely incorporated into operating and reclamation practices at the site. Diavik is also examining the effect of the arctic climate on diamond waste rock piles, an area of which little is known. This research will facilitate long-term protection of the environment and has long-term applications throughout the world.

Mine Planning

All of the development activities described to this point constitute *mine planning*. However, the term as used here refers specifically to the planning of the mine workings, including gaining access to the mineral deposit, removing the valuable mineral, and handling any waste material produced. The activity as comprehended here also includes tasks described as *mine design*. Although the details of these processes are described in the next section, planning for them is begun in the development stage, and is thus discussed at this point.

In mine planning, the specific day-to-day operations of the mine are set out, analyzed, and documented. Mine planning continues throughout the life of every mine to account for changing geologic and economic conditions. The objective of mine planning at each point in time is to determine the manner in which the mine should be operated to optimize the goal(s) of the operating entity, usually the return on investment. Although mine planning varies with site-specific conditions, the following points must be determined in the initial plan, and continually reevaluated throughout the life of the mine:

- The extent of the mineral deposit
- The market for anticipated products of the mine
- The manner in which the deposit will be accessed for extraction
- The equipment and personnel that will be used for extraction
- The operating sequence for extraction
- The disposition of extracted material, both waste and valuable mineral
- The interactions of mine workings with adjacent or overlying areas and properties

Initial mine planning will obviously take place concurrently with the environmental planning and permitting, and the consideration of environmental consequences of the initial mine plan will be included in this process.

Extraction

Mining methods may be classified according to a variety of schemes. Here it is convenient to distinguish surface mining, underground mining, aquatic or marine mining, and solution mining. Solution mining is the removal of valuable minerals from in-place deposits by dissolving the mineral in a suitable liquid that is then removed for recovery of the desired constituent. It may also be called in-situ mining or in-situ leaching. Solution mining uses techniques similar to those used in the extraction of petroleum and natural gas, and is thus not discussed further in this chapter. The operational details and environmental considerations of surface mining, underground mining, and aquatic or marine mining are discussed separately.

Surface Mining

Surface mining is the removal of material from the earth in excavations that are open to the surface. In some cases, material is removed directly from the earth's surface; for example, sand and gravel may be removed directly from deposits of those materials put in place by ancient lakes or rivers. In other cases, material that has no economic value (overburden) covers the valuable material and must be removed.

A typical operational cycle for surface mining, described in detail by Saperstein (1992), is as follows:

1. Install erosion and sedimentation controls.
2. Remove topsoil from areas to be mined.

3. Prepare the first drill bench by leveling the bench with a bulldozer, inspecting and scaling the highwall as required, and laying out the blastholes.
4. Drill the blastholes.
5. Blast the rock.
6. Load the fragmented material.
7. Haul the fragmented material—waste to the waste dumps and product to the load-out for sale or to subsequent processing.
8. Manage the waste dumps as required by contouring waste piles to a stable configuration or returning waste to mine workings for use in reclamation.
9. Prepare mine workings for reclamation by
   a. Recontouring to the original contour, or to another approved and stable configuration.
   b. Returning the stored topsoil to the mine site and spreading it uniformly on the recontoured surfaces.
10. Reclaim the prepared surfaces by
    a. Revegetating with an approved mixture of seeds and plantings.
    b. Irrigate and maintain revegetated areas as required until a stable condition is reached.
11. Remove temporary drainage controls and stream diversions.

The environmental considerations that must be addressed during surface mining include the following:

- Control drainage from mine workings to avoid contamination of surface water, groundwater, and the existing ecosystem. Treatment may be required to remove particulates or chemical contamination.
- Control inflow or surface water and storm runoff so these waters are not contaminated by passing through the mine workings.
- Carefully analyze the groundwater regime in and around the mine workings, and provide monitoring wells as required. In some cases, it may be advisable to minimize the interaction of the mine workings with groundwater by pumping out the aquifers in and around the mine. There are many potential uses for this water. For example, it might be used in the processing of ore, discharged directly to surface drainages or discharged to constructed wetlands on the surface.
- Consider the formation of "pit lakes" when mined-out surface workings fill with water. This water, which may originate from surface runoff or flow from underground aquifers, may become acidified or otherwise contaminated, and the effects of such contamination on the environment (including wildlife, plant life, and humans) must be managed.
- Design and construct waste dumps and tailing impoundments to minimize erosion and protect surface and groundwater.
- Control emissions of dust and noise to meet the requirements of local regulations and the reasonable expectations of persons living nearby. In particular, if explosives are used, control air blast and ground vibration as required.
- When mining is done at night, consider the effects of artificial light on wildlife and humans living near the mine.
- Control slope stability and landslides. Of course, this is also necessary for successful mining operations, but inadequate control of slope stability may also lead to environmental damage. Slope failure may block or contaminate streams, damage wildlife habitat, and cause flooding that endangers wildlife and humans living near the mine.
- Consider the effects of increased traffic to and from the mine site, especially when product haulage will result in a marked increase in heavy truck traffic.

Underground Mining

Underground mining is the removal of material from the earth in excavations below the earth's surface. Access to such underground workings may be gained through a drift or adit, a shaft, or a slope. Drifts and adits are horizontal tunnels, usually in a hillside, that connect to the mineral deposit. In the case of minerals like coal that occur in seams (near-horizontal deposits of fairly uniform thickness and considerable areal extent), the drift may be developed in the mineral itself. Travel in drifts is by rail or rubber-tired vehicles. Shafts are vertical tunnels developed from the surface to access mineral bodies below. Travel in shafts is by cages or cars, which are lowered and raised by a mechanism on the surface, similar to elevators in tall buildings. Slopes are tunnels neither vertical nor horizontal and may be lineal or spiral. Travel in lineal slopes may be by rubber-tired vehicles or hoists but rarely by rail. Travel in spiral slopes (also called ramps) is by rubber-tired vehicles.

Saperstein (1992) has described in detail a typical operational cycle for underground mining in which material is fragmented by drilling and blasting, as summarized:

1. Enter the workplace after the previous blasting round is detonated.
2. Ensure that the workplace is in good condition and safe for continued work by checking that ventilation is adequate and that blasting fumes have been removed; providing for dust suppression; checking for the presence of hazardous gases; and inspecting for and removing loose material.
3. Load the fragmented material.
4. Haul the fragmented material to the appropriate location.
5. Install ground support as required.
6. Extend utilities as required: ventilation, power (electricity or compressed air), and transportation.
7. Survey and drill blastholes for the next round.
8. Load the explosives and connect the detonation system.
9. Leave the workplace and detonate the round.

This cycle is typical for the mining of narrow, steeply dipping veins (typical of metal ores), and for massive deposits of limestone, salt, and dimension stone, where the vertical extent of the valuable mineral is 6 m (6.6 yd) or higher.

The operational cycle for methods in which material is mechanically fragmented and removed in a continuous process may be similarly summarized:

1. Enter the workplace after the required ground support has been installed.
2. Ensure that the workplace is in good condition and safe for continued work by checking that ventilation is adequate and that blasting fumes have been removed; providing for dust suppression; checking for the presence of hazardous gases; and inspecting for and removing loose material.
3. Cut and load the fragmented material until the limit for advance is reached.
4. Concurrently, haul the fragmented material to the appropriate location.

5. Remove fragmentation, loading, and hauling equipment from the workplace.
6. Install ground support as required.
7. Extend utilities as required: ventilation, power (electricity or compressed air), and transportation.
8. Survey as required to ensure that the mined opening is maintaining the required dimensions and directional orientation.

This cycle is typical for mining in near-level seams of relatively soft material that have considerable areal extent and are thinner than 6 m (6.6 yd), such as coal, trona, phosphate, and potash.

Seven environmental considerations must be addressed during underground mining:

1. Locate ventilation fans and hoist houses to minimize the effects of noise on wildlife and humans living nearby.
2. Whenever possible, dispose of mine waste in underground mine workings.
3. When waste dumps are constructed on the surface, design them to minimize erosion and protect surface and groundwater.
4. Control drainage from mine workings to avoid contamination of surface water, groundwater, and the existing ecosystem. Treatment may be required to remove particulates or chemical contamination.
5. Control inflow or surface water and storm runoff so these waters are not contaminated by passing through the mine workings.
6. Carefully analyze the groundwater regime in and around the mine workings, and provide monitoring wells as required. In some cases, it may be advisable to minimize the interaction of the mine workings with groundwater by pumping out the aquifers in and around the mine, and discharging the pumped water to constructed wetlands on the surface.
7. Analyze and predict the subsidence likely to result from mine workings. Design workings to minimize the effects of subsidence on surface structure, utilities, and important natural features such as lakes, streams and rivers, and wildlife habitat.

Aquatic or Marine Mining

Aquatic or marine mining is the removal of unconsolidated minerals that are near or under water, with processes in which the extracted mineral is moved by or processed in the associated water. This type of mining may also be referred to as alluvial mining or placer mining. The two major types of aquatic or marine mining are dredging and hydraulicking.

Materials typically recovered by aquatic or marine mining have usually been deposited in fluvial, aeolian, or glacial environments, and are thus unconsolidated. They include aggregate (sand and gravel) and materials deposited because of their relatively high specific gravities. The latter deposits are called placers and include native (naturally occurring) precious metals, tin (as the oxide cassiterite), heavy mineral sands (oxides of zirconium, hafnium, titanium, and others), and precious stones. In some cases, placer deposits are mined by methods described in the section on surface mining; in such cases, the environmental precautions given for those methods apply.

Dredging is the use of a powered mechanism to remove unconsolidated material from a body of water. The mechanism is almost always a type of bucket or shovel. In the simplest case, it may be a metal bucket moved by chains or steel cables that are attached to a pole. The bucket is dropped through the water and into the solid material on the bottom. As the bucket is retracted, its weight and trajectory force its leading edge into the solid material, and the bucket fills. When the bucket comes to the surface, it is emptied. This type of dredge is usually installed on the shore near a body of water that covers a valuable mineral deposit.

More complex dredge mechanisms attach several buckets to a wheel or a ladder. A ladder is a structure designed to support a series of buckets attached to a chain, which moves continuously in a loop. Both mechanisms are usually installed in a floating vessel, the dredge. While moving, the bucket wheel or the dredge ladder is lowered into the unconsolidated material below the surface, picking up that material and returning it to the dredge where it is either further processed or transferred to the shore for further usage. The dredge vessel may operate in a natural body of water or in an artificial body called a dredge pond. A typical operational cycle for dredging is comprised of the following steps:

1. If dredging in a dredge pond, complete subitems a–g; if not, proceed to Step 3.
   a. Locate a source of water for filling the pond.
   b. Install erosion and sedimentation controls, and divert surface water as required.
   c. Prepare dikes or dams required for the dredge pond. The perimeter of the dredge pond must extend beyond the extent of the mineral to be recovered to allow for deposition of overburden or tailings removed in the first pass of the dredge.
   d. Fill the dredge pond.
   e. Remove vegetation.
   f. Remove and stockpile topsoil.
   g. If necessary, remove overburden with excavating equipment, and place overburden in stable piles.
   h. Proceed to Step 3.
2. If dredging from the shore, prepare the site for installation of the dredge mechanism.
3. Install the dredge.
4. Remove by dredging any overburden that was not removed in Step 1g.
   a. When dredging in a natural body of water, the overburden will be deposited under the water in an area from which the valuable mineral has already been removed or in an area under which there is no valuable mineral.
   b. When dredging in a dredge pond or from the shore, the overburden will be deposited beside or behind the dredge in an area from which the valuable mineral has already been removed or in an area under which there is no valuable mineral. When mining in a dredge pond, the overburden will for a time be at least partially under water; when mining from the shore, it will not. However, in both cases, the overburden will over time drain and be left exposed. It will thus require reclamation as described in Steps 12 and 13.
5. Remove the valuable mineral by dredging.
6. Process the valuable mineral as required to concentrate the valuable constituent(s). This processing is almost always done on the dredge and is integrated with the dredging of the material.

   a. When dredging in a natural body of water, the tailings will be deposited under the water in an area from which the valuable mineral has already been removed or in an area under which there is no valuable mineral.
   b. When dredging in a dredge pond or from the shore, the tailings will be deposited beside or behind the dredge in an area from which the valuable mineral has already been removed, or in an area under which there is no valuable mineral. When mining in a pond, the tailings will for a time be at least partially under water; when mining from the shore, it will not. However, in both cases, the tailings will over time drain and be left exposed. They will thus require reclamation, as described in Steps 12 and 13.
7. Remove the valuable constituent(s) for sale or further processing off-site.
8. Deposit the tailings under the water in an area from which the valuable mineral has already been removed or in an area under which there is no valuable mineral.
9. Continue dredging until reaching the limits of the dredge's cables and other connections, the limits of the pond, or the boundary of the deposit.
10. If dredging in an artificial pond, prepare and fill the next pond as in Step 1, and transfer the dredge. If dredging in a natural body of water, move the dredge to the next location.
11. Begin dredge operation in the new location by returning to Step 3. Simultaneously, and in accordance with the approved reclamation plan, reclaim overburden and tailings piles from previous work, according to Steps 12 and 13.
12. Prepare mine workings for reclamation:
   a. Recontour to the original, stable contour, or to another, approved and stable configuration.
   b. Return the stored topsoil to the mine site, and spread it uniformly on the recontoured surfaces.
13. Reclaim the prepared surfaces:
   a. Revegetate with an approved mixture of seeds and plantings.
   b. Irrigate and maintain revegetated areas as required until a stable condition is reached.
14. Remove temporary drainage controls and stream diversions.

There may be considerable variation in the cycle, depending on how the dredge is transported between sites.

Hydraulicking is a method of mining placer deposits that was used extensively in the past but has fallen into disfavor because of the potential for serious effects on the stability of the remaining surface and on nearby surface waters.

Hydraulicking required a large deposit of auriferous alluvium and a source of water that would provide sufficient volume and pressure head. Overburden and pay gravel were both removed by high-pressure water that flowed through a monitor—a large nozzle that could be rotated horizontally and vertically. Material removed by the flow from the monitor moved to the bottom of the valley, where the flow was controlled so that overburden passed directly into the stream channel and pay gravel flowed through a sluice or similar recovery device for recovery of the ore. Tailings from the sluice also flowed into the stream channel.

As mentioned earlier, hydraulicking of the placer gold deposits in the famous California Gold Rush of 1849 led to severe contamination of the rivers that drained the area of the gold deposit. The solids from the hydraulicking operations filled rivers with solids, which were eventually deposited downstream with serious consequences for agriculture in the downstream areas.

Hydraulicking is still a very inexpensive method for moving large volumes of unconsolidated material and is still used on a limited basis with five precautions:

1. Material discharge from a hydraulicking operation must be captured and treated to remove solids, including, in particular, any fine, suspended solids. This will require a settling pond, and chemical flocculants may also be necessary. Even water that appears to be clear must be tested by appropriate methods and treated on the basis of those tests.
2. Tailings, overburden, and deactivated settling ponds must be reclaimed appropriately, usually by recontouring and revegetation. It may be necessary to remove and stockpile topsoil for use in reclamation. Coarse gravel, which may accumulate in separate piles, should receive special attention to ensure it is reclaimed properly.
3. The area of the mining operation should be isolated from the flow of surface streams and runoff to prevent contamination of those waters.
4. Discharge of water from the hydraulicking operation should be managed to prevent interference with the existing flow regimes in the drainage. The quantities and velocities of discharge should not modify the existing stream flow in a manner that will cause erosion, undercutting of banks, or flooding.
5. Highwalls and embankments produced by hydraulicking should be reclaimed, again by recontouring and revegetation. Even when topsoil is removed and stockpiled, there may not be enough topsoil for the reclamation required. In such cases hydroseeding will likely be required.

CONCLUSION

Activities associated with mining have direct and lasting effects on both the physical and the human environments. In the recent past, mining was done with little concern for its effects on the environment. The consequences of this approach often resulted in significant damage to the natural environment. However, as political and cultural norms changed, and new legal requirements were enacted, almost all major mining companies adopted rigorous policies and procedures for sustainability, community engagement, and environmental risk assessment and mitigation. These companies apply such policies throughout their operations, many of which are worldwide. In addition, many mining companies work actively to remediate environmental damage caused by historic mining operations in areas where they have past or current operations.

Thus, environmental considerations are an important part of the modern mining industry. These considerations include preproject planning, permitting, compliant operation, reclamation, and closure. These considerations must be included in all project planning, and feasibility studies must account for the influence of environmental considerations on project schedules and costs.

CHAPTER 16.2

Mining and Sustainability

R. Anthony Hodge

INTRODUCTION

The 1987 publication of the report, *Our Common Future* by the United Nations (UN) World Commission on Environment and Development (WCED), brought the concept of sustainable development into the limelight. Chaired by the former Prime Minister of Norway, Gro Harlem Brundtland, and following hearings held across the world, the commission proposed an agenda for world development that would enhance security and reduce North–South disparities. It would be development "which meets the needs of the present without compromising the ability of future generations to meet their own needs" (WCED 1987).

Since then, a rich debate has ensued about what this means in practical terms. Though many other sets of words have been suggested for defining the phrase *sustainable development*, the Brundtland Commission definition has stood the test of time and remains the anchor. For a rich discussion, see the "definitions" portal of the International Institute for Sustainable Development, or IISD (SD Gateway n.d.)

In recent years, the word *sustainability* has also found its way into common use. The idea is simple. Sustainability is the persistence over a long time—indefinitely—of certain necessary and/or desired characteristics of both human society and the enveloping ecosystem (Robinson et al. 1990). These characteristics range from primary needs such as air, water, food, clothing, shelter, and basic human rights to a host of conditions that would collectively be called *quality of life*, not only for people but for other life forms as well.

It is here that the definitional issue becomes difficult for some, because the choice of which characteristics are to be sustained and the degree to which they will be sustained depends on the particular values that are applied. In turn, these depend on who is doing the applying. In other words, it is not a closed definition. What a company CEO chooses as important may be different than a politician, doctor, or librarian; what a Mexican chooses may be different from, for example, a Tanzanian or Australian. Because of these potential differences, a fair and effective process of interaction and seeking consensus is critical to the practical application of these ideas. Herein lies the rationale for why it is essential to always address not only the *what*, or the *substantive* part of human action, but also the *how*, or the *process* part. In other words, in the practical application of sustainable development concepts, not only what we do is important but how we do it.

Thus, the ideas of sustainable development and sustainability are different but synchronous. *Sustainability* is a more general term that captures the idea that we need to maintain certain important aspects of the world over the long term. *Sustainable development* is the human or action part of this set of ideas: As a society, we want to make choices about our actions that allow us to provide for the present without undermining the possibility for future generations to provide for themselves.

Together, these ideas are very appealing. However, their translation to practical action remains much debated. This is not surprising. Human society is complex. There are about 10,000 cells in the standard industrial classification—our way of classifying human activities within the market economy. This does not account for many more activities outside the market economy. There are about 200 countries across the world, and the global ecosystem is complex and not fully understood.

For its part, the mining, minerals, and metals industry has been a particularly active locus of sustainability-related policy and practice innovations because

- The potential implications—both positive and negative—of mining activities and the minerals and metals that result are significant;
- Many interests are touched by mining;
- The role of many of these interests in decision making is growing (e.g., communities and indigenous people);
- The nature of contemporary communications systems has brought the often dramatic nature of mining operations into the public eye; and
- Industry, governments, civil society organizations, and the public, in general, are all anxious to ensure mining makes a positive contribution that is fairly shared.

Importantly, the concept of sustainable development has not disappeared like so many "flavor of the month" ideas. Rather,

R. Anthony Hodge, President, International Council on Mining & Metals; Professor, Mining & Sustainability, Queen's University, Kingston, Ontario, Canada

it has grown in prominence and is now deeply entrenched in legislation, government, and corporate policy and practice. Sustainability is the subject of university curricula, given as a label to vice presidents and departments of mining companies, incorporated into the names of service providers, and included as an element of key performance indicators.

This chapter provides an overview that links the ideas of sustainable development and sustainability to the mining, minerals, and metals industry. To do so, a particular template is used for organizing the many interlinked bodies of knowledge that must be brought together: the Seven Questions to Sustainability (7QS) (MMSD North America 2002).

This template is pragmatic though much informed by the theoretical foundation of systems theory. It recognizes that to bring sustainability ideas into practice for the mining, minerals, and metals industry, the hard (well-defined) and the soft (ill-defined) systems of the real world must both be addressed, as well as the objective (independent of judgment) and the subjective (dependent on judgment). In doing so, all must be treated, if not exactly scientifically (which is not always possible), at least in a way that is characterized by intellectual rigor (see discussion of systems theory and sustainability in Hodge 1995 and 1996). The 7QS template weaves together ideas from many disciplines but recognizes that deeper exploration is often warranted depending on site-specific conditions. In this context, the objective of this chapter is to open a door as a first step to practical application.

MINING AND METALS INDUSTRY RESPONSE TO SUSTAINABLE DEVELOPMENT

The 1970s and 1980s were a time of reaction to dramatic change for mining. Echoing increasing concern for the environment across society, the late 1980s saw a number of leading mining companies publish "state-of-environment" reports related to their operations. Taking another important step, 30 leading mining and metals companies from across the world came together in 1991 to create the International Council on Metals and the Environment (ICME). ICME would give the industry an international voice on environmental matters.

Also in the early 1990s, many of these same companies joined with senior governments, labor unions, aboriginal peoples, and environmental nongovernmental organizations (NGOs) in a broad review of mining practices in Canada. The Whitehorse Mining Initiative turned out to be a precursor of a number of initiatives convened to bring sustainability ideas to practical application around the world. The resulting Leadership Accord (Whitehorse Mining Initiative Leadership Council Accord 1993) is a summons to change, framed within the context of a commitment to social and environmental goals. It seeks a sustainable mining industry within the framework of an evolving and sustainable society. The ideas it champions and the multi-interest process it uses elegantly capture sustainable development in practice.

For the mining industry, the decade of the 1990s was a bleak period. Commodity prices dropped while public criticism skyrocketed, much driven by a civil society that was quick to take advantage of newly available and quickly evolving computer-based communications. As a whole, the industry found itself under attack and in a defensive posture. Its *social license* to operate was threatened (though that particular label was to come later). In the late 1990s and faced with growing concern about access to capital, land, and human resources, the chief executive officers of nine of the world's largest mining companies took an unprecedented step.

Working through the World Business Council for Sustainable Development, they initiated the Global Mining Initiative (GMI). As part of GMI, they commissioned the International Institute for Environment and Development (London) to undertake a global review that would lead to the identification of how mining and minerals can best contribute to the global transition to sustainable development. The resulting project, Mining, Minerals, and Sustainable Development (MMSD), sparked a large and rich literature, including the project's final report, *Breaking New Ground: Mining, Minerals and Sustainable Development* (MMSD 2002).

Before the GMI was completed, participants moved to create an organization that would carry the resulting recommendations forward to implementation. Thus, in 2001 and building on the foundation established by ICME, the International Council on Mining and Metals (ICMM) was created. Many of the ideas summarized in this chapter have emerged from or been refined through subsequent work of ICMM.

Almost simultaneously with these events, NGO pressure on the World Bank Group led to the initiation in 2001 of a multi-interest review of the group's involvement in extractive industries. The Extractive Industries Review sought to test whether or not industry projects could be compatible with the World Bank Group's goal of sustainable development and poverty reduction. In its final report, *Striking a Better Balance* (Salim 2003), the review concluded in the affirmative but only if three enabling conditions were in place:

1. Public and corporate governance advocacy for the poor, including proactive planning and management to maximize poverty alleviation through sustainable development
2. Much more effective social and environmental policies
3. Respect for human rights

The resulting refocused World Bank policy emphasizes strengthened governance and transparency, ensuring that benefits reach the poor, mitigating environmental and social risks, protecting human rights, and promoting renewable energy and efficiency to combat climate change. This refocusing has in turn influenced mining approaches to implementing sustainable development on the ground. In sum, this process has served to elucidate and reinforce the concepts of sustainable development addressed in this discussion.

MINING'S CONTRIBUTION TO SUSTAINABLE DEVELOPMENT

At the base of the interlinked ideas of sustainability and sustainable development lies the simple idea that any human activity—including mining—should be undertaken in such a way that the activity itself and the products produced together provide a net contribution to human and ecosystem well-being over the long term.

From an engineering design perspective in general and a mine design perspective in particular, this simple idea gives rise to an overarching two-dimensional design criterion. That is, mining activity (or any human endeavour for that matter) should be designed to achieve (through the activity itself and the products that result) a net contribution to both human and ecosystem well-being over the long term. The achievement of design success should, in turn, be tested against this design criterion.

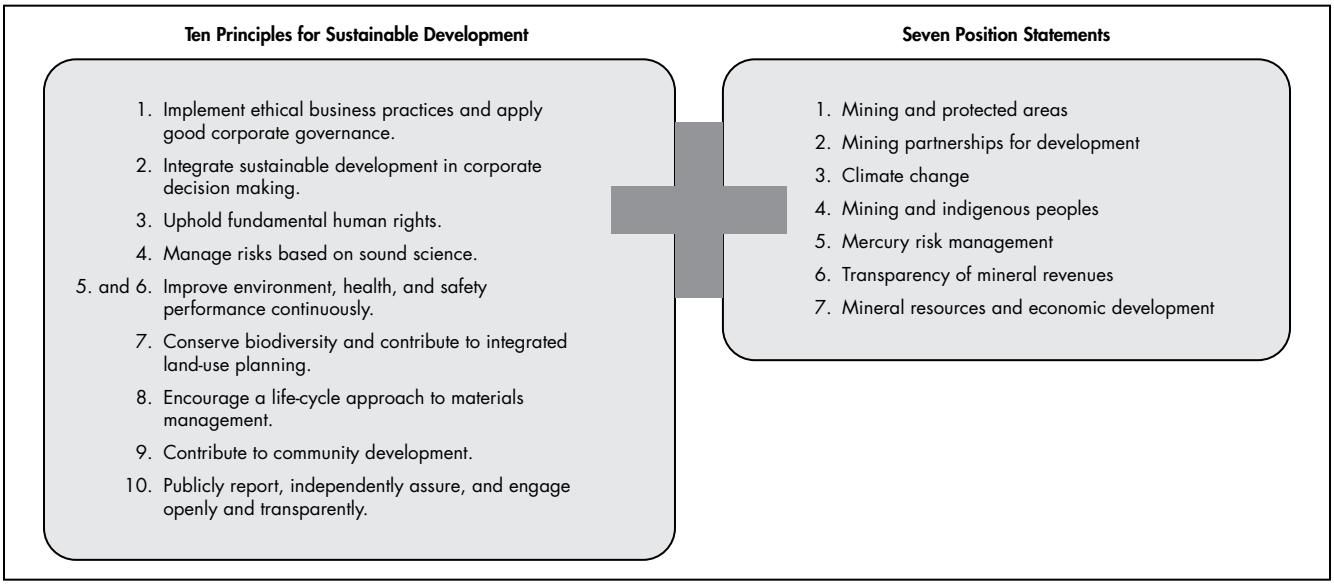

Figure 16.2-1 Principles and position statements that comprise the sustainable development framework of ICMM

Thus, the focus here is not on how mining can be sustainable—any mining project as a discrete activity cannot continue indefinitely—but on how mining, minerals, and metals can contribute to sustainable development. This is a conceptual shift away from a singular analysis and mitigation of *impacts* to a more comprehensive analysis and encouragement of *contribution*.

The focus on contribution is a tougher but fairer approach. It demands consideration of both the good and the bad. (The idea that the mining and metals industry should be designed for and tested against its contribution to the well-being of people and the environment—to sustainable development—was first proposed by Professor Robert Gibson in 2000 and later taken up in development of the 7QS template [MMSD North America 2002; Hodge 2004].) That a mining activity might be challenged to make a positive contribution to the ecosystem over the long term may seem a tough, even impossible challenge to some. However, articulating explicit engineering design criteria in this way sets a design objective that is essential if mining and metals-related activity and the resulting products are to achieve the sustainable development contribution that is being demanded by society.

Application of these ideas is not simply a *greening* phenomenon; it is related as much to well-being and security of people as the environment. And, interestingly, the mining industry's capacity to deal with the environmental aspects is currently stronger than its ability to address the full range of social aspects. This is likely because many environmental issues can be addressed through *hard* scientific and technical solutions, whereas social issues often require *soft* behavioral-type solutions, which can be much harder to design and implement—and which often fall outside the engineer's training.

These ideas also veer sharply away from thinking in terms of a trade-off between human and ecosystem well-being—it is not a balancing act that pits people against the environment. There are obviously many small trade-offs in any practical application: between interests, between components of the ecosystem, across time, and across space. This is particularly the case for mining and the related process of concentrating and refining. However, in an overarching sense, the ideas of sustainability and sustainable development call for both human and ecosystem well-being to be maintained or improved over the long term. Doing one at the expense of the other is not acceptable because, either way, the foundation of life is undermined.

PRINCIPLES AND FRAMEWORKS

The nature of applied sustainability is evident from the many attempts to articulate sustainable development principles. For a listing of more than 100 such principles, see the the "principles" portal of the IISD (n.d.). In short, there is no one-size-fits-all approach to defining, framing, and characterizing the ideas of sustainable development and sustainability. One set of principles of particular relevance to the mining industry is the 10-part set developed by the ICMM, along with its complementary set of position statements. ICMM brings together 19 of the largest mining companies of the world and, on an annual basis, member companies assess performance against these commitments using a procedure that includes third-party independent assurance (ICMM 2010a).

The ICMM principles and position statements as of 2010 are summarized in Figure 16.2-1. Just as many definitions and principles have been proposed, so too have many organizing frameworks been designed to bring theory to action. A comparative analysis of about 30 such characterizations or frameworks is found in Hodge 1997.

Almost three decades before the popularization of sustainable development ideas, geographer Walter Firey pointed out that three broad groupings of knowledge were pertinent to natural resource use (Firey 1960; and see discussion in Hodge 1997):

1. Ecological (environmental)
2. Ethnological (social/culture)
3. Economic

In the late 1980s, Firey's three-part model of natural resource use was adopted by a number of those attempting to operationalize the concept of sustainable development (Mitchell 1991). Since then, the three-part environmental–social–

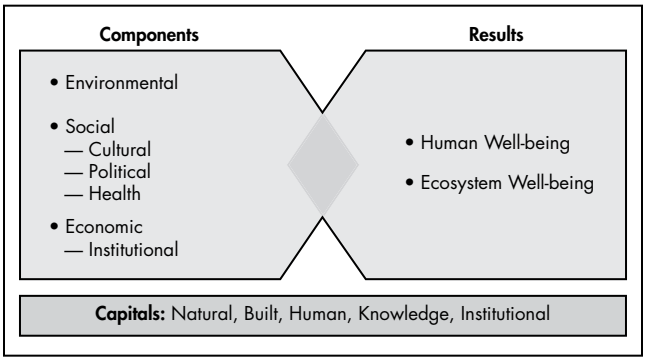

Figure 16.2-2 Different characterizations of sustainable development

economic characterization of sustainable development has gained broad usage. A significant limitation of this approach, however, arises because of the lack of common treatment for the social element.

Many other frameworks have also emerged that make sense for the particular application: population health, healthy communities, sustainable communities, foreign aid, urban design, agriculture, forestry, fisheries, indigenous peoples' needs, and so forth. From one particularly important perspective, the World Bank Group has used the lens and insights of economics to offer a "capitals" model to apply sustainable development ideas: natural, built, human, knowledge, and institutional. Figure 16.2-2 is a synthesis that brings a number of the alternatives together.

Another perspective that offers practical insight comes from an analysis of mine closure options that was undertaken for the Faro mine project in the Yukon Territory, Canada (Hodge and Merkhofer 2008). In this case, a sophisticated multi-attribute utility analysis—driven by a multistakeholder process—was used to assess the alternatives. Multi-attribute utility analysis is a form of decision analysis in which a set of objectives is articulated and each alternative's performance is assessed against those objectives. The underlying principle is that the alternative that best performs against the objectives is the best one. The foundation of this kind of analysis is the articulation of objectives that can be translated to a scale, which can be assessed in terms of a direction (e.g., more is better, less is worse) and magnitude (e.g., how much better or worse).

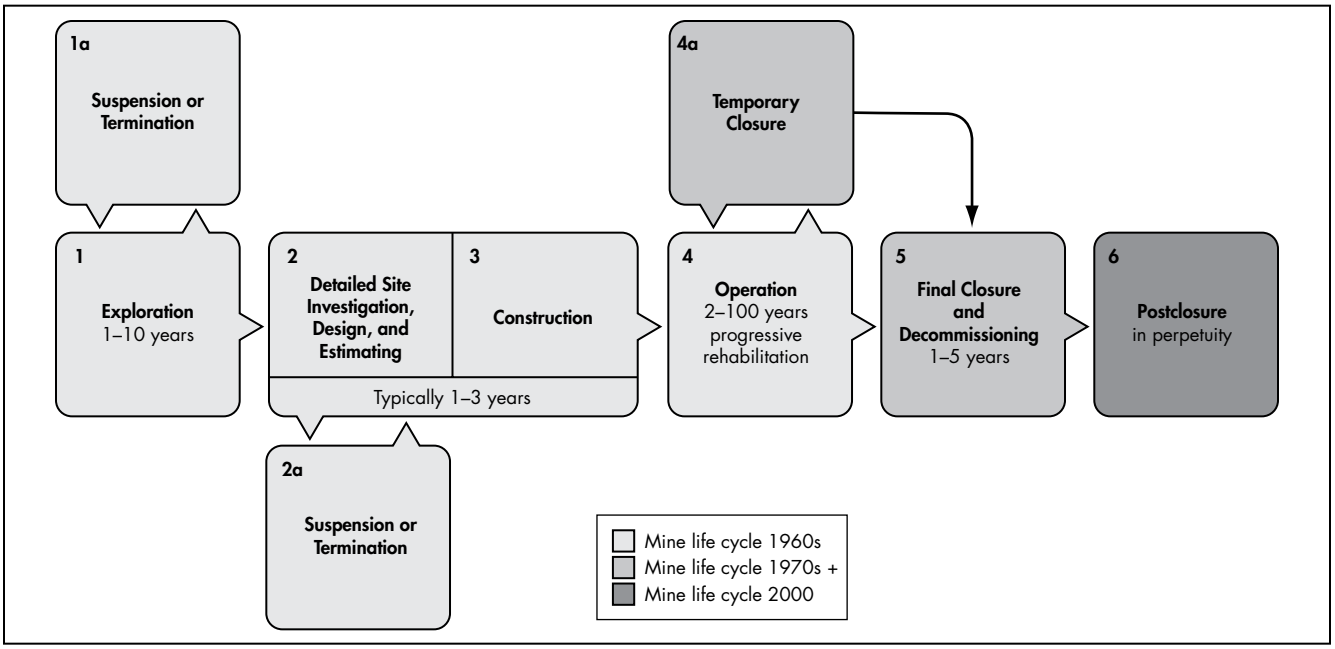
The rigorous scaling and multi-interest process of assessing and judging are complex. In the Faro analysis, two time horizons were used in the assessment: (1) short, 15–40 years; and (2) long, 500–1,000 years. Of relevance to this discussion is the framework of closure objectives, because it was set to reflect an overarching government policy of sustainable development. Eight objectives were used for assessing closure alternative at the Faro mine (Yukon Territory, Canada):

1. Maximize public health and safety
2. Maximize worker health and safety
3. Maximize restoration, protection and enhancement of the environment
4. Maximize local socioeconomic benefits
5. Maximize Yukon socioeconomic benefits
6. Minimize cost
7. Minimize restrictions on traditional land use
8. Minimize restrictions on local land use

As with all sustainable development frameworks, a broad range of topics is captured. However, this example is particularly useful for another reason. It is clear that the simultaneous treatment of all objectives sets up tensions that must ultimately be resolved: In a comparative analysis of alternatives, different value sets might well judge performance differently and, at the same time, place greater weight on certain objectives. This is a poignant example of applied sustainability in practice. Here again the process of finding common ground can be seen as critical to practical implementation of sustainable development ideas.

From a different but important perspective, as part of the World Bank Group response to the Extractive Industries Review, the International Finance Corporation (IFC) prepared and adopted a sustainability framework that consists of (1) the Policy on Social and Environmental Sustainability, (2) the Policy on Disclosure of Information; and (3) a set of performance standards on social and environmental sustainability.

In its performance standards, the IFC addresses eight topics:



1. Social and environmental assessment and management systems
2. Labor and working conditions
3. Pollution prevention and abatement
4. Community health, safety, and security
5. Land acquisition and involuntary resettlement
6. Biodiversity conservation and sustainable natural resource management
7. Indigenous peoples
8. Cultural heritage

Here again is another definition of what is appropriate to include in addressing application of sustainability concepts to mining. The IFC sustainability framework is currently under review with the expectation that a revised package is targeted for release in 2011. The IFC has also published a number of Good Practice Notes/Handbooks (IFC 2006) relevant to the practical issues of sustainability. Most importantly, the performance standards along with the World Bank Group's Environmental, Health, and Safety Guidelines form the basis of the Equator Principles, which have been adopted by 67 lending institutions worldwide (the Equator Principles lending institutions), many of whom provide financing for mining activities. The Equator Principles are a voluntary set of standards for determining, assessing, and managing social and environmental risk in project financing. They are considered the financial industry gold standard for sustainable project finance.

Another important framework is the Global Compact, a principle-based framework for businesses, which was established by the United Nations in 2000. The Global Compact is the world's largest voluntary corporate citizenship initiative and states 10 principles in the areas of human rights, labor, the environment, and anticorruption. Members are committed to aligning their operations and strategies with the 10 principles (United Nations Global Compact n.d.).

For their part, the Millennium Development Goals are eight international development goals that all 192 UN member states and at least 23 international organizations have agreed to achieve by the year 2015:

1. Eradicating extreme poverty and hunger
2. Achieving universal primary education

Source: Adapted from John Gadsby (personal communication) and MMSD North America 2002.
Figure 16.2-3 Mine project life cycle

3. Promoting gender equity and empowering women
4. Reducing child mortality
5. Improving maternal health
6. Combating HIV/AIDS, malaria, and other diseases
7. Ensuring environmental sustainability
8. Developing a global partnership for development

Each of the approaches to capturing what sustainability means in terms of principles and frameworks is useful for the relevant driving application. There is no single panacea that applies in all cases. However, taken together they capture the breadth of issues and topics that must be considered.

NONRENEWABLE NATURE OF MINING, MINERALS, AND METALS

Much of the literature through the 1980s and 1990s focused on renewable resource management and the idea of living off the interest of a continuing core stock. For some, nonrenewable resource-related activities such as mining simply did not fit into the sustainability concept, although the hat might be tipped toward recycling and reuse of nonrenewable materials as helpful strategies.

One result of this early emphasis was the marginalization, to a great extent, of concerns and perspectives about nonrenewable resources. Interestingly, the fact that minerals are nonrenewable (or stock) resources and, in some sense, fixed in absolute quantity turns out to be relatively unimportant from a sustainability perspective—at least at the macro scale (MMSD North America 2002). The nonrenewable character of minerals received a great deal of attention in the literature from 1950 into the 1970s. However, the long statistical record of continued output at relatively constant prices, together with growing understanding first of environmental issues and then of sustainability, has served to deemphasize this concern. At the same time, recognition is growing that the products of mining are needed both to provide for the world's population and, even more so, to support approaches that will allow society to walk more lightly on the earth. For example, all the strategies needed for development, transmission, and use of renewable energy sources depend on mined metals and minerals. Similarly, strategies to move to a carbon-reduced economy are only possible through creative uses of mined minerals and metals.

Thus, the sustainability-related focus is now appropriately on mining as an activity and its implications for the communities and ecosystem within which minerals are embedded. At any given site, whether a mining, smelting, refining, primary metals manufacturing, or recycling operation, there is a beginning and end: No mining/mineral activity can be expected to have an indefinite life span. However, the implications of that activity (not only as a direct result of the activity but also through the product that is produced) go on indefinitely.

In that sense, mining/mineral activities serve as a bridge to the future. The sustainability challenge is to ensure that the implications of mining activities and the products that result are net positive for people and ecosystems over the long term: It is the well-being of human society and the enveloping ecosystems that need sustaining. Limited-term mining projects can serve sustainability objectives if they are designed and implemented in ways that ensure they meet that challenge.

BOUNDARY CONDITIONS FOR APPLYING SUSTAINABILITY TO MINING

Bringing sustainability ideas into mine design has a significant impact on mine design boundary conditions. Four aspects of boundary conditions apply in this case, each of which has implications for setting the time and space dimensions and helps to identify the system components that must be considered:

1. Mine project life cycle (Figure 16.2-3)
2. Mineral life cycle (Figure 16.2-4)
3. Time horizon (Table 16.2-1)
4. Communities of interest

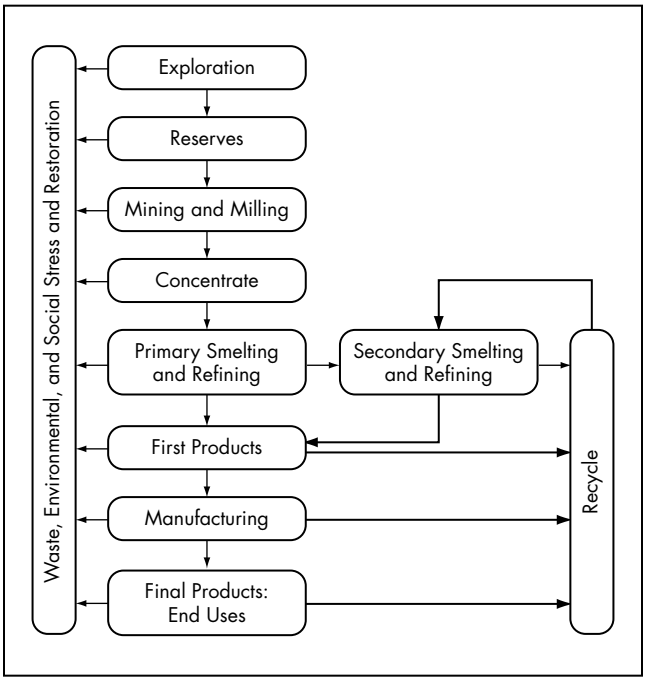


Figure 16.2-4 Mineral life cycle

First, the mine design process must take into consideration the full life cycle of a mine project. Many of the greatest problems facing the mining industry today stem from the fact that this has not been done in the past. In the 1960s, the mine design process was limited to the end of operations. In the 1970s and driven by rising environmental consciousness, the need for mine reclamation gave rise to concerns about closure, which at the time focused on cleaning and grooming a site, with revegetation being a key activity. It is only in the last decade that the realization has set in that a postclosure phase can in some cases extend indefinitely because of the geochemical processes at work in waste rock piles, tailings, and exposed workings. These give rise to potential liabilities that must be factored into annual financial statements and the calculation of share value.

Second, the mine design process must consider the mineral life cycle. The mining industry has come to learn that it must not only consider the production of minerals and metals but also their use. Too often in the past, the mine design process has limited its perspective in time and space to the immediate mine operation. In fact, many significant implications extend across space and time in a kind of ripple effect (Figure 16.2-5). Some of these—both positive and negative—are significant. And all must be taken into consideration to ensure that the full contribution is accounted for.

Third, the time horizon to be used needs particular mention. Table 16.2-1 lists different perspectives on the time horizons relevant to applied sustainability. This element of the boundary conditions for the mine design, operation, and closure processes has changed dramatically in the last few decades. The mine project life cycle shown in Figure 16.2-3 illustrates how the time horizon evolved after the 1970s to eventually take into considerations the postclosure phase, which can sometimes stretch environmental and social obligations of mining operations into perpetuity. This is new terrain for all interests—industry, government, host communities, and civil society organizations—and is not yet fully understood or appreciated.

Table 16.2-1 Perspectives on the time horizons for applied sustainability

Perspective	Typical Time Horizon
Financial/tax cycle	Annual or quarterly
Election cycle	2, 4, or 5 years
Standard engineering design life	Up to 50 years
Social time horizon (seven generations)	Up to 200 years
Environmental time horizon	200 to 10,000+ years

Source: Adapted from Freeze 1987.

The fourth and final aspect of defining the boundary conditions for applying sustainability relates to identifying the communities of interest that must be considered in the mine design, operation, and closure process. In times past, a company and government would simply come to a bilateral agreement on conditions that would govern mine activities. Today that is no longer the case. Many interests play active roles, and the definition of those roles itself requires great care and attention. Interests important to mining are

- Industry (investors, employees, industry associations, other companies);
- Support services (financial, consultants, contractors, suppliers);
- Government (federal, state/provincial, county/regional district, local);
- Indigenous people and their organizations;
- Organized labor;
- Mining-affected communities (by economic, social, and/or environmental [e.g., watershed] dependency);
- NGOs or civil society organizations; and
- Academic, learning, and research and development support (universities, technical schools, private and public research centers).

SEVEN QUESTIONS TO SUSTAINABILITY

One product of the mining industry's MMSD project was a template aimed at assessing the compatibility between mining operations and sustainability criteria (MMSD North America 2002; Hodge 2004, 2006). The 7QS offers seven queries for consideration in the mine design and assessment process. Each question is the interrogative form of a goal statement. Seen in another light, these seven goals define the application of sustainability concepts. The technique of using the interrogative form in this way is drawn from the accounting profession's approach to auditing and assuring the validity and accuracy of financial statements.

The focus on applying the 7QS approach is not on how a given mine can be sustainable—mining as a discrete activity cannot continue indefinitely—but on how the process of mining and the products it produces can best contribute to sustainable development. Thus it enshrines the conceptual shift away from analysis and mitigation of *impacts* to analysis and encouragement of *contribution*.

The seven questions are summarized in Figure 16.2-6. In this section, the 7QS template is used to systematically organize the parts of applied sustainability, rendering their application more practical. (The material presented in this section is modified from MMSD North America 2002.) In applying this

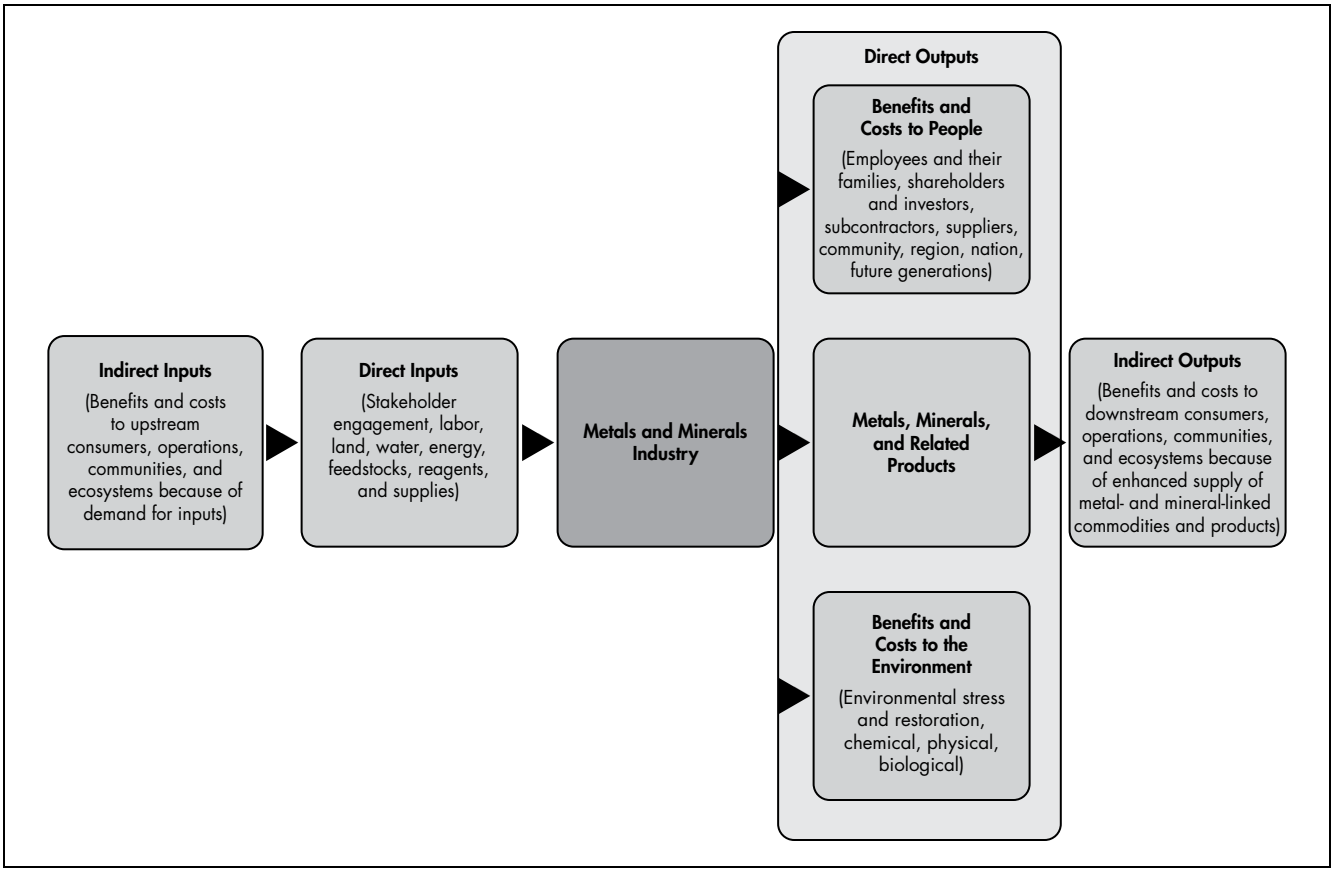

Figure 16.2-5 Ripple effect

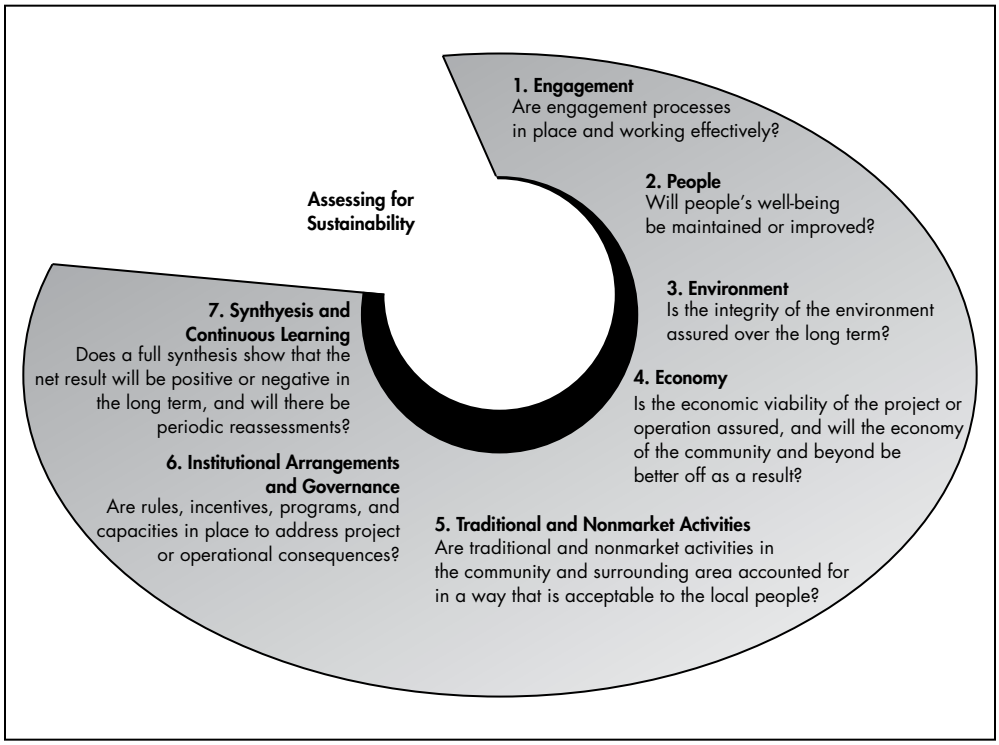
template, attention must be paid to the compilation and analysis of both quantitative and qualitative insights. Ultimately in assessing effectiveness, efficiency, and progress, four distinct steps are essential (Hodge 2007):

1. Drawing the qualitative insight that comes through understanding the **story** that is relevant to the object(s) of the assessment
2. Undertaking and compiling the relevant quantitative **measurement**
3. Applying a systemic approach to synthesizing, setting criteria, and **judging** significance
4. Effectively **communicating** the results to different key interests



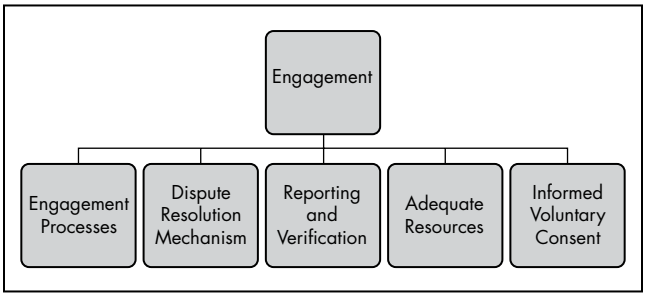
The 7QS approach encompasses four categories of insight:

1. **Relationships.** Question 1 in Figure 16.2-6 (engagement) deals with the state of relationships that are important to any given project or within any region that is being assessed (see Thomson and Joyce 2000 for a succinct discussion of this topic). A key issue facing many projects is the sense that the distribution of costs, benefits, and risk is unfair. This sense can cause stakeholder reactions that range from feelings of discontent to outright civil disobedience and damage to persons and property. Although detailed procedures will vary from site to site, the 7QS approach calls for addressing this issue early and in a way that facilitates constructive relationships achieved over the full project life cycle.
2. **Ends.** Questions 2 (people) and 3 (environment) focus on the end results that must be achieved and against which the success of any project must be tested—human and ecosystem well-being over the long term.
3. **Means to achieving ends.** Questions 4 (economy), 5 (traditional and nonmarket activities), and 6 (governance and institutions) cover the various means of achieving human and ecosystem well-being.
4. **Feedback.** Lastly, Question 7 (synthesis and continuous learning) provides the feedback mechanism that allows managers and others to ensure accountability and to learn from the inevitable mistakes, adapt and improve designs as necessary, and celebrate the successes, giving credit where due.

Effective Engagement

If relationships with those important to a mining/minerals/metals project are unhealthy, the chance of achieving a successful project—one that contributes to sustainability—is greatly reduced. Although this is a simple idea and one that is key to many successful nonmining businesses around the world, application of this idea is only now gaining momentum across the industry.

At any point in time, mining activities must align with the norms and values of society as a whole. When it does, a social license to operate is the result—an unwritten approval. If that alignment is not apparent, the social license will be challenged. Within the mining industry, elucidation of this concept has been led by Ian Thomson and Susan Joyce (2008).



Courtesy of the International Institute for Sustainable Development.

Figure 16.2-6 Seven Questions to Sustainability

Thomson and Joyce (2006) have also played a lead role in recognizing the central role of the explorationist and junior companies (that are the first to enter an area) in either creating lasting positive relationships or a climate of long-term tension. Working to entrench such acceptance is an insurance policy that includes both the ability to recognize meaningful change and the ability to consider accommodating these changes.

Building a constructive engagement with the local community involves a series of challenging steps to (1) identify key interests, (2) learn how to listen to each interest's concerns amid all the noise of existing pressures, and (3) develop a way forward for mining and metals operations based on mutual respect, trust, and integrity. It requires effort and resources, sometimes just as much as many technical aspects of a project. And today, with the changing and growing role of many interests in society, if care is not taken to build the needed relationships, implications for proceeding effectively and efficiently on a project can be seriously undermined. At worst, physical conflict can occur.

A leading example of addressing community relationship issues has been completed by Newmont Gold Corporation (2009). In this case, concerns over conflict led an ethical investor to ask for a complete review of the relationships between Newmont operations and its host communities. The initial work, completed over 2 years, included an independent review panel. Building on existing and past attempts to build effective relationships, it led to a series of company–host community interactions that, in turn, changed Newmont's own internal management system. One result was that, in 2010, Newmont was ranked 16th in *Corporate Responsibility* magazine's 11th Annual List of 100 Best Corporate Citizens in the United States (*Corporate Responsibility* 2010), the only mining company in the top 20 and joining such businesses as Hewlett-Packard, Intel, Gap, IBM, and Microsoft.

Courtesy of the International Institute for Sustainable Development.

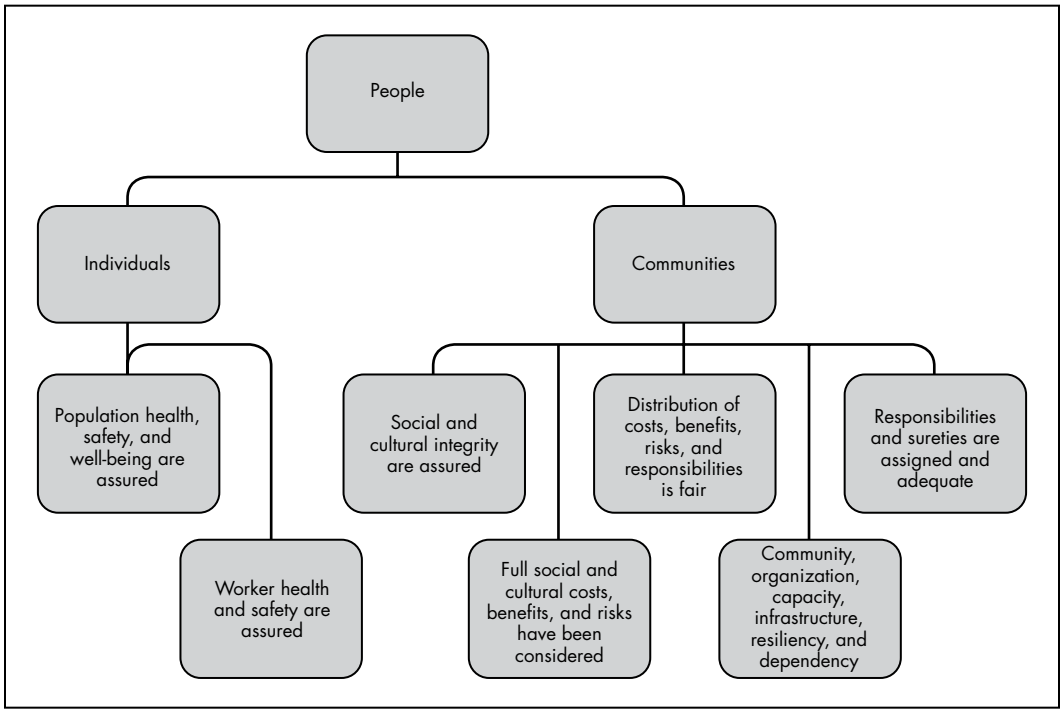
Figure 16.2-7 Assessing the effectiveness of relationships between operations and other interests

A particularly important issue for the mining industry is building effective relationships with indigenous people. A useful overview of issues relevant to this topic can be found in Render 2006. A current perspective on how to best achieve effective working relationships with indigenous people is provided in ICMM 2010b. This is especially relevant for countries where the legal system does not provide strong protections for indigenous peoples. In the last decade, indigenous peoples' concerns have led to the emergence of special impact benefit agreements that formally entrench special arrangements for participation. A current tool kit addressing such agreements is now available (Gibson and O'Faircheallaigh 2010).

Considerations important to building effective relationships are shown in Figure 16.2-7. Table 16.2-2 is modified from the 7QS work and lists the ideal answer to the question,"Are engagement processes in place and working effectively?,"and offers example indicators that can be considered for compilation in order to assess how close a given mining or metals

Table 16.2-2 Engagement: Are engagement processes in place and working effectively?

Question (Goal)	Ideal Answer (Objectives)	Example Indicators
Are processes of engagement committed to, designed, and implemented that • Ensure all affected communities of interest (including vulnerable or disadvantaged subpopulations due to, for example, minority status, gender, ethnicity, or poverty) are well informed and have the opportunity to participate in decisions that influence their own future; • Are understood and agreed upon by implicated communities of interest; and • Are consistent with the legal, institutional, and cultural characteristics of the community and country where the project is located?	Satisfactory processes of engagement have been designed and implemented that • Ensure all affected communities of interest (including vulnerable or disadvantaged subpopulations due to, for example, gender, ethnicity, or poverty) are well informed and have the opportunity to participate in the decisions that influence their own future; and • Are understood, agreed upon, and consistent with the legal, institutional, and cultural characteristics of the community and country where the project is located.	Input ⇓ Output ⇓ Result
	As indicated by:	
	Engagement processes. Engagement processes are in place for all phases of the project/operation life cycle to serve as a mechanism for • Collaboratively identifying desired objectives, best approaches for gathering evidence in support of achieving objectives (quantitative and qualitative), assessment criteria, trade-offs and the bases for judging trade-offs; and • Overseeing the application of the approach to assessing the contribution to sustainability articulated here.	• Comprehensive mapping of interests completed. • Design of engagement strategy completed, including guidelines that are agreed upon by all interests • Full and satisfactory disclosure of project-related information • Effective implementation as signaled by participant satisfaction
	Dispute resolution mechanism. An agreed upon, affordable dispute resolution mechanism (or set) exists and is understood by and accessible to all communities of interest.	• Dispute resolution mechanism(s) • Effective mechanisms as signaled by participant satisfaction
	Reporting and verification. Appropriate systems of reporting and verification are in place.	• Systems in place • Systems working effectively from perspective of various interests
	Adequate resources. Adequate resources have been made available to ensure that all communities of interest can effectively participate as needed. Note: Responsibility for ensuring that this capacity is in place rests with a mix of government, company, and the local community itself. The exact distribution of this responsibility should be worked out collaboratively.	• Adequate resources available • Satisfaction with level of support • Effective participation achieved as assessed by company, community, indigenous peoples, and government
	Informed and voluntary consent. The informed and voluntary consent of those affected by the project or operation has been given. Note: Inclusion of this factor does not imply that consent be given as a requirement for a project to proceed. The responsibility for approval lies with the relevant regulatory agency that is mandated by the laws of the country. Rather, this factor is included as a means to assess the extent of concurrence of those affected by a project. If that concurrence is high, the potential for achieving a net positive contribution to sustainability is greatly enhanced. In contrast, if negative feeling toward a project or operation is extensive, that potential is greatly reduced.	• Broad community support



Source: Adapted from MMSD North America 2002.

operation is to achieving the ideal answer. In turn, the breadth of knowledge that Table 16.2-2 spans provides an indication of what any mining operation might be expected to take into consideration when addressing this aspect of sustainable development.

Contributing to Human Well-Being

Most inside the mining industry take it for granted that mining activities contribute to society in general, to investors that risk their capital, to management and workers who are gainfully employed as a result, and to the many host communities who experience the secondary and tertiary benefits that ripple out from any mining activity. However, following hard on the heels of the rise of the contemporary environmental movement came close examination of the social and economic implications of mining activities, particularly in emerging nations. One observation that emerged was that examples of developing economies suggested a link between mining activity and ongoing poverty. In these instances, was the presence of natural resources in fact a "resource curse" resulting from a combination of poor governance, corruption, and civil war? There is a large amount of literature on this subject (e.g., see Davis 2009, Crowson 2009, Auty 1993, and Sachs and Warner 1995).

More recently, work completed by the ICMM (McPhail 2008) has demonstrated that the resource curse needn't occur if appropriate collaborative action is taken. The ICMM work has identified six key areas of focus: (1) poverty reduction,

Courtesy of the International Institute for Sustainable Development.

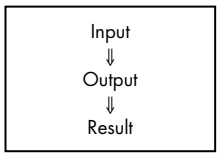
Figure 16.2-8 Example factors to consider in assessing the contributions of mining and/or metals operations to human well-being

(2) revenue management, (3) regional development, (4) local content (the use of local labor and locally derived services and supplies), (5) social investment, and (6) dispute resolution. The key to success is the use of collaborative approaches involving host governments, companies, civil society, and donor agencies.

One spin-off of the emergence of sustainability ideas starting in the mid-1980s, the resource curse debate of the 1990s and 2000s, and the ongoing challenging of the mining industry by NGOs and in some cases host governments is a realization that much greater effort is required to understand, capture, and share the nature and extent of mining and metal's contribution to human well-being. No longer can it simply be taken for granted.

A key issue requiring attention in emerging economies is a documented gender bias in mining whereby benefits (such as employment, income, training, education, and health care) accrue largely to men and the local elite while most risks (such as family and social disruption, domestic violence, alcoholism, HIV/AIDS, increased prostitution, loss of gardens for subsistence agriculture, pollution, and water losses) fall on the poorer women, the less advantaged, and the families they care for (see Eftimie et al. 2009a and 2009b). A company purchasing the bulk or all of its produce needs locally can be beneficial for local farmers and landowners who see prices increase for their produce, but this can also have the unintended effect of worsening the situation for the poor community women who may be unable to afford the higher food prices. These are complex issues that require careful management approaches for any mining company.

Figure 16.2-8 offers example factors to be considered in answering the question—"Will people's well-being be maintained or improved" by a given mining, minerals or metals operation? These factors draw on the foundation provided by socioeconomic impact analysis but use the lens of contribution. Table 16.2-3 then provides both the ideal answer as well as examples of the kind of indicators that might be considered in assessing how close a given operation is to meeting the ideal answer. As in the previous section, the range of topics provides a sense of what sustainable development means to mining from this particular perspective.



Contributing to Ecosystem Well-Being

The relationship between a mining operation and its host environment is the focus of the environmental impact assessment and the resulting environmental management plan and related environmental management systems. The approach used here builds on this foundation.

Figure 16.2-9 shows one way of conceptualizing the environmental implications of a mining operation. It looks at chemical, physical, and biological implications from both the generation of environmental stress and the linked potential for ecosystem restoration. The concept of restoration that is used here is *not* the idea that everything needs to be returned to a chemical, physical, and biological premining state. Rather, a robust ecosystem is sought that is naturally reproducing and sustainable. This is the domain of the emerging science and art of *restoration ecology*.

A chemical, physical, and biological characterization of environmental implications is traditional and helpful from several perspectives, including (1) often regulatory requirements are organized in this manner; (2) the professional expertise that must be drawn on is often organized in this way; and (3) traditional education is offered in this way and therefore management's understanding is often aided by this approach.

Table 16.2-3 People: Will people's well-being be maintained or improved?

Question (Goal)	Ideal Answer (Objectives)	Example Indicators
Will the project/operation lead directly or indirectly to maintenance of people's well-being, preferably an improvement • During the life of the project or operation, or • In postclosure?	The project or operation will lead directly or indirectly to the maintenance or improvement of people's well-being • During the life of the project or operation or • In postclosure As indicated by:	
	Community organization and capacity. Effective and representative community organization and capacity (knowledge, skills, and resources) are in place in the local community, including representation of women and the disadvantaged in community leadership and decision making. Note: Responsibility for ensuring this capacity is in place rests with a mix of government, company, and the local community itself. The exact distribution of this responsibility should be worked out collaboratively.	• Presence of an organizational structure that links and represents the community in project-related decision-making processes • Training facilities in place • Local education/skills level to serve project needs and provide basis for postclosure activities • Community access to the information and expertise needed to ensure that properly informed decisions are made
	Social/cultural integrity. All communities of interest have a reasonable degree of confidence that social and cultural integrity will be maintained or preferably improved in a way that is consistent with the vision and aspirations of the community. Involuntary resettlement and other interventions will be undertaken in such as way as to maintain or preferably improve social and cultural integrity. Note: This category is particularly dynamic and will change as a project proceeds.	• Existence of community and regional visions expressed explicitly in development and land-use plans • Presence of key indicative social structures and their states • Sense of satisfaction signaled by all interests that social and cultural integrity will be maintained or improved (including separate consultations with community women and representatives of disadvantaged groups in the community) • Social and cultural indicators identified as significant by the community • Preparation and implementation of community-supported and project-induced migration management plans to help manage the impacts of the inflow of outsiders that occurs when a mining development is expected or announced
	Worker and population health, safety, and well-being. Improvement of indicators of worker and population health, safety, and well-being are maintained or improved. Note: Responsibility for gathering this data and information lies with a mix of company (in terms of workers), community, and government. However, statistics on population health, training and education, jobs, income, poverty, debt, community resiliency, and community dependency typically fall to government.	• Baseline studies completed that include basic demographics to track population change (birth rate, infant mortality, morbidity rates, in/out-migration), household incomes, and so forth, including gender disaggregated data • Worker health and safety • Population health • Training and education • Jobs, income, poverty, debt • Crime and security • Community resiliency • Community dependency
	Availability of basic infrastructure. The infrastructure to meet basic needs is available to workers and residents.	• Water supply, sewage and wastewater treatment, power, communications, transportation, education, health services
	Consideration of all direct, indirect, and induced or diffuse effects. All communities of interest have a reasonable degree of confidence that all direct, indirect, and induced or diffuse effects have been considered and addressed. Note: Requirements will change through the project.	• Direct, indirect, and induced or diffuse economic, social, and cultural effects of project • Changes in social behavior as a result of the project
	Full social/cultural costs, benefits, and risks. All communities of interest have a reasonable degree of confidence that the full costs, benefits, and risks to people have been identified and factored into project or operation-related decision making (as it applies throughout the full project or operation life cycle).	• Satisfaction that all social/cultural costs, benefits, and risks found across the full life cycle from exploration through postclosure have been identified and addressed

Source: Adapted from MMSD North America 2002.

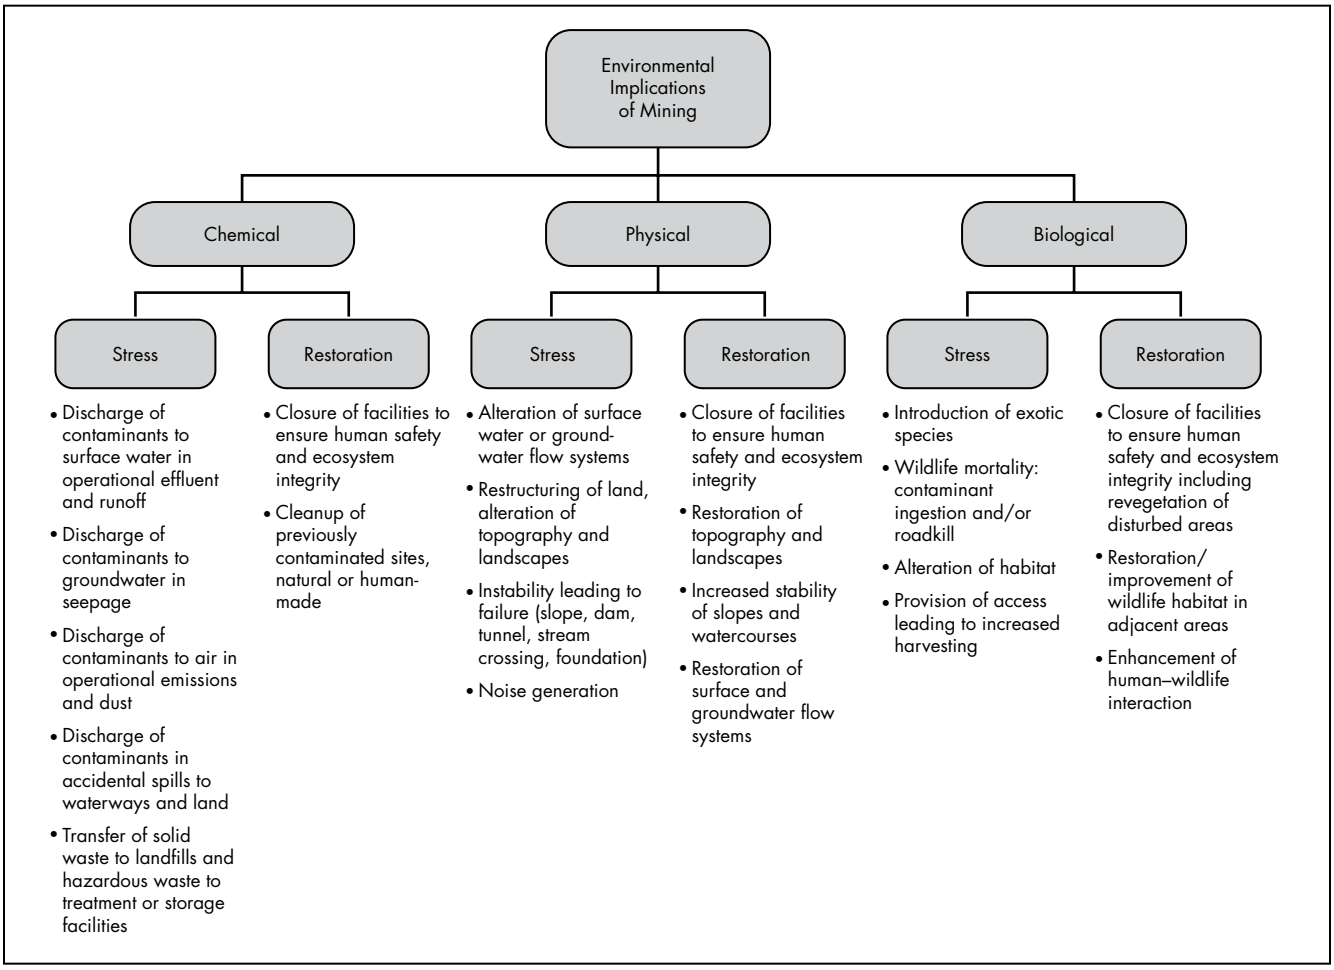


Figure 16.2-9 Chemical, physical, and biological implications of mining/metals operations

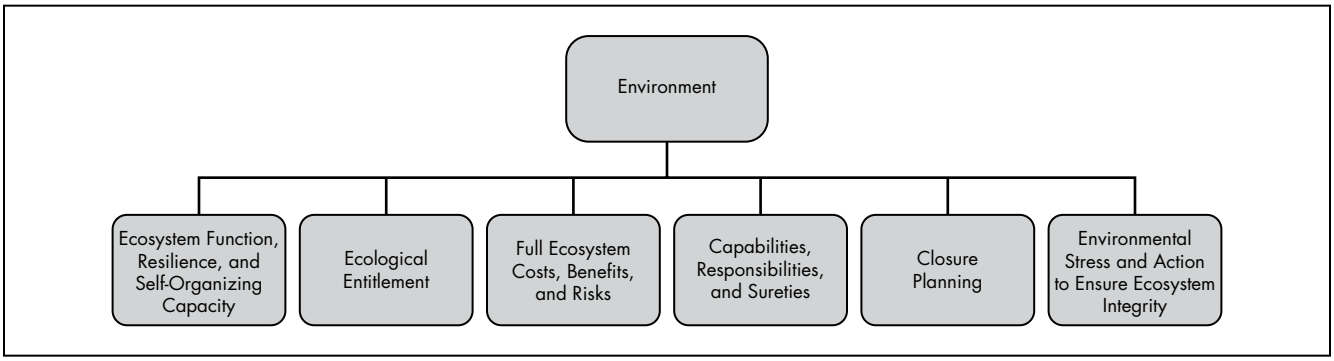

However, the ecological system does not function in such a compartmentalized way, and those expert in ecology in general and ecological restoration in particular have offered alternative ways of addressing this challenge. Figure 16.2-10 offers such an approach, and Table 16.2-4 addresses the question—"Is the integrity of the environment assured over the long term?"—and provides both an ideal answer to this question as well as an example set of indicators that, if compiled, would serve to facilitate an assessment of how compatible a mining/metals operation would be with sustainable development An increasingly important emerging issue is understanding the full life-cycle environmental contribution of the metals. Much remains to be learned about the technique of life-cycle analysis.

Economic Viability: Project, Community, Nation

Understanding the economics of a project lies at the heart of successful mining from a management and investment perspective. Two key factors govern project economic stability: (1) the licensing and fiscal regimes under which mining takes place—that they are efficient, noncorrupt, and result in security of tenure; and (2) an equitable sharing of costs, benefits, risks, and responsibilities between the host country and the investor.

For any project to be successful, the deposit, the company, and industry must all be economically viable. The typical economics of a mine is such that the first few years (generally, years 1 to 5) are usually very profitable, which is necessary to serve investors who require a return on invested capital. Middle years are moderately profitable (generally, years 6 to 15), and older mines are usually marginally viable. Company managers strategize from this perspective because it is their legal responsibility to protect the investors. If a large number of operating mines within their system are in the older phase, a company can be vulnerable. However, from the perspective of an employee or service provider, the mine is meaningful as long as it operates and provides employment. And the concern from the local, regional, or national government is that the mine leads to a lasting contribution—however that is achieved. These different perspectives all factor into the sustainable development equation.

However, they do not imply that a project/company should be assuming responsibility for the local, regional, or national economy. Rather, it is often possible that by working in collaboration with in-country partners, benefits can be achieved for the host community, region, or country that involve little cost to the company but have significant benefits for the host. Further, if unintended economic consequences related to this broader perspective arise and are not recognized, they may result in a liability to the company over the long term that can have grave consequences, including the possibility of the national/local business environment deteriorating to the point

Figure 16.2-10 Elements for assessing the contribution of mining/metals operations to the environment over the long term

Table 16.2-4 Environment: Is the integrity of the environment assured over the long term?

Question (Goal)	Ideal Answer (Objectives)	Example Indicators
Will the project or operation lead directly or indirectly to the maintenance or strengthening of the integrity of biophysical systems so that they can continue in postclosure to provide the needed support for the well-being of people and other life forms?	The project or operation will lead directly or indirectly to the maintenance or strengthening of the integrity of biophysical systems, as indicated by:	Input ⇓ Output ⇓ Result
	Ecosystem function, resilience, and self-organizing capacity. All communities of interest hold a reasonable degree of confidence that ecosystem function, resilience, and self-organizing capacity will be maintained or improved over the long term.	• Baseline studies completed • Monitoring systems in place • Projected effects of project on indicator species of aquatic and terrestrial flora and fauna (identified through both scientific assessment and traditional ecological knowledge studies) • Projected long-term well-being of water systems and renewable resources in the area of the mine/mineral project • Tracking rapid geological change
	Ecological entitlement. All communities of interest have a reasonable degree of confidence that the capacity of project-affected renewable and nonrenewable resources will be maintained or improved such that the needs of both present and future generations will be met.	• Degree of confidence
	Full ecosystem costs, benefits, and risks. All communities of interest have a reasonable degree of confidence that the full costs, benefits, and risks to the ecosystem have been identified and factored into project/operation-related decision making (as it applies throughout the full project/operation life cycle).	• Full or total cost-accounting tools to assess the implications of the project • Satisfaction that all social/cultural costs, benefits, and risks related to the full life cycle from exploration to postclosure have been identified and addressed
	Capabilities, responsibilities, and sureties. All communities of interest have a reasonable degree of confidence that the responsibilities and sureties for ensuring both short- and long-term ecosystem well-being have been fully and fairly assigned and accepted and that those responsible have the capacity and willingness to fulfill their roles (including responsibilities attached to company, community, government, or NGO).	• Financial sureties and mechanisms to address potential present and future environmental liabilities and effort required to ensure the continuing integrity of biophysical systems • Satisfaction that sureties and mechanisms will provide adequate bridging to postclosure state.
	Closure planning. All communities of interest are satisfied that closure plans meeting best industry practice have been completed; mine design and implementation are driven by closure requirements to ensure that long-term financial, environmental, and social costs are minimized.	• Closure plans to best industry practice are in place and fully integrated into mine design and implementation

(continues)

Table 16.2-4 Environment: Is the integrity of the environment assured over the long term? (continued)

Question (Goal)	Ideal Answer (Objectives)	Example Indicators
Will the project or operation lead directly or indirectly to the maintenance or strengthening of the integrity of biophysical systems so that they can continue in postclosure to provide the needed support for the well-being of people and other life forms?	**Environmental stress and action to ensure ecosystem integrity.** Physical, chemical, and biological stress imposed on the ecosystem by the project or operation does not threaten the function, resilience, and self-organizing capacity of the biophysical system; and appropriate actions are taken to ensure the continuing integrity of biophysical systems.	• Material inputs/flows—water (surface, ground), energy (by form and source), reagents (e.g., cyanide), fuels, solvents, lubricants, other supplies • Recycling – Material recovery, oil, solvents, lubricants, batteries, tires, etc. – Waste – Hazardous and solid waste generated and discharged • Water quality – Surface water: effluent chemistry, ambient water quality downstream, stream sediment storage and load – Groundwater: contaminant plume, plume chemistry, ambient quality downstream • Water quantity—maintenance of surface and groundwater supplies • Acid rock drainage and metal leaching—tailings, waste rock, workings; short- and long-term treatment required • Soils – Chemical, biological, and physical change – Erosion • Rapid and long-term landscape change – Deep open pits, mountaintop removal – Landslides and avalanches • Air quality – Emissions chemistry – Indoor air quality – Greenhouse gas emissions • Noise, on- and off-site • Environmental incidents, on- and off-site • Reclamation and restoration, on- and off-site • Environmental effects monitoring system in place

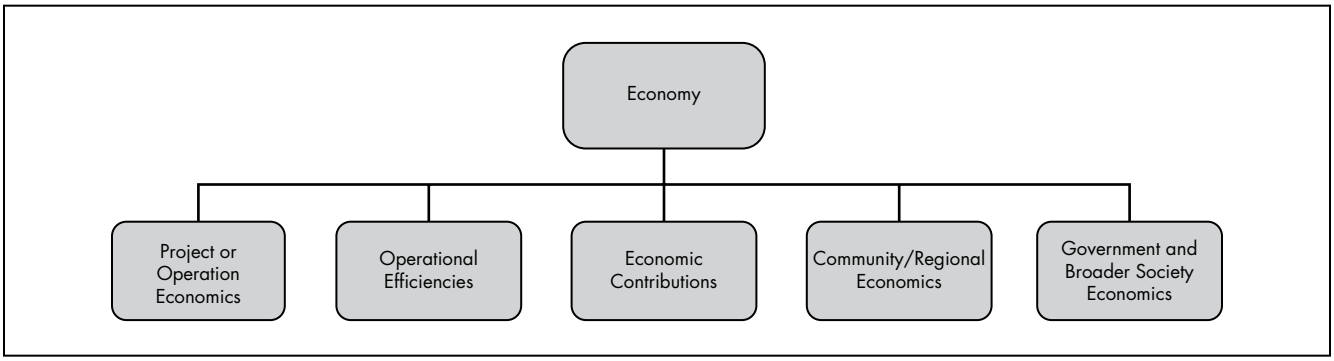
Source: Adapted from MMSD North America 2002.

where the company can no longer operate efficiently or, in the worst case, not at all. These are significant risks.

Figure 16.2-11 is a simple characterization of the economic aspects that require consideration. Table 16.2-5 responds to the question—"Is the economic viability of the project assured; will the community and broader economy be better off as a result?" It then offers an ideal answer to that question and a set of example indicators that can be compiled to assess how close a given operation is to the ideal condition.

Traditional and Nonmarket Activities

Since the 1980s, recognition has been growing of the significance of traditional and nonmarket activities—human activities that are not part of the market economy and therefore not captured in the accounting systems that underlie our systems of taxation or the national accounts.



National accounts are used to track the flow of goods and services in the economy. Contributing data are organized in an indtustry classification system, which provides a useful indication of human activity. The compiled data are used to calculate such indicators as national income and gross domestic product or gross national product. However, many activities important from a sustainability perspective lie outside the formal market economy. One way of getting a sense of these is to consider the vast array of organizations of civil society, those engaged in not-for-profit work. Table 16.2-6 is a listing of the general categories of a classification of nonprofit institutions, which was developed at Johns Hopkins University and subsequently adopted by the United Nations (2003).

Often, reacting to public criticism, mining companies focus on environmental or social advocacy groups. A more strategic approach would be to consider all aspects of civil society that are important in a given community, ensuring that the contribution of the mining/metals activity to nonmarket and traditional activities is as efficiently and effectively pursued as possible. Traditional culture-based activities of indigenous people lie within this aspect of the sustainability equation and are of particular importance to mining/metals operations in many parts of the world.

Figure 16.2-12 is a simple characterization of the traditional and nonmarket aspects that require consideration. Table 16.2-7 responds to the question—"Are traditional and nonmarket activities in the community and surrounding area accounted for in a way that is acceptable to the local people?" It then offers an ideal answer to that question and a set of example indicators that can be compiled to assess how close a given operation is to the ideal condition.

Institutional Arrangements and Governance

This category addresses the effectiveness of the formal and informal rules that society creates to govern activities such

Figure 16.2-11 Elements for assessing the economic viability of mining/metals operations over the long term

Table 16.2-5 Economy: Is the economic viability of the project assured?

Question (Goal)	Ideal Answer (Objectives)	Example Indicators
Is the financial health of the project/company assured and will the project or operation contribute (through planning, evaluations, decision making, and action) to the long-term viability of the local and regional economy in ways that will help ensure sufficiency for all and provide specific opportunities for the less advantaged?	The financial health of the project/company is assured and the project or operation will contribute (through planning, evaluations, decision making, and action) to the long-term viability of the local, regional, and global economy, as indicated by:	Input ⇓ Output ⇓ Result
	Project or operation economics. Project or operation economic success targets are achieved.	• Demonstrated positive project economics as calculated in the feasibility study; economic targets met as the project proceeds
	Operational efficiencies	• Mining efficiency • Processing efficiency • Refining efficiency
	Economic contributions: annual/total	Contributions • To the local economy • To the regional economy • To the national economy • To the global economy • Total
	Community/regional economics. Community and adjacent regional economic success targets are met, including direct employment, indirect employment, and small and medium business development.	• Demonstrated positive project economics as calculated in the feasibility study; economic targets met as project proceeds • Distribution of economic benefits resulting from the project between the company, government, and local community, and within the local community between men and women and between the wealthy and the disadvantaged
	Government/broader society economics. A net economic contribution to governments and broader society is achieved.	• Net financial gain for government as the project proceeds and meets economic targets, which contributes to economic growth and increased standards of living

as mining/mineral projects and operations. This is a complex area that includes internal corporate management systems as well those found in broader society. Although some rules are written, others are unwritten and simply accepted as part of culture—internal corporate culture and culture of the host community and country.

Internal Management Systems

Adaptation of internal management systems to sustainability is well under way. A useful overview of many related issues is provided by Botvin 2009. An early foundation was provided by the work of the International Organization for Standardization (ISO), which has developed widely accepted quality management systems (ISO 9001), environmental management systems (ISO 14001), and risk management principles and guidelines (ISO 31001).

Reporting and Assurance

Since the mid-1990s, there have been a number of significant developments regarding how a mining/metals company publicly reports its sustainability-related performance and how that reported progress is assured using independent third-party assurance. Three initiatives are particularly relevant to the mining industry:

Table 16.2-6 United Nations classification of nonprofit institutions

Group	Subgroups
1. Culture and Recreation	Culture and Arts, Sports, Other
2. Education and Research	Primary and Secondary, Higher, Other, Research
3. Health	Hospitals and Rehabilitation Nursing Homes, Mental Health and Crisis Intervention, Other

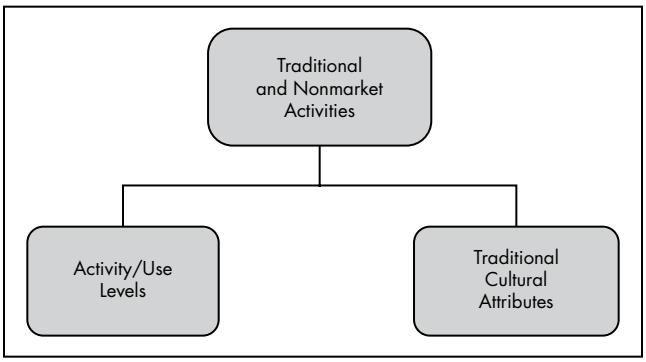
1. Mining and Metals Sector Supplement (MMSS) of the Global Reporting Initiative (GRI)
2. ICMM Reporting and Assurance System
3. Towards Sustainable Mining (TSM) system of the Mining Association of Canada (MAC)

All of these initiatives recognize that for the industry to improve its reputation and credibility, improved performance linked to an alignment with public values is essential. From a company perspective, there is a close link to risk management. All three of these initiatives are cognizant of the need to synchronize.



GRI MMSS. The GRI is a network-based organization that over the past decade has pioneered the development of the world's most widely used sustainability reporting framework. The GRI framework sets out principles and indicators that organizations can use to measure and report their economic, environmental, and social performances. At its heart sits the generic 2006 G3 Guidelines that refer to all applications. In addition, sector supplements and national annexes are being developed over time. As of 2010, 15 sector supplements have been developed, one of which is focused on mining.

Following 6 years of intense multistakeholder development, the GRI MMSS was released in March 2010 (ICMM 2010c). MMSS addresses the following nine main sector topics:

1. Biodiversity
2. Emissions, effluents, and waste
3. Labor
4. Indigenous rights
5. Community
6. Artisanal and small-scale mining
7. Resettlement
8. Closure planning
9. Materials stewardship

ICMM's reporting and assurance system. ICMM's system serves as a means to demonstrate that members have delivered on the commitments contained in the 10 ICMM principles and the related position statements (Figure 16.2-1). Members must meet GRI reporting requirements, and independent third-party assurance is required on an overall company system basis.

MAC's TSM initiative. MAC describes TSM as "a strategy for improving the mining industry's performance by aligning its actions with the priorities and values of Canadians; and a process for finding common ground with our communities of interest, to build a better mining industry today and in the future" (MAC 2010). TSM focuses on company management systems and provides a means of evaluating their quality, comprehensiveness, and robustness. As of 2010, four performance elements were finalized: (1) tailings management, (2) energy use and greenhouse gas emission management, (3) external outreach, and (4) crisis management planning. In addition, work on aboriginal relations, biodiversity conservation, safety and health, and mine closure is in varying states of implementation.

Figure 16.2-12 Elements for considering implications of mining/metals operation on traditional and nonmarket activity

Nation-Based Mining Law

In all cases, host countries own the natural resources. Thus complex systems of laws and regulations are put in place to guide exploration, production, closure, use, reuse and recycling. Every company is responsible for developing an understanding of the particular regulatory regime that is in place where it is active.

Important International Agreements

A large number of international agreements have significant implications for the mining, minerals, and metals industry. These range from the transport of hazardous materials to human rights and chemicals management. Here, too, it is the responsibility of companies to understand this complex part of the operating environment.

Table 16.2-7 Traditional and nonmarket activities: Are traditional and nonmarket activities accounted for in a way that is acceptable to the local people?

Question (Goal)	Ideal Answer (Objectives)	Example Indicators
Will the project/operation contribute to the long-term viability of traditional and nonmarket activities in the implicated community and region?	The project/operation will contribute to the long-term viability of traditional and nonmarket activities in the implicated community and region, as indicated by:	Input ⇓ Output ⇓ Result
	Activity/use levels. Maintenance of activity/use levels is designated by the community in question.	• Baseline study of traditional and nonmarket activities completed • Dependency levels on traditional and nonmarket activities
	Traditional cultural attributes. Maintenance of traditional cultural attributes is designated by the community in question.	• Use of indigenous language • See also Table 16.2-3

Assessing the Effectiveness of Institutional Arrangements and Governance

Elements that could contribute to an assessment of the effectiveness of institutional arrangements and governance are shown in Figure 16.2-13 and are described in greater detail in Table 16.2-8.

Synthesis and Continuous Learning

Many companies employ an internal system of planning, decision making, implementation, performance assessment, and adjustment as a matter of course. This element of the 7QS framework calls for the same kind of approach to be taken but using the lens of sustainability as the driver. Example elements that could contribute to an assessment of the effectiveness of an overall integrated evaluation and capacity for continuous learning and improvement are summarized in Figure 16.2-14 and described in greater detail in Table 16.2-9.

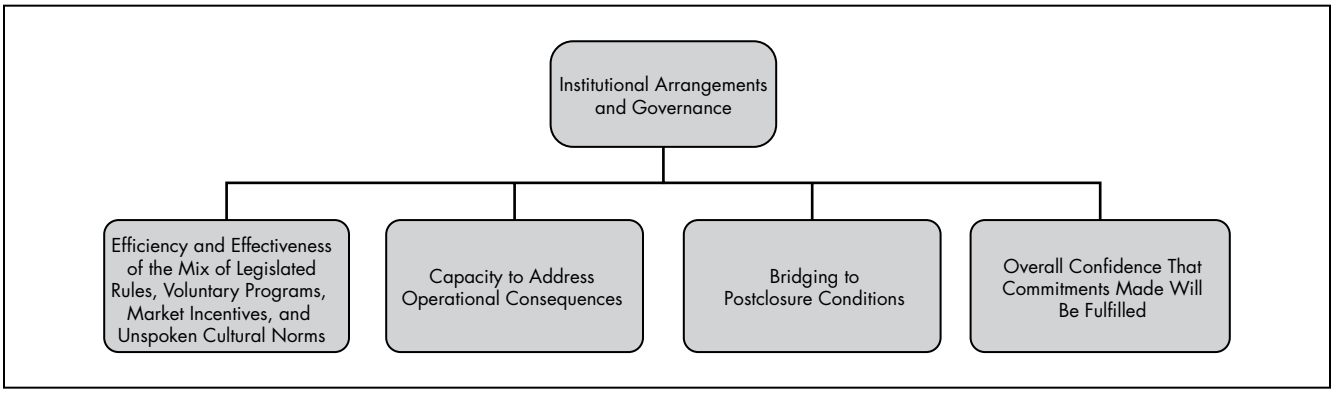
PERSPECTIVES BY PROJECT LIFE-CYCLE PHASES

Application of sustainability concepts to the mining, minerals, and metals industry requires attention paid to the full project and mineral life cycles (see earlier discussion in the "Boundary Conditions for Applying Sustainability Ideas to Mining" section). A cursory summary of phase-by-phase observations follows. (This discussion is modified from MMSD 2002.)

Exploration

Exploration is the starting point of the entire mineral project life cycle. However, only 1 out of 1,000 exploration projects ever evolves to the next level of activity (often more exploration). Explorationists generally have the objective of getting into and out of areas quickly and moving on to the next evaluation. Exploration is highly competitive and therefore secretive by design. Without positive relationships with the local community, serious tensions can occur. For their part, local residents want to know what is happening and how their lives might be affected. Left to ferment, anger and/or unintended expectations can grow—either of which can subsequently cause difficulty. Although the extent of the human and environmental implications is less than in later phases of activity, they can be profound. Oftentimes concerns center on access routes, which can open up large areas of untouched territory.

Exploration is the first time that the desirability or appropriateness of mining in a particular area is considered. Because exploration sets the stage for all that follows, the nature of the relationship established between the exploration team and affected communities of interest sets the tone going forward. Only in the last few years have models for appropriate engagement during exploration begun to emerge (e.g., see Thomson and Joyce 2006 and 2008).



The leading node of guidance on exploration and sustainability comes from the Prospectors and Developers Association of Canada (PDAC) and its e3 Plus Framework for Responsible Exploration (PDAC 2010). The program is aimed at helping exploration companies continuously improve their social, environmental, and health and safety performances and to comprehensively integrate these three aspects into all their exploration programs. It includes a set of overarching principles and explanatory guidance notes; and three comprehensive tool kits addressing social responsibility, environmental stewardship, and health and safety. For their part, the principles deal with

- Responsible governance and management,
- Ethical business practices,
- Human rights,
- Project due diligence and risk assessment,
- Engagement with host communities and other affected and interested parties,
- Contributing to community development and social well-being
- Protecting the environment, and
- Safeguarding the health and safety of workers and the local population.

The e3 Plus program is currently examining options for reporting and assurance that will echo those described. A significant driver is the demand by senior firms that the conditions they might inherit through acquisition of advanced exploration projects take into consideration the full range of sustainability components, in particular the need for effective engagement with host communities.

Design and Construction

Relative to other phases of activity, the design and construction phase is short. However, this intense pulse of activities and related social and environmental implications can be destructive if not carefully managed. This phase of activity

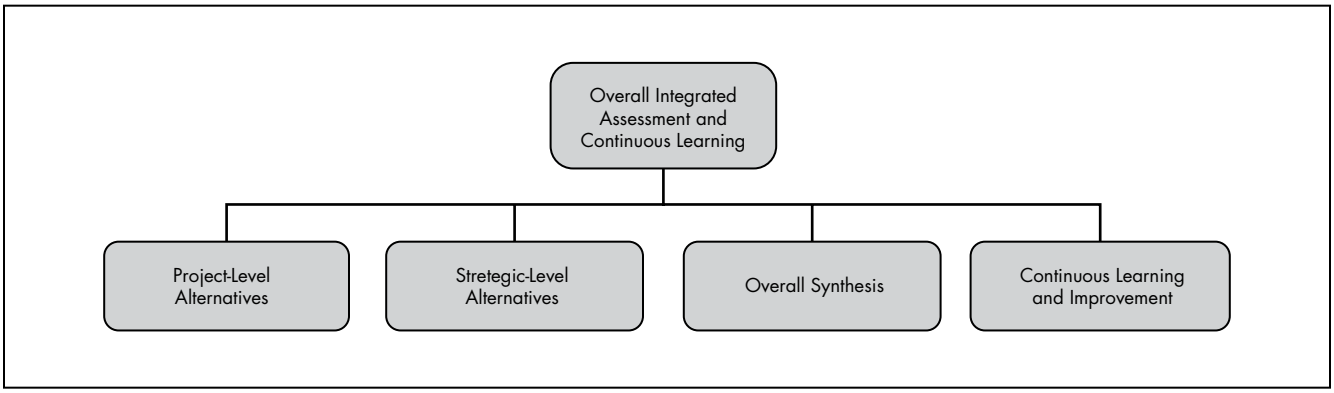
Figure 16.2-13 Example elements for assessing the effectiveness of institutional arrangements and governance

Table 16.2-8 Institutional arrangements and governance: Are capacities in place to address project or operational consequences?

Question (Goal)	Ideal Answer (Objectives)	Example Indicators
Are the institutional arrangements and systems of governance in place to provide a reasonable degree of confidence that the capacity to address project or operation consequences will continue to exist through the full life cycle, including postclosure?	Satisfactory institutional arrangements and governance mechanisms are in place, as indicated by:	Input ⇓ Output ⇓ Result
	Mix of rules, market incentives, voluntary programs, and cultural norms. An effective mix of legislated rules, market incentives, voluntary programs, and cultural norms is in place for governing project activities.	• Satisfaction with mix from the perspective of the various communities of interest, including company, community, indigenous peoples, NGOs, government
	Capacity. A reasonable degree of confidence is held by all communities of interest that the capacity to address project or operation consequences is in place now and will continue to exist throughout the full project/operation life cycle, including postclosure.	• Capacity of community support infrastructure to meet the needs of residents and workers of the region • Monitoring and enforcement programs in place with adequate resources committed for the full project life cycle
	Bridging. A reasonable degree of confidence is held by all communities of interest that sufficient local capacity and commitment will be developed and an adequate level of resources will be accumulated and set aside throughout the life of the project/operation to ensure a smooth transition to an acceptable postclosure condition (ecological, social, cultural, economic) for the community that remains.	• Existence of community-based *nonmining* economic and social development initiatives
	Confidence that commitments made will be fulfilled. A reasonable degree of confidence is held by all communities of interest that commitments that have been made will be fulfilled.	• System of publicly reported reporting and assurance in place • Level of funding to cover rehabilitation/reclamation costs during operations and at closure



Source: Adapted from MMSD North America 2002.

also marks the time that formal approvals are sought and received. During approvals processes, key opportunities exist for engagement with communities of interest (see previous discussion of effective engagement in the "Effective Engagement" section).

The influx of outsiders seeking employment and new opportunities can create significant changes within the community—often for the worse—and preparation and implementation of a project-induced migration management plan that is acceptable to the established community population can help manage the impacts. Many of the activities are undertaken by subcontractors who may or may not follow the same practices as the project owner or manager. Effective systems (policy, management, oversight, incentives) for ensuring good practices are essential.

Operation

The operation phase typically receives the greatest amount of attention. When the general public conjures an image of a mining/mineral project or operation, it is the operation phase that is imagined, whether the activity be mining, smelting, refining, metals manufacturing, or recycling. Economic, social, cultural, and environmental implications are relatively well understood, although their treatment is uneven in practice.

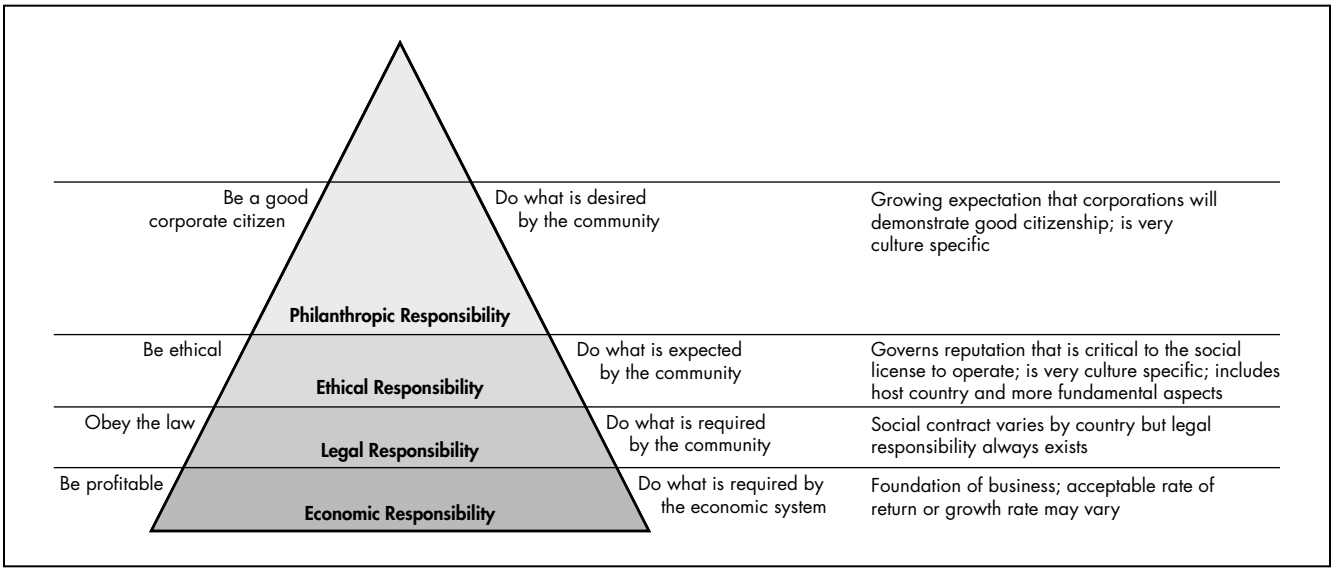
Figure 16.2-14 Synthesis and continuous learning—elements to consider

Table 16.2-9 Synthesis and continuous learning: Does synthesis show that the net result will be positive or negative?

Question (Goal)	Ideal Answer (Objectives)	Example Indicators
Has an overall evaluation been made and is a system in place for periodic revaluation based on • At the project level, consideration of all reasonable alternative configurations and designs (including the no-go option in the initial evaluation); • At the overarching strategic level, consideration of all reasonable alternatives for supplying the commodity and the services it provides for meeting society's needs; and • A synthesis of all the factors raised in this list of questions, leading to an overall judgment that the contribution to people and ecosystems will be net positive in the long term?	An overall evaluation been made and a system is in place for periodic revaluation based on consideration of • At the project level, consideration of all reasonable alternative configurations including the no-go option; • At the overarching strategic level, consideration of all reasonable alternatives for supplying the commodity and the services it provides for meeting society's needs; and • Synthesis of all the factors raised in this list of questions, leading to an overall judgment that the contribution to people and ecosystems will be net positive in the long term; As indicated by:	Input ⇓ Output ⇓ Result
	Project-level alternatives. All reasonable project alternatives have been considered.	• All key alternatives considered, for example: – Access – Transportation – Energy supply – Water supply – Local infrastructure – Tailings and effluent management – Mineral processing options
	Strategic-level alternatives	• Strategic level review that confirms project need
	Overall synthesis. A synthesis has been completed, and the system is in place to for periodic reassessment.	• Synthesis undertaken
	Continuous learning and improvement. A commitment to continuous learning and improvement is held by all interests, including company, community, government, and others.	• Mechanism(s) and resources in place to periodically repeat the overall sustainability assessment and report the results publicly



Source: Adapted from MMSD North America 2002.

Closure: Temporary, Final, Post

Temporary closure (due to changing metal prices, accident, disaster, or labor strife) rarely receives the pre-event planning and consideration that it should. Though often a temporary closure can run a few short days or weeks, sometimes so-called temporary closures can stretch into many years' duration.

While concepts of *design-for-closure* date from the 1970s (J. Gadsby, personal communication), concepts of sustainability now demand *design-for-postclosure*. Huge benefits can be realized by ensuring that closure and postclosure activities are conceived of and implementation is begun during the design and construction and operational phases of activity. Today, design-for-closure includes (1) physical environmental aspects, (2) social and community sustainability aspects, and, importantly, (3) financial assurance that resources will be available for needed closure and postclosure activities.

Design-for-postclosure involves a significant increase in the time horizon governing project design criteria, whether the focus be social or environmental in nature. Furthermore, successful design-for-postclosure identifies a need for involvement of those affected by postclosure conditions from the earliest phases of any project. Fortunately, in the case of closure and postclosure, research and experience have produced a number of successful models. One thing emerges from all

Source: Carroll 1991.

Figure 16.2-15 Carroll's pyramid of corporate responsibility and performance

of them: *succeeding custodians*, the people who will remain nearby long after mining operations cease, need to be at the table. It is only with their presence that their values can be factored into project implementation and the bridging role of a mine/mineral project or operation can be realized.

One delicate issue that the industry is now examining, which emerges because of the longer time horizons now being considered combined with the societal demand for greater transparency, is the whole question of estimating long-term closure liability and related financial assurance.

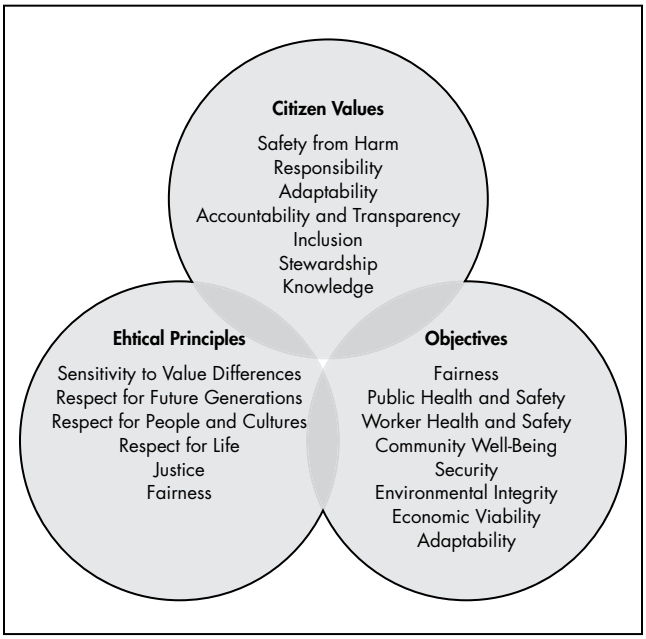
CORPORATE SOCIAL RESPONSIBILITY

Application of sustainability concepts to the mining, minerals and metals industry evokes yet another perspective that is growing in importance—the issue of corporate social responsibility (CSR). Establishing the nature and extent of a company's social responsibility is of deep importance in today's world. CSR provides a critical and natural overarching supplement to sustainable development and sustainability ideas and provides another direct connection to values through the addition of an ethical lens. At the same time, contemporary ideas of applied sustainability provide a foundation for CSR; they are closely linked but not the same.

Values are "something which is prized as of great worth and desirability: that which is respected and which motivates action...concepts which motivate actors in a general way to more specific goals" (Chadwick 1978). The described treatment of applied sustainability starts with a values-based proposition, one that says that we care for both people and the environment. In contrast, *ethics* is the science of right or wrong. It provides rules of behavior that signal what is considered decent and honest as opposed to misleading, dishonest, or unscrupulous.

Values and ethics combine to establish the boundaries of appropriate CSR. Over the last decade, there has been growing emphasis on CSR. The events in the financial services industry that sparked the 2008 recession have added fuel to the debate. Carroll (1991) offers an interesting and helpful pyramid of corporate responsibility and performance (Figure 16.2-15) and serves to illustrate a kind of hierarchy that applies to corporate responsibility.

Revenue Transparency and the Extractive Industries Transparency Initiative



One dimension of CSR that has been in the limelight has been the question of the revenues that flow from an active operation to the government. Concerns that these revenues were being intercepted for personal gain led to the creation of the Extractive Industries Transparency Initiative (EITI). Launched at the World Summit on Sustainable Development in Johannesburg, South Africa, in September 2002, EITI has grown to become a broad coalition of governments, major organizations of civil society, institutional investors, international organizations, international financial institutions, and companies (oil and gas, mining). EITI is active in 47 countries in which mining plays a significant role in the economy.

EITI represents a global standard for (1) extractive companies to publish the revenues they pay to governments in implementing countries (taxes, royalties, licenses, fees); (2) national governments to disclose what they receive; and (3) the payments and receipts to be reconciled in a third-party assured process. Each national application is overseen by an in-country tripartite multistakeholder committee consisting of representatives of industry, government, and civil society.

Bridging Issue of Human Rights

Respecting human rights is clearly part of corporate responsibility. For the 19 corporate members of ICMM and the 30 affiliated mining associations that, in turn, link to another 1,500 companies, respect for human rights is a key aspect of sustainable development.

In 2005, the UN secretary-general appointed John Ruggie, Berthold Beitz professor in human rights and international affairs at the Kennedy School of Government, Harvard University, as his special representative on business and human rights. Five thousand companies are now engaged worldwide in this initiative (Business and Human Rights Resource Centre n.d.). Ruggie played a central role

Source: Data from Joanna Facella, Nuclear Waste Management Organization, Toronto, Ontario, Canada.

Figure 16.2-16 Toward an ethical lens for mining

in preparing the UN Millennium Summit in 2000, including drafting the summit's final "Declaration," which adopted the Millennium Development Goals that have brought renewed energy and focus to the fight against global poverty. In 2008, Ruggie produced the now well-accepted "Protect, Respect, and Remedy" framework for corporate responsibility, which outlined in clear terms the distinctive but complementary roles of government and corporations regarding human rights: While governments have the primary responsibility for the protection of human rights, companies have a responsibility for respecting them. The reporting and assurance systems described previously include treatment of company respect for human rights.

Toward an Ethical Lens for Mining

It is inevitable that the material described in this chapter, taken together, signals that the world is moving toward developing a kind of *ethical lens* for assessing the mining, minerals, and metals industry. During the period 2002–2005, a Canadian initiative undertook a comprehensive review of alternatives for managing used nuclear fuel over the long term. Figure 16.2-16 shows the results of an extensive discussion with Canadians about the values (Watling et al. 2004), ethical principles (NWMO 2005), and related objectives that were used to assess options for long-term management of used nuclear fuel (NWMO 2004). Together they serve as an innovative ethical lens that is as applicable to mining in general as it is to the management of nuclear waste.

LOOKING FORWARD

Ongoing Issues

A number of issues remain to be fully addressed (modified from MMSD North America 2002 and Hodge 2004):

- **Fair distribution:** Detailed site-specific procedures for describing and addressing the distribution of costs, benefits, risks, and responsibilities among governments, men and women, rich and poor, and present and future generations.
- **Decision making, trade-offs:** Designing and implementing optimum decision making systems and approaches that effectively and fairly address trade-offs in any given site application.
- **Need and alternatives:** Effectively and fairly assessing the need for a given project and/or commodity in light of considerations and alternatives that span local to global implications.
- **Achieving a whole system perspective:** Seeing, understanding, and factoring in a sense of the whole system, not just the small component parts.
- **Uncertainty, precaution, and adaptive management:** Dealing with uncertainty using an appropriate level of precaution and an adaptive management approach.
- **Attribution problem and dealing with cumulative impacts:** Effectively addressing the common situation where a project is one of a number of contributors to social, cultural, economic, and environmental change or stress—establishing the cumulative implications, apportioning responsibility, and deciding who should take responsibility for the analysis.

These issues are not new. Together, they are a testament to some of the complexities that must be faced in bringing the ideas of sustainability from theory to practice. In addition to the previous list, the following practical issues remain to be resolved to improve the contribution of the mining industry to sustainability:

- **Capacity building:** Creating the necessary national and local governance systems that can facilitate effective and principled engagement among industry, government, and civil society.
- **Voluntary codes of conduct:** Increasing participation in and enhancement of values-based, principled codes of conduct that lift broad industry performance above legislated minimums.
- **Climate change:** Establishing how the mining industry can most effectively contribute to addressing the issue of global warming.
- **Artisanal and small-scale mining:** Establishing how such mining can be best managed in various countries and within the context of sustainable development, taking into account environmental and social implications as well as links to large-scale mining (for a comprehensive treatment of these issues, see CASM n.d.).
- **Consistent application of performance standards:** Achieving consistency in the application of sustainable development ideas within countries, between countries, and across the industry from juniors to majors.
- **Effective human resource management:** Effectively creating the foundation of education, training, and support that is required to ensure the needed flow of skilled personnel (see Freemen and Miller 2009).

All the issues listed are critical to effective application of sustainable development concepts to the mining and metals industry.

New Perspectives

In current public debate, many challenge the consumptive nature of modern society. Professor Saleem Ali has offered an

alternative perspective on this divisive topic that has significant implications for the mining, minerals, and metals industry (Ali 2009). He argues that simply disavowing consumption of materials is not likely to help in planning for a resource-scarce future, given the extent of inequity in today's world, development imperatives, and our goals for a democratic global society. Rather than suppress the creativity and desire to discover—which he calls "the treasure impulse"—Ali proposes a new environmental paradigm, one that accepts our need to consume "treasure" for cultural and developmental reasons but warns of our concomitant need to conserve.

In evaluating the impact of treasure consumption on resource-rich countries, he argues that a way exists to consume responsibly and alleviate global poverty. Ali's thesis brings a much needed additional perspective relevant to applying sustainability ideas to the mining industry.

Change and Change Management

The role of metals and minerals in providing for both human and ecosystem well-being is critical, and the mining and metals industry enjoys a deep and rich heritage. However, this same heritage brings with it an innate resistance to change that can impede needed change. There are many contributing factors to this resistance, including

- Tradition: "We've always done it this way and it has worked, why change now?" or "If it's not broken, why fix it?";
- A number of economic factors that tend to favor risk-averse behaviors, including the volatility and uncertainty inherent in commodities markets, the scale and complexity of operations, the highly competitive nature of the business, and the resulting thin margins (Peterson et al. 2001); and
- A range of factors that can come into play at a personal level and apply not only in mining but in any industry. Examples include uncertainty, lack of training, lack of understanding about how change might affect a given job or activity, loss of job status, loss of security, and timing (summarized from Stanislao and Stanislao 1983).

To overcome this resistance requires well-thought-out and appropriate change strategies. Sometimes this calls for a catalytic role, sometimes a role in bringing people together, sometimes the provision of resources, and sometimes the design of a new and innovative solution. The key is to be strategic.

Since the 1980s, a number of factors have emerged to provide a vital and exciting climate of change in the mining industry. These factors include

- Increased public scrutiny of mining activities and the rise in the activity level, sophistication, and significance of civil society organizations;
- Public recognition of the significance of environmental and social risks and liabilities associated with mining practices and, in both regulatory and financial services industry practices, a shift that clearly assigns those liabilities to project owners and proponents;
- Changing practices in the financial services industry that are increasingly linking access to capital to a demonstration of corporate responsibility using sustainability criteria in the assessment process—a factor much reinforced by the 2008–2009 financial crisis;
- Consolidation among both operating firms and technology suppliers in response to commodity-price pressures and the desire to achieve economies of scale;
- Globalization of mining activities and the increased role of developing regions in mineral production and of mining in the developing countries' economies;
- Conflict in weak governance zones;
- Increasing worldwide consumption of key mined commodities with increasing demand in emerging economies;
- Increased dependence on metals to support a shift to a green economy; and
- Growing formal recognition that no one party can do it alone.

These drivers of change are not going to disappear; if anything, their significance will increase. The result is that the mining industry is embracing change in an unprecedented manner, and the concepts that have emerged to guide that change in a strategic and systematic way are those of sustainability and sustainable development.

ACKNOWLEDGMENTS

This chapter greatly benefited from reviews by Laeeque Daneshmend, head of the Department of Mining Engineering, Queen's University, Kingston, Ontario, Canada; Dirk van Zyl, professor of mining, University of British Columbia, Vancouver, Canada; Leigh Freeman, principal, Downing Teal, Denver, Colorado, United States; and John Strongman and colleagues in the Mining Group at the World Bank, Washington, D.C., United States. Peter Darling provided ongoing useful guidance throughout. Gemma Lee proofread and caught the many inevitable small mistakes. All of these inputs are greatly appreciated. However, while the comments received added much richness, responsibility for the substance as it stands and, in particular, any remaining errors rest with the author.

CHAPTER 16.3

Impacts and Control of Blasting

Charles Dowding

Control of blast effects near critical rock masses or constructed facilities depends on two main considerations:

1. The amount of explosives detonated per volume of rock and the shot pattern must be adjusted to ensure adequate fragmentation and relief.
2. Shot designs must reduce the amount of explosives detonated at any instant and adjust the initiation sequence to reduce resulting ground and airborne disturbances.

Therefore, the initiation sequence must be simultaneously concentrated appropriately in space but spread out in time. There is an optimum design that achieves both objectives: adequate fragmentation and control of disturbances. This optimum can be reached only through an understanding of the physics, rock mechanics, and geology of rock masses, structural and rock mass response to blast disturbance, and the interaction between rock fragmentation and shot design.

This chapter summarizes the state of the art in vibration measurement and structural response to facilitate optimum blast design. It also summarizes shot design for fragmentation. In addition, it applies the principles of earthquake engineering and nuclear blast protective design to blast-vibration monitoring and summarizes scientifically acceptable experimental observations of mining-induced ground motions and structural response. These technologies are integrated with the summary of the state of the art to mitigate several trends described in the following paragraphs.

There has been a general downward trend in regulatory limits on allowable blast-induced vibrations. This drift can be attributed, in part, to the tendency to take the limit of the last study and divide it in half to be safe. Unfortunately, too many studies whose limits were divided were themselves only summaries of past work that had also been divided past limits. This chapter presents the background of and references to original experiments conducted to determine safe blasting controls and therefore enables the reader to set appropriate limits based on original past work within the framework of existing regulations.

Another trend is the misapplication of peak particle-velocity limits that were determined for cosmetic cracking of residential structures. These limits have been applied to concrete tunnel liners, welded steel pipelines, radio towers, slabs on grade, and the curing of concrete, to name just a few instances. This chapter draws attention to studies that determined limits specifically for these and other cases. Where no studies exist, it presents methods based on response spectra or ground strains that allow setting of appropriate criteria or limits.

Frequency of vibration and ground strain form the foundation for the presentation. The importance of frequency cannot be overemphasized, as it is as critical as peak particle velocity in determining the response of aboveground structures. For belowground structures, frequency, in combination with propagation velocity, controls the response of the rock mass and embedded structures. In both cases, cracking results from induced strains, where particle velocity is used as an index of strain.

In addition, this chapter describes computerized monitoring instrumentation. Computerization simultaneously increases monitoring efficiency and decreases costs, both original capital costs and costs associated with record keeping. The labor-saving efficiencies associated with automated record keeping continue to be undervalued by many mining operations.

RANGE OF BLAST EFFECTS

Blast effects on surrounding earth materials and structures can be divided into two categories: permanent and transient displacements. Although the focus of this chapter is transient displacements, effects of permanent displacements are presented because they are associated with significant transient effects at relatively small distances.

Permanent Degradation and Displacement of Adjacent Rock

Permanent effects, with the exception of fly rock, are described within only a few hundred feet. They can be divided into two categories: degradation and displacement.

Degradation

Degradation is normally described by cracking intensity. Such blast-induced cracking has been observed experimentally to

Charles Dowding, Professor of Civil and Environmental Engineering, Northwestern University, Evanston, Illinois, USA

vary with hole diameter and rock type (Siskind and Fumanti 1974; Holmberg and Persson 1978). Small-hole-diameter construction blasting has induced cracking at distances of 3.5 to 7 ft (1 to 2 m). Likewise, large-hole-diameter mining blasting has induced cracking at distances of 35 to 70 ft (10 to 20 m). Careful blast design can dramatically reduce these maximum distances.

Displacement

Displacement can be produced by either delayed gas pressures (those that accumulate during detonation) or vibration-induced shaking. Delayed gas pressure has dislocated blocks as large as 1,300 yd^3 (1,000 m^3) during construction blasting (Dowding 1985). Such movement is unusual but is associated with isolated blocks, gas leaks along open joints, and poor shot design with large burdens. Vibratory or shaking-induced displacement is normally associated with unstable blocks in rock slopes and can occur wherever static factors of safety are low and ground motions produce permanent displacements that are greater than the first-order asperity wavelength (Dowding and Gilbert 1988). Gas-pressure-related displacement can occur out to several hundred feet.

Two special cases of permanent displacement exist:

1. **Fly rock.** Fly rock is a special case of permanent displacement of rock by explosive expulsion from the top of the blasthole. Rock has been observed to have been propelled as far as 330 to 3,300 ft (100 to 1,000 m) (Roth 1979). Statistical studies have shown that the probability of these extreme events is quite low under normal circumstances, 1 in 10,000,000 at 2,000 ft (600 m) (Lundborg 1981). Since the probability increases with decreasing distance, blasting mats are required in any construction blasting in an urban environment to prevent all fly rock.
2. **Soil densification or compaction.** Another special case of permanent displacement is the vibratory densification of a nearby mass of loose, clean sand. The propensity for such densification is a function of the soil's density, mineralogy, grain-size distribution, and saturation. Soils that are densifiable are loose sands with <5% of silt-size particles found below the water table. For example, such sands were densified out to distances of 70 ft (20 m) after detonation of single 11-lb (5-kg) charges within the loose sand mass itself (Ivanov 1967). Soils that are slightly cemented, contain >5% fines, or are above the water table are less subject to vibratory densification from typical ground motions.

Transient Structural Response

Transient effects result from the vibratory nature of ground and airborne disturbances that propagate outward from a blast. In this discussion, it is assumed that no permanent displacements are produced. Thus the only effects are those associated with the vibratory response of facilities in or on the rock or soil mass surrounding the blast. Transient means that the peak displacement is only temporary and lasts <1/100th of a second, and the structure returns to its original position afterward.

Transient structural effects can be arranged to reflect the expected distance from a blast. Beginning with the closest, transient effects are in this order: structural distortion, faulted or displaced cracks, falling objects, cosmetic cracking of wall coverings, excessive instrument and machinery response, human response, and microdisturbance. The first four effects, those that relate to structural response, are normally grouped together for experimental observation as structural response and do not normally occur when vibration levels are regulated to prevent cosmetic cracking.

Excessive structural response has been separated into three categories (Northwood et al. 1963; Siskind et al. 1980b). In order of declining severity and increasing distance of occurrence, beginning with effects that occur closest to the blast, the categories are as follows:

1. Major (permanent distortion): Seriously weaken the structure (e.g., large cracks or shifting of foundations or bearing walls, major settlement resulting in distortion or weakening of the superstructure, and walls out of plumb)
2. Minor (displaced cracks): Are surficial, and do not affect the strength of the structures (e.g., broken windows, loosened or fallen plaster, hairline cracks in masonry)
3. Threshold (cosmetic cracking): Open old cracks and formation of new plaster cracks, dislodging of loose objects (e.g., loose bricks in chimneys)

These specific definitions of response should not be described collectively as "damage." To do so blurs the distinction between threshold or cosmetic cracking and major response or structural distress.

Regulatory controls in North America are based on the occurrence of threshold cracking of plaster and gypsum wallboard in residential structures (Siskind et al. 1980a; Dowding 1985, 1996). Observed cracking is cosmetic in nature and does not affect structural stability. These cosmetic cracks are hair-sized and are similar to cracks that occur during the natural aging of structures. In fact, they are indistinguishable from cracks that result from natural aging. Control limits are based on direct observations of test homes immediately before and immediately after blast events, to avoid confusion with similar cracks that might occur from natural processes. These controls do not apply to engineered structures that are constructed of steel and concrete, buried structures, or adjacent rock.

Distinction Between Blast-Induced Cracking and Natural Cracking

Control of blast-induced transient effects to prevent threshold or cosmetic cracking reduces blast-induced displacement or strains in structures to or below that caused by everyday human activities and weather changes (Stagg et al. 1984; Dowding 1988). These cosmetic cracks in many cases are smaller than cracks caused by other natural or occupant-initiated processes that are active in all constructed facilities. Thus blast-induced threshold cracks can be scientifically observed only with visual inspection immediately before and after each blast. Observations made under less stringently controlled conditions have little scientific merit because of the high probability of environmentally produced cracks occurring between or before visual inspections.

Several institutional references present excellent summaries of the multiple origins of cracks (BRE 1977; Association of Casualty and Surety Companies 1956; Thoenen and Windes 1942). Basically, cracks are caused by the following:

- Differential thermal expansion
- Structural overloading
- Chemical changes in mortar, bricks, plaster, and stucco
- Shrinkage and swelling of wood
- Fatigue and aging of wall coverings
- Differential foundation settlement

Table 16.3-1 Strain levels induced by daily environmental changes and household activities with their corresponding blast levels

Loading Phenomena	Site*	Microstrain Induced by Phenomena, μin./in.	Corresponding Blast Level†	
			in./s	mm/s
Daily environmental changes	K_1	149	1.2	30.0
	K_2	385	3.0	76.0
Household activities				
Walking	S_2	9.1	0.03	0.8

Source: Stagg et al. 1984.
*K_1 and K_2 were placed across a tape joint between two sheets of gypsum wallboard.
†Blast equivalent based on envelope line of strain vs. ground vibration.

Over time, all of the causes listed are likely to crack walls, whether or not blasting occurs. This list has three important implications: (1) Structures expand and contract preferentially along existing weaknesses (cracks). Seasonal expansion and contraction along these cracks return patching and repainting to the original cracked state within several years. This persistent cracking is annoying to owners who are unaware of the difficulty of patching existing cracks of any kind. (2) The distortion that caused the cracking also creates stress concentrations that may lower the resistance of a wall covering to vibration cracking; however, current regulatory limits already implicitly include these distortion effects as explained in the paragraphs that follow. (3) Natural cracks continue to occur over time. Therefore, any postblast inspection at low vibration levels is likely to find new cracks from natural aging unless preblast inspection is conducted immediately before the blast.

Response of Structures to Everyday Activities

A comparison of relative levels of strain gives perspective to the observation of cracking at low particle velocities. Table 16.3-1 compares strain levels from daily environmental changes (temperature and humidity) and from household activities measured in the U.S. Bureau of Mines (USBM) test house, and lists their corresponding blast levels; a door was slammed adjacent to the wall on which the strains were measured.

Apparently, in the course of daily life, an active family produces strains in walls similar to the strains produced by blasting vibrations of 0.1 to 0.5 in./s (2.5 to 12 mm/s). Most astonishing are the measurements, in a wood-framed house, of relatively enormous strains from daily changes in temperature and humidity. These strains alone are great enough to crack plaster.

Blast-Induced Air Overpressures

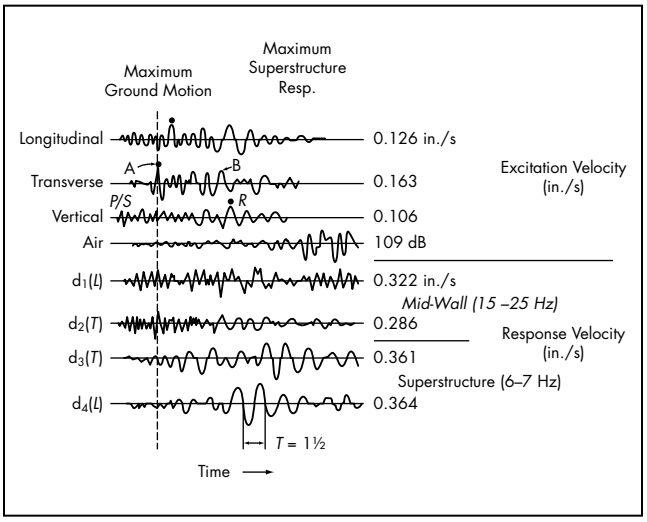
Blast-induced air overpressures are the air pressure waves generated by explosions. The higher-frequency portion of the pressure wave is audible and is the sound that accompanies a blast; the lower-frequency portion is not audible, but it excites structures and in turn causes a secondary and audible rattle within a structure.

Overpressure waves are of interest for three reasons: (1) the audible portion produces direct noise; (2) the inaudible portion by itself or in combination with ground motion can produce structural motions that in turn produce noise; and (3) they may crack windows, although air-blast pressure alone would have to be unusually high for such cracking. Response noise within a structure is the source of many complaints. Blast-induced air overpressures often generate sounds by means of the response of components such as loose windows and doors or highly flexible structural panels. Delicately balanced loose objects may rattle or fall at low levels of motion, generating even further concern.

Human Response

Humans are quite sensitive to motion and noise that accompany blast-induced ground and airborne disturbances. Therefore, human response is significant in the reporting of blast-induced cracking. Motion and noise from blasting can be startling and lead to a search for some physical manifestation of the phenomena. Frequently, a previously unnoticed crack provides such confirmation of the event. Furthermore, if a person is worried and observes a crack that was not noticed before, the crack's perceived significance increases over that of one noticed in the absence of any startling activity. These concerns are real and, in the mind of the observer, are sincere.

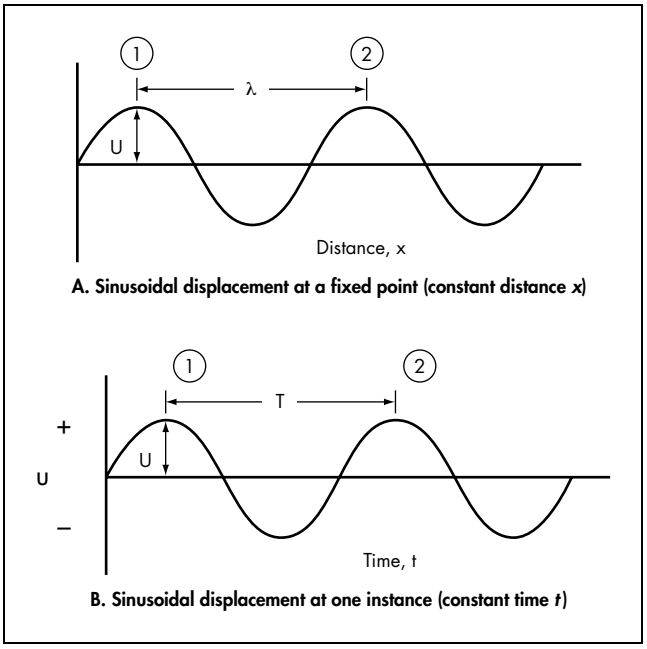
In typical mining situations, significant blast-induced inaudible air overpressure and audible noise immediately follow the ground motion and intensify human response. Both ground and airborne disturbances excite walls, rattle dishes, and together tend to produce more noise inside a structure than outside. Thus both the audible noise and the wall rattle produced by inaudible pressures contribute to human response. To complicate matters even more, inaudible air overpressures can vibrate walls to produce audible noise at large distances, and are inaccurately reported by occupants as ground motions because the audible effects are so similar.



CHARACTER OF BLAST EXCITATION AND STRUCTURAL RESPONSE

Figure 16.3-1 shows blast excitations by ground and airborne disturbances and the response of the walls and superstructure of a residential structure. Measurements were made about 2,000 ft (600 m) from a typical surface coal-mining blast. Both ground and airborne disturbances (the upper four time histories) produce structure responses (the lower four time histories). Because of the importance of frequency, the full waveform or time history should be recorded. When a critical location is known, blast response is best described by the strain at that location. Alternatively, particle velocity (shown in the figure) can be measured outside the structure of concern, as many recent cracking studies have correlated cracking with excitation particle velocity measured in the ground.

Ground Motion



Ground motion can be described by three mutually perpendicular components: longitudinal (L), transverse (T), and vertical (V) (Figure 16.3-1). The L and T directions are oriented in the horizontal plane with L directed along the line between the blast and recording transducer. When a study focuses on structural response, axes can be labeled H1, H2, and V, with H1 and H2 oriented parallel to the structure's principal axis.

Variation of peak motions in each component (L, V, and T in Figure 16.3-1) has led to difficulty in determining which is most important. Horizontal motions seem to control the horizontal response of walls and superstructures; vertical motions

Source: Adapted from Dowding 1996.

Figure 16.3-1 Blast excitations by ground and airborne disturbances and the response of the walls and superstructure of a residential structure

Source: Dowding 1985.

Figure 16.3-2 Sinusoidal approximations

seem to control the vertical response of floors. In an absolute sense, the peak ground motion is actually the maximum vector sum of the three components, which usually occurs at the largest peak of the three components, the dashed line in the figure. This *true* maximum vector sum is not the *false* maximum vector sum calculated with the maxima for each component (dots in the figure), no matter their time of occurrence. The false maximum vector sum may be as much as 40% greater than the true maximum vector sum, which is normally 5% to 10% greater than the maximum single-component peak.

In general, experimental observations of threshold or cosmetic cracking, which form the basis of blasting controls in North America, have been correlated with the maximum single component regardless of direction. Therefore, use of the false maximum vector sum, for control, provides a large unaccounted-for factor of safety.

Two wave types are produced by blasting, *body* and *surface*, and are illustrated by the ground motion in Figure 16.3-1. Body waves travel through earth materials; surface waves travel along surfaces and interfaces of earth materials. The most important surface wave is the Rayleigh surface wave, denoted *R* on the vertical trace in the figure. Body waves can be further subdivided into *compressive* (compression/tension) or soundlike waves and *distortional* or *shear* waves, denoted *P*/*S* on the vertical trace in the figure. Explosions produce predominantly body waves at small distances, which propagate outward in a spherical manner until they intersect a boundary such as another rock layer, soil, or the ground surface. At this intersection, shear and surface waves are produced. Rayleigh surface waves become important at large transmission distances, as shown in the vertical trace by the relatively large amplitude of *R* compared to that of *P*/*S*.

Sinusoidal Approximations

Typical blast vibrations, no matter the wave type, can be approximated as sinusoidally varying in either time or distance along the radial or longitudinal line, as shown by the time variations in Figure 16.3-2. This approximation is useful because it makes calculations for strain and for acceleration from particle velocity much simpler than they are for irregular pulses. Ground motion from a blast is similar to the motion of a floating cork caused by a passing water wave produced by dropping a stone in a pond. Displacement of the cork from its at-rest position is similar to the displacement u of a particle in the ground from its at-rest position. Similarly, the cork's velocity u as it bobs up and down is analogous to that of a particle in the ground; hence the term *particle velocity.*

The water wave that excites the cork can be described by its wavelength γ, which is the distance between wave crests; the wave speed or propagation velocity c at which it travels outward from the stone's impact; and the frequency f, which is how many times the cork bobs up and down in 1 second. Frequency f is equal to $1/T$, or the reciprocal of the period (time that it takes the cork to complete one cycle of motion). Frequency is measured in cycles per second or Hertz (Hz). Propagation velocity c should not be confused with particle velocity $\mathring{u}$, as c is the speed at which the water wave passes by the cork and $\mathring{u}$ is the speed at which the cork moves up and down while the wave passes. In the same fashion as for the water wave, blast-vibration waves can be described by their wavelength, propagation velocity, and frequency.

Kinemetric Relationships of Ground Motion

The general form for the sinusoidal approximation is best understood by beginning with the equation for sinusoidal displacement u:

$$u = U \sin(2\pi ft) \qquad (16.3\text{-}1)$$

where

U = maximum displacement
f = frequency
t = time

The relationship between maximum particle displacement u, maximum particle velocity $\mathring{u}_{max}$, and maximum

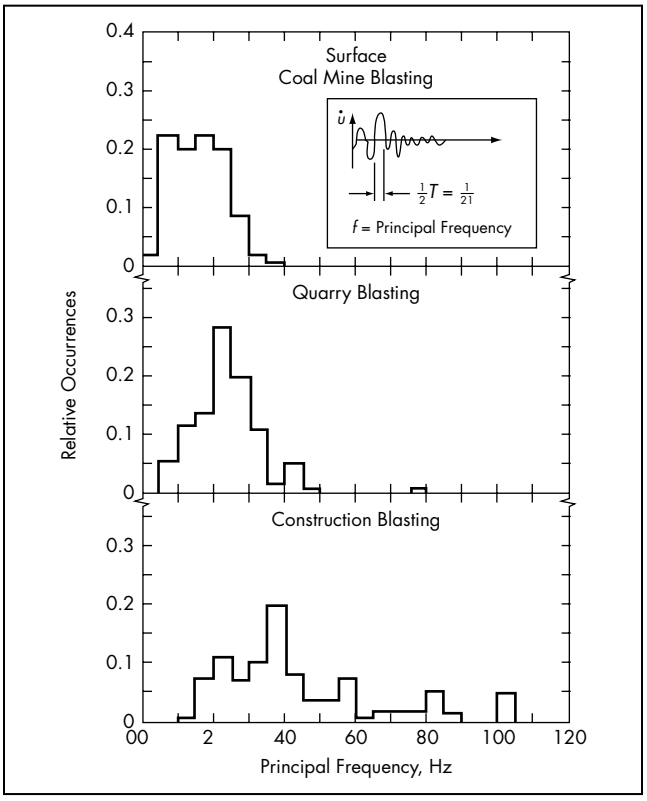
acceleration $\ddot{u}_{max}$ is also greatly simplified by the sinusoidal approximation and is found by differentiation with respect to time whenever the sin/cos function maximizes at l:

$$\begin{aligned} u_{max} &= U \\ \mathring{u}_{max} &= U\,(2\pi f) = 2\pi f u_{max} \\ \ddot{u}_{max} &= U\,(4\pi^2 f^2) = 2\pi f \mathring{u}_{max} \end{aligned} \qquad (16.3\text{-}2)$$

Usually, acceleration is normalized (i.e., divided by gravitational acceleration, 386.4 in./s^2 [9,814 mm/s^2]). Therefore, an acceleration of 79 in./s^2 (2,000 mm/s^2) is 2,000/9,814 = 79/386 = 0.2 g, or two-tenths that of gravity.

Kinemetric relations among particle displacement, velocity, and acceleration for complex waveforms are exactly related by integration or differentiation of any of the waveforms. For instance, integration of an acceleration time history gives a velocity time history; integration of the latter in turn gives a displacement time history. Even though a particle-velocity record can be differentiated to find acceleration, it is not recommended, as the procedure is sensitive to small changes in the slope of the velocity time history. Further discussion of the inaccuracies of differentiation and integration can be found in Dowding (1985) and in texts devoted to interpretation of time histories (e.g., Hudson 1979).

Transient Nature of Blast Motions



Great care should be taken not to confuse the effects of steady-state, single-frequency motions with those of transient blast motions. Most vibration studies conducted by personnel trained in mechanical and electrical engineering and in geophysics implicitly assume that the motions are continuous (last many cycles) and steady-state (have constant frequency and amplitude). However, as is evident in Figure 16.3-1, blast-induced motions last only one or two cycles at a relatively constant amplitude and frequency. Such conditions are not similar enough to steady-state motion to allow specific application of steady-state approximations such as resonance.

Estimation of Dominant Frequency

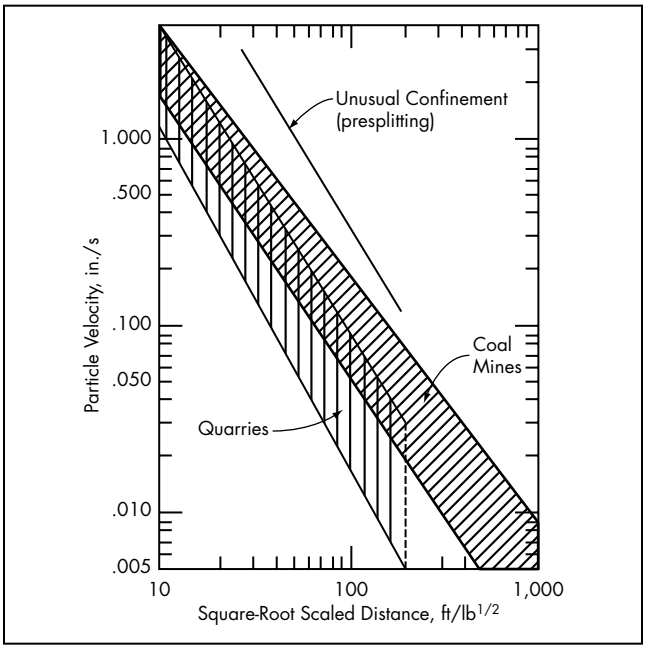
The use of frequency-based vibration criteria has made the estimation and calculation of dominant frequency an important concern. Dominant frequency can be estimated by visual inspection of the time history or calculated from Fourier frequency spectra or, alternatively, response spectra.

The accuracy or difficulty of visually estimating the dominant frequency depends on the complexity of the time history. The easiest type of time-history record for estimating frequency is one with a single dominant pulse like that shown in the inset of Figure 16.3-3. This dominant frequency can be determined by hand measurement of the time of the two zero crossings on either side of the peak. The difference between these times is one-half of the period, which is the inverse of twice the frequency of the dominant peak, as show in the inset.

Figure 16.3-3 shows that the relatively large blasts produced by surface coal mining, when measured at typically distant structures, tend to produce vibrations with lower principal frequencies than do construction blasts. Construction blasts involve smaller explosions, but the typically small distances between a structure and a blast, as well as rock-to-rock transmission paths, tend to produce high frequencies. The high-frequency motions associated with construction blasts are less apt to crack adjacent structures (Dowding 1985).

Source: Adapted from Siskind et al. 1980b.

Figure 16.3-3 Dominant-frequency histograms of blasts for three types of industry, measured at structures adjacent to the blast (the inset defines dominant frequency)



The most difficult type of record to interpret is one that contains nearly equal peaks at two dominant frequencies, such as that shown Figure 16.3-1. The two dominant frequencies are the initial 15- to 20-Hz portion (peak A) and the later 5- to 10-Hz portion (peak B). The initial portion produces the highest wall response; the second portion produces the greatest superstructure response. For the best frequency correlation of both types of response, both frequencies should be calculated.

The best computational approach to determining the dominant frequency involves the response spectrum. The response spectrum is preferred over the Fourier frequency spectrum because it can be related to structural strains (Dowding 1985). A compromise approach is to calculate the dominant frequency associated with each peak by the zero-crossing method described previously.

Since histories do not often contain as broad a range of dominant frequencies as that in Figure 16.3-1, most approaches require only the calculation of the frequency associated with the maximum particle velocity for blasts that produce small particle velocities. More complex frequency analyses are needed only when peak particle velocities approach control limits.

Propagation Effects

Ground motion always decreases with increasing distance. The effects of constructive and destructive interference and geology are included in the scatter of data for the mean trend of the decay of amplitude with distance. Although this scatter is

Source: Adapted from Siskind et al. 1980b.

Figure 16.3-4 Attenuation relationships showing scatter from geological and blast design effects as well as high expected velocities from confined shots such as presplitting

large, the associated decay with distance is observed in all blast-vibration studies. Typical examples of this decay are shown in Figure 16.3-4 where maximum particle velocity is plotted as a function of square-root-scaled distance from the blast.

Square-root scaling, or plotting peak particle velocity as a function of the distance R divided by the square root of the charge weight, $R/W^{1/2}$, is more traditional than cube-root scaling, which incorporates energy considerations (Hendron 1977). Both square- and cube-root scaling can be used to compare field data and predict the attenuation or decay of peak particle velocity; however, square-root scaling is more popular.

Several square-root attenuation relationships used in the United States are shown in Figure 16.3-4. They are banded to reflect scatter, which is typical of blasting operation. The upper (unusual confinement) line should be used for presplitting, cratering, and beginning new bench levels. It is also the basis for U.S. Office of Surface Mining Reclamation and Enforcement (OSM) regulations for conservative shot design when monitoring instruments are not used.

Dominant frequencies tend to decline with increasing distance and increasing importance of surface waves. At larger distances typical for mining, higher-frequency body waves begin to have relatively lower peak amplitudes than do lower-frequency surface waves, as shown in Figure 16.3-1. Since lower frequencies can induce greater structural response (Medearis 1976), OSM scaled-distance limits decline with increasing absolute distance.

Blast-Induced Air Overpressures

As for ground motions, the waves from blast-induced air overpressures can be described with time histories as shown in Figure 16.3-1. The higher-frequency portion of the pressure wave is audible sound. The lower-frequency portion, although not audible, excites structures, causing a secondary and audible rattle within the structure. Air-blast excitation of the walls is evident from a comparison of the last one-quarter of the time histories of air blast and wall response in Figure 16.3-1. Unlike ground motions, air overpressures can be described completely with only one transducer, since at any one point air pressure is equal in all three orthogonal directions.

Propagation of blast-induced air overpressures has been studied by numerous investigators and is generally reported with cube-root-scaled rather than square-root-scaled distances. Peak pressures are reported in terms of decibels (dB), defined as

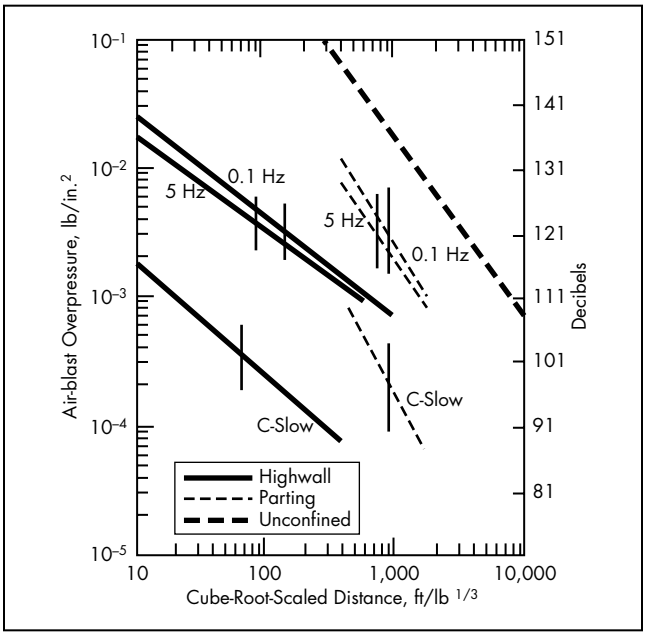
$$\text{dB} = 20 \log_{10} (P/P_0) \tag{16.3-3}$$

where

P = measured peak sound pressure
P_0 = reference pressure of 2.9×10^{-9} psi (20×10^{-6} (P_a)

Figure 16.3-5 summarizes the effect of two important instrumentation and shot variables:

1. The effect of the weighting scales in the sound-pressure-level meter is dramatically evident. C weighting greatly reduces the recorded peak pressure at any scaled distance. This does not mean that the peak is reduced by changing instruments, but rather that the C weighting system does not respond to low-frequency pressure pulses. However, low-frequency pressure peaks excite structures and occupants whether or not they are sensed by measurement instruments. The other (5- and 0.1-Hz) labels denote the lower-frequency bounds of the recording capabilities of "linear" systems.
2. The effect of venting caused by inadequate stemming is also evident from the higher average pressures produced by the parting shots at any scaled distance. Parting shots are detonated in thin rock layers between coal strata in surface mines. Consequently, there is less hole height available for stemming, and these shots frequently eject the stemming and thereby produce abnormally high air overpressures. The unconfined relationship should be used for the demolition of structures after modification for the effects of weather and ground reflection.



Various effects of wind have been reported and should be added to the average relations presented in Figure 16.3-5. Wiss and Linehan's (1978) study of air overpressures produced by surface coal mining show that, in moderate winds, the typical 7.7-dB reduction for each doubling of distance is reduced by

$$7.7 - 1.6\, V_{\text{mph}} \cos\theta \text{ dB} \tag{16.3-4}$$

where

V_{mph} = wind velocity, in miles per hour
θ = the angle between the line connecting the blast and transducer and the wind direction

An air-temperature inversion causes the sound-pressure wave to be refracted back to the ground and at times to be amplified at small 16-acre- (0.65-km^2-) sized locations. Such inversions occur when the normal decrease in temperature with altitude is reversed because of the presence of a warmer upper layer. Schomer et al. (1976) showed that, for propagation distances of 2 to 40 mi (3 to 60 km), inversions produce zones of intensification of up to 3 times the average attenuated or low air overpressures at those (but not smaller) distances;

Source: Adapted from Siskind et al. 1980a.

Figure 16.3-5 Attenuation relationships for air overpressures produced by confined (highwall) and partially confined (parting) surface coal-mining blasts and unconfined blasts

the average increase is 1.8 times (5.1 dB). At distances of <2 mi (3 km), where high air overpressures are likely to occur, his measurements show no inversion effects.

Structural Strains vs. Particle Velocity

Although particle velocity is the traditional measurement of choice, structural strains control cracking. They should be measured directly from relative displacements on structures or within rock masses when critical locations are known, and can be obtained with a variety of strain and relative displacement gauges (Stagg et al. 1984). Unfortunately, critical locations may be either unknown or too many in number to measure economically. Therefore, some means of estimation is necessary.

Ground-motion and air-overpressure time histories can be used to calculate the relative displacement of structural components with a knowledge of the responding structure's dynamic-response characteristics (Dowding 1985, 1996). These relative displacements can in turn be used to calculate strains. The accuracy of these estimates is limited by the degree to which the structure behaves as a single-degree-of-freedom system and the accuracy of the estimate of dynamic response characteristics.

Measurement of Particle Velocity

Although any of the three kinemetric descriptors (displacement, velocity, or acceleration) can be used to describe ground motion, particle velocity is the most preferable. It has the best correlation with scientific observation of blast-induced cracking, which forms the basis of vibration control. Furthermore, it can be integrated to calculate displacement. If acceleration is desired, it should be measured directly to avoid differentiation of the particle-velocity time history.

The location for measurement varies throughout the world. In North America, excitation or ground motion is measured on the ground adjacent to the structure of interest. In Europe, it is measured on the structure's foundation. The difference stems from historical precedent and location of transducers during scientific observation of cracking rather than from difference in philosophy. In North America, it is frequently impossible to place transducers on adjacent property owned by a party not involved in the project. Excitation motions should be measured outside of and not on the structure. Structural-response motions should be measured on the most responsive structural members, which are not the basement or foundation walls because of the restraint provided by the ground.

Time histories of the three components of motion should be measured because of the importance of excitation frequency. Recording of peak motions alone does not yield information about the dominant frequency and time history details that control structural response. Peak motions and dominant frequency can be used to describe low-level, noncritical motions. Therefore, machines used to monitor critical motions should be capable of recording time histories of selected critical motions. Machines that record only peak motions can be used with those that record time histories to provide redundant measurement where frequency content does not vary widely.

USE OF MEASUREMENT INSTRUMENTS

This section describes the characteristics of instruments that measure ground motions (acceleration, velocity, displacement) and air blasts (air overpressure). Since there are many excellent sources for information on instruments, the principal characteristics of available systems are summarized rather than exhaustively reviewed. The most complete single reference for detailed instrumentation information is the *Shock and Vibration Handbook* (Harris and Crede 1976).

Almost all field-portable vibration-monitoring systems are now built around a digital central processing unit (sometimes called a data logger) and an analog-to-digital (A/D) converter. Geophone or air-pressure transducers convert time-varying velocity ground motion or air pressure into an analog (or continuous) voltage signal. The A/D converter translates this analog signal into digital (or discrete) form at a constant rate of sampling (typically 1,000–2,000 samples per second) and saves the data to a file in system memory. The onboard computer or central processing system analyzes the data and generates reports for download to and display on a portable computer. Typical A/D converters subdivide the transducer voltage range into 2^{12} (4,096) or more divisions; some new systems are capable of 2^{24} subdivisions. Every year, sampling speed increases and A/D converters become more precise. Some of these systems are self-contained and are the size of a brick. Others connect to exterior transducers and are the size of a thick notebook computer. In development are systems the size of a deck of playing cards that may eventually replace current instruments, provided that smaller batteries become available.

Transducers

Transducers are one of the weaker links in the measurement system because they must translate kinemetric motions or pressures into electrical signals. The remaining components transform electrical signals or light beams and are not restricted by mechanical displacement. The main characteristics of transducers that affect their performance are sensitivity and frequency response.

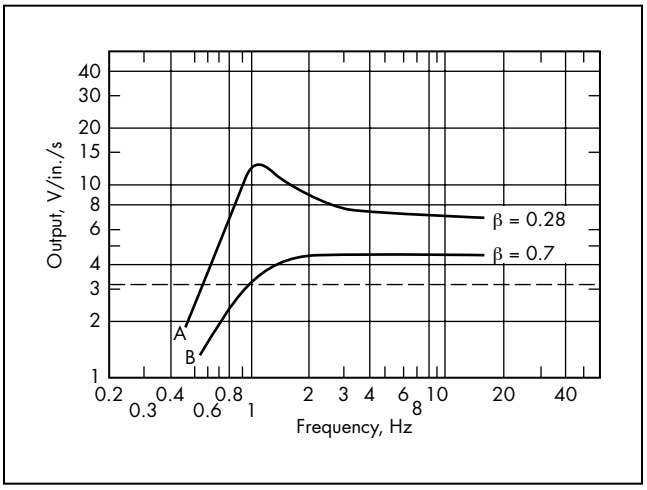
For energy-converting transducers (i.e., those that do not require an energy source), instrument sensitivity is the ratio of

the electrical output to the kinemetric displacement, velocity, and acceleration or overpressure. Since allowable limits are specified in terms of ground-particle velocity, all blast monitors come equipped with velocity gauges.

Frequency response is the frequency range over which electrical output is constant with constant mechanical motion. This constancy is normally expressed in terms of decibels. For instance, "linear within 3 dB between 5 and 200 Hz" means that the transducer produces a voltage output that is constant within 30% between 5 and 200 Hz, and up to 450 Hz on some European machines. Generally, it is better to look at the transducer's response spectra (such as those shown in Figure 16.3-6) to determine the frequencies where this difference occurs. For example, the difference occurs at low frequencies for the velocity transducers in the figure. At 70% of critical damping, the velocity transducer in the figure is ±3 dB (±30%) down at 1 Hz.

One of the most critical aspects of vibration monitoring is how the transducer is mounted in the field, which depends on the particle acceleration of the wave train being monitored. When the measurement surface is horizontal and the vertical maximum particle acceleration is <0.3 g, the type of mounting is not particularly critical, as the possibility of rocking is small and the transducer needs no device to hold it. When the measurement surface consists of soil and vertical maximum particle acceleration is in the range 0.3–1.0 g, the transducer should be buried completely (Johnson 1962). When the measurement surface consists of rock, asphalt, or concrete, the transducer should be fastened to the measurement surface with double-sided tape, epoxy, or quick-setting cement (Hydrocal or other gypsum-based cements set in 15–30 minutes). If these methods are unsatisfactory or accelerations exceed 1.0 g, only cement or bolts are sufficient to hold the transducer to a hard surface.

All transducers mounted on vertical surfaces should be bolted in place. Air-overpressure transducers should be placed at least 3 ft (1 m) aboveground, pointed downward to prevent rain damage and fitted with a windscreen to reduce wind-excitation-induced false events.



Instrument Calibration

It is obvious that the entire vibration-measurement system should be calibrated, as it is futile to record data if they cannot be exploited because of a lack of reference. Manufacturers supply calibration curves with their instruments that are similar to the response spectra for transducers shown in Figure 16.3-6. Recalibration or checking requires special vibrating platforms where frequency and displacement are controlled, and, in the field, a calibrating circuit to pulse the magnetic core of the geophone (Stagg and Engler 1980).

Number of Instruments

Although the obvious irreducible number of instruments for each blast is one, two instruments provide more thorough documentation of the spatial distribution of effects. If only one instrument is used, it should be located at the nearest or most critical receiver. This single instrument should be what we term a Type I instrument and should record time histories of the three axes of particle velocity as well as air overpressure. Since it must monitor continuously, it must trigger (begin recording) automatically and be capable of monitoring even while printing or communicating results.

When blasting will occur at more than one general location (i.e., will involve nearest structures separated by

Source: Dowding 1985.

Figure 16.3-6 Sample response spectra for velocity transducers with differing percentages of damping

hundreds of feet or meters), then minimally two and optimally four instruments should be used, including a spare to ensure continuous coverage in case of failure.

Additional instruments other than the spare can be Type II, which provide a lesser level of service. They must at least continuously record the peak particle velocity in one axis and may or may not measure air overpressure. The best axis is the vertical, since no horizontal-direction decision is required and surface waves usually involve a significant vertical component regardless of the direction of the maximum horizontal component. These instruments should be located at distances greater than the nearest structure to monitor a large area.

The spare instrument can be either Type I or II. Where air overpressures are problematic or frequencies are critical, the spare should be Type I. The spare instrument can also be used to monitor sites where complaints develop. Such public-relations work is essential in North America where lawsuits arise even when all blast effects comply with regulatory guidelines.

This approach describes the least number of instruments. Applicable regulations and mining schedules may require a larger number.

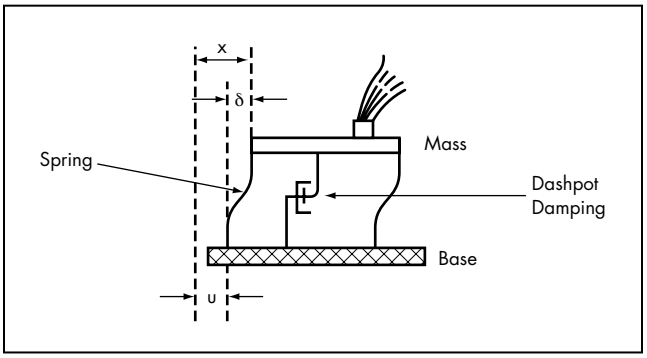
Instrument Deployment During Test Blasts

When blasting projects begin, when geological conditions change radically, or when new initiation systems are introduced, test blasts should be conducted to minimize the number of instruments necessary to monitor production blasts. The test blasts should produce project-specific attenuation relationships for both air overpressures and ground motion. Such relationships vary from project to project because of changes in geology and blasting practices. Additionally, the test blasts should enable determination of the frequency of motions at different scaled and absolute distances. Frequency is important in estimating structural response by response-spectrum analyses.

The attenuation relationship is not solely a site property. Although it depends on geology, it also depends heavily on blast geometry and timing. For instance, with the same charge per delay, a blast with a larger burden produces an attenuation relationship with a similar slope or decay with distance but a larger intercept. Furthermore, differing initiation timing changes the time history in terms of both length and frequency.

During test blasts, at least four instruments should be used to measure peak particle velocities at widely differing scaled distances for the same blast. Therefore, for any one blast design, parameters and initiation sequences are constant, and the resulting attenuation relationship shows the effect of only distance, direction, and/or geology. Seismographs and/or transducers should be placed along a single line with constant geology to best determine the attenuation relationship, or at all critical structures to determine the effects of direction and variable geology. Ideally, linear orientation should be along a path with constant soil thickness and not cross any large geologic discontinuities such as faults. If geology changes radically, then two such attenuation lines are necessary, but not necessarily with each blast.

EVALUATION OF MEASUREMENTS



Documentation of blast effects involves two radically different endeavors: measurement of ground and air disturbances as well as observation of cosmetic cracking. Measurement can now be accomplished remotely with computers to eliminate completely human interaction, whereas scientific observation must involve meticulous human inspection immediately before and after a blast. While the focus of this section is instrumental monitoring, the alleged appearance of cracking by neighboring property owners is nonetheless a very serious consideration.

Principal problems in the evaluation of measured effects involve (1) accounting for geologic and weather effects on the overall attenuation with a small number of instruments and (2) incorporating structural response and frequency effects. Principal problems with the observation of blast-induced cracks involve (1) discriminating between blast-induced cracks and environmentally and human-induced cracks and (2) reducing the enormous amount of time necessary for direct observation. Observational problems are normally overcome by using instrumentally measurable blasting controls at levels that are low enough to avoid the threshold of cosmetic cracking even for old, degraded structures or to eliminate cracking altogether. Otherwise blast-induced cracks can be observed only by immediate before-and-after blast inspection.

Structural Response and Frequency Effects

Structures respond to both ground and airborne disturbances, as shown by the bottom four time histories in Figure 16.3-1. Walls respond more to the higher-frequency (15–20 Hz) waves that occur early during ground motion; the superstructure or overall skeleton of the structure responds more to the lower-frequency (5-Hz) waves that occur late during ground motion. Walls are again excited by the arrival of the air-pressure wave. Structural response can be calculated from ground motion if the natural frequency and damping of structural components are known or estimated.

Langan (1980) showed that measured structural response has a higher correlation with calculated single-degree-of-freedom (SDF) response than with peak ground motion. Therefore, structural motions can be estimated more accurately by assuming that they are proportional to response-spectrum values at a particular structure's natural frequency than by assuming that they are proportional to the peak ground motion. This improved correlation is largely a result of the consideration of frequency in the response spectrum, which is calculated from the SDF response.

Source: Dowding 1985.

Figure 16.3-7 Single-degree-of-freedom model of a house, showing the relative displacement of the walls δ, and the analogy between model mass and roof mass, model stiffness, and wall stiffness

Origin of the SDF Model

One of the critical structural response factors is the amount of differential displacement (δ in Figure 16.3-7) that occurs between or along structural members, because it is proportional to strain, which, in turn, causes cracking. Such displacements can be computed by mathematical idealization of the SDF model shown in the figure.

To make calculations practical, it is necessary to simplify most structures. The fundamental characteristics of a structure that govern its behavior under vibratory or dynamic loading are (1) the masses of the main components (analogous to floor and roof masses), (2) the spring stiffness of the main components (analogous to wall stiffness), and (3) the amount of damping or energy dissipation (analogous to differential movement in cracks, joints, and connections). The behavior of one- and two-story buildings is directly analogous to the behavior of an SDF system when movement in only one direction is considered. For multiple-story structures, it is necessary to model the structure as multiple-degrees-of-freedom systems. However, even such systems can be idealized as SDF systems to enable calculation of the fundamental mode of response.

If a structure's damped natural frequency f_d and its fraction of critical damping β are known, the values of dynamic properties f_d and β can be accurately measured from a free-vibration time history of the building response. These measured parameters automatically account for factors that are difficult to quantify, such as the degree of fixity of the columns and the damping coefficient. As shown in Figure 16.3-l, these parameters can be measured from the structure's free response. The time between peaks is the period $T = 1/f_d$ and the decay of free oscillation is proportional to the damping β.

Estimation of Dynamic Response Properties

The fundamental natural frequency f_d of the superstructure of any tall building can be estimated from compilations of work in earthquake engineering (Newmark and Hall 1982):

$$f_d = 1/0.1N \qquad (16.3\text{-}5)$$

where N is the number of stories. Substitution for N of 1 and 2 for residential structures yields f values of 10 and 5 Hz for one- and two-story structures, respectively, which compares favorably with the results of actual measurements.

Table 16.3-2 Natural frequencies for unusual structures

Type of Structure	Height, m	*f*, Hz
Radio tower	30	3.8
Petroleum distillation tower	21	1.2
Coal silo	60	0.6
Bryce Canyon rock pinnacle	27	3

Source: Medearis 1975; Dowding and Kendorski 1983.

Damping β is a function of building construction and, to some extent, the intensity of vibration. Thus it cannot be simplified as easily as can the natural frequency. Measurements reveal a wide range of damping values for residential structures, with an average of 5% (Dowding et al. 1981). This value is appropriate for initial estimates for taller engineered structures. Further details for engineered structures are available in Newmark and Hall (1982).

Walls and floors vibrate independently of the superstructure and have their own but similar fundamental frequencies of vibration in the range 12–20 Hz and averaging 15 Hz (Dowding et al. 1981). Floors in office buildings with large floor spans tend to have natural frequencies that are lower than those of floors in residential structures, but similar to those of walls in residential structures.

Dynamic-response properties of some unusual tall structures cannot be estimated with the 1/0.1*N* equation (Equation 16.3-5). Field-measured natural frequencies for these types of structures are given in Table 16.3-2.

Response Spectra

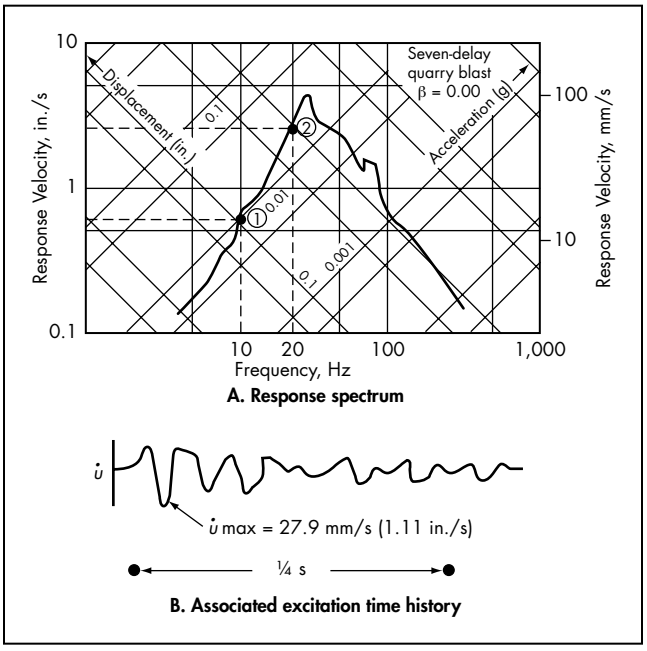
The pseudo-velocity response spectrum of a single ground motion, such as that of the seven-delay quarry blast in Figure 16.3-8, is generated from the relative displacement δ_{max} values of a number of different SDF systems when excited by that motion. In the figure, the time history is operated on by the SDF equation to produce a computed relative displacement δ, which is then multiplied by the circular natural frequency ($2\pi f$ or $2\pi 10$ for point 1) to produce the pseudo-velocity response *PV*.

Consider two different components of the same structure: a 10-Hz superstructure and a 20-Hz wall. If the ground motions $\mathring{u}(t)$ of the quarry blast are processed twice by the SDF equation with $f = 10$ and 20 Hz and β is held constant at 3%, two δ_{max} values result. For the 10-HZ system, the associated values are

$$p = 2\pi(f) = 2\pi(10)$$

$$\delta_{max} = 0.25 \text{ mm } (0.01 \text{ in.}) \qquad (16.3\text{-}6)$$

$$PV_{10} = \delta_{max} = 2\pi(10)(0.25) = 15.7 \text{ mm/s } (0.62 \text{ in./s})$$



For the 20-Hz system, the associated values are

$$p = 2\pi(\text{f}) = 2\pi(20)$$

$$\delta\text{max} = 0.5 \text{ mm } (0.02 \text{ in.}) \qquad (16.3\text{-}7)$$

$$\text{PV20} = 2\,\pi(20)(0.5) = 63.5 \text{ mm/s } (2.5 \text{ in./s})$$

The *PV* values for the two systems are shown in Figure 16.3-8A as points 1 (PV_{10}) and 2 (PV_{20}). If the same ground-motion time history in Figure 16.3-8B is processed a number of times for a variety of *f* values and β is held constant, the resulting pseudo-velocities form the solid line in Figure 16.3-8A.

Source: Dowding 1985, 1986.

Figure 16.3-8 Construction of a pseudo-velocity response spectrum

Computers enable easy calculation of spectra from time histories. The two most commonly used spectra are the Fourier frequency and the pseudo-velocity response spectra. Although they are essentially different in meaning and typical use, they are similar for undamped response where the maximum motion occurs near the end of the time history (Dowding 1985; Hudson 1979). Since response spectra are calculated for damped response and peaks normally occur in the middle as well as the beginning of the time history, the two spectra are not usually the same.

Only the pseudo-velocity response spectrum can be used to directly calculate structural response. Because of the similarity of Fourier frequency and response spectra, either can be used to determine the dominant frequency in the ground motion.

Case Histories

Figure 16.3-9 compares time histories and response spectra from the longitudinal components for an urban construction blast and a surface coal mine blast. Although the peak particle velocities are similar—0.15 in./s (3.8 mm/s) for the construction blast (Figure 16.3-9A), and 0.13 in./s (3.3 mm/s) for the coal-mine blast (Figure 16.3-9B)—the response spectra in the frequency range 5–20 Hz differ greatly. This difference is greatest in the range of natural frequencies for residential structures and their components, 5–20 Hz. In this range, surface-mining motions produce response velocities that are 10 times greater than those for construction motions.

Urban Construction Blast

Ground motion induced by the construction blast was produced by a much smaller shot than that induced by the surface-mining blast. Five holes (12 ft [3.6 m] deep, 1.5 in. [38 mm] in diameter) were arranged in a single row. Each hole was charged with a stick of gelatin dynamite and initiated

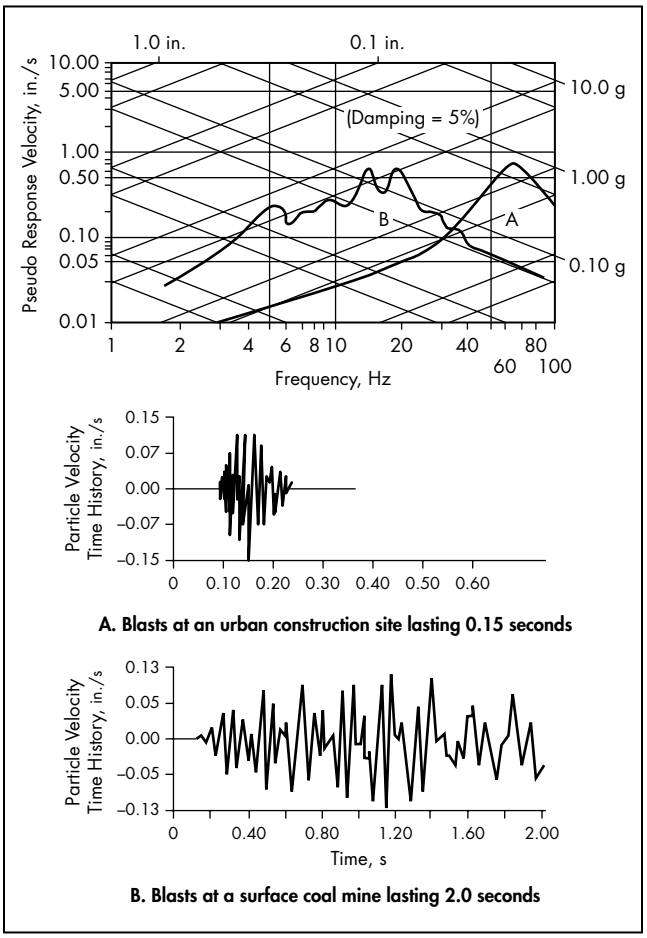


Figure 16.3-9 Time histories and response spectra

separately after a delay held constant at 25 ms. The burdens and hole spacings were small, approximately 2–3 ft (0.6–0.9 m). The total charge was 20 lb (9 kg), and the maximum charge per delay was 5 lb (2.3 kg).

The structure of concern, a historic theater, and the recording transducers were located 50 ft (15 m) away. The rock being fragmented consisted of granitized biotite schist. The shot produced peak particle velocities along the L, T, and V axes of 0.15, 0.16, and 0.28 in./s (3.8, 4.1, and 7.1 mm/s), respectively, with dominant frequencies between 75 and 125 Hz.

Surface Mine Blast

Ground motion induced by the surface-mining blast was produced by a multiple-row blast. Some 60 holes (83 ft [25 m] deep, 15 in. [380 mm] in diameter) were arranged in a four-row pattern. The burden between rows was 20 ft (6.1 m) and the hole spacing was 25 ft (7.6 m). Each hole contained four decks (charges that are detonated after an interval held constant at ≥17 ms). The ammonium nitrate and fuel oil (ANFO) charge weight per deck ranged from 100 to 130 lb (45 to 60 kg). Therefore, the largest charge per delay was 130 lb (60 kg), and the total charge was 27,700 lb (12,600 kg).

The geology between the blast and the transducer, which was located at the nearest residence, consisted of sedimentary rock with 10–30 ft (3–10 m) of overlying silty glacial till. A small gully (33 ft [10 m] deep) was located 1,300 ft (400 m) north of and between the blast and the transducer. The soil at the transducer was 10–15 ft (3–4 m) deep. Some 2,750 ft (825 m) separated the shot from the transducer, where the longitudinal velocity time history in Figure 16.3-9 with a peak of 0.13 in./s (3.3 mm/s) was recorded. The accompanying transverse and vertical peak particle velocities were 0.18 and 0.09 in./s (4.6 and 2.3 mm/s) with dominant frequencies between 11 and 13 Hz. Other similarly designed shots with distances between 1,900 and 2,700 ft (580 and 825 m) produced peak particle velocities between 0.17 and 0.23 in./s (4.3 and 5.8 mm/s) with dominant frequencies between 13 and 17 Hz.

These particle velocities are high at 2,700 ft (825 m), according to scaled-distance relationships. The high values may result from unusual confinement (too large a burden) of delay overlap. For instance, if two delays overlap so as to add, then the maximum charge per delay doubles and the square-root-scaled distance declines by 30%. Particle velocities measured at smaller-scaled distances are closer to expected levels.

Restrained Structures and Rock Masses

Aboveground structures such as homes and rock pinnacles, due to their capacity for free response, can selectively amplify incoming ground motions. In contrast, buried or restrained structures such as pipelines and rock masses cannot respond freely. Regardless of whether the response to strain is restrained or free, however, cracks are still initiated by strains. Strains in freely responding structures are proportional to the relative displacement between the ground and the superstructure, as shown in Figure 16.3-7; strains in restrained structures such as pipelines are usually those of the surrounding ground and can be approximated as the strain produced by plane-wave propagation (Dowding 1985, 1996):

$$\varepsilon = \mathring{u}_c/c_c \text{ and } \gamma = \mathring{u}_s/c_s \qquad (16.3\text{-}8)$$

where

ε = axial strain
$\mathring{u}_c$ = maximum compressive-wave particle velocity
c_c = compressive-wave propagation velocity
γ = shear strain
$\mathring{u}_s$ = maximum shear-wave particle velocity
c_s = shear-wave propagation velocity

For cases involving one critical location along a pipeline, pipe strains should be measured directly on the metal. For cases involving tunnels and/or cavern liners, critical strains can be estimated by calculation of the relative flexibility of the rock and liner (Hendron and Fernandez 1983).

CONTROL OF BLAST EFFECTS

When discussing blast design, it is important to mention the significance of burden. The two most familiar blast design parameters, charge per delay and powder factor, do not optimize the absolute burden between holes. Charge per delay (or instant of time) distributes the detonation process in time; powder factor distributes the detonation process in space. Unfortunately, powder factor alone cannot be used to calculate the maximum or optimum burden, which often controls external blast effects such as ground motion. Burden is often "designed" by general rules such as "*k* times borehole diameter." Proportioning maximum burden by borehole diameter tends to promote larger-diameter holes for a given powder factor, since the larger the hole diameter, the larger the burden

and thus the fewer the number of holes per unit volume and the lower the drilling cost. Unfortunately, large burdens for a given geology and rock type can lead to too large a separation of blastholes, which can lead to excessive back break and vibration.

One simple factor that can be used to check shot designs for excessively large burdens is the so-called drill factor, equal to (holes per unit surface area times hole depth)/unit volume. Experience with pipeline trench blasting reveals that shots designed with powder factors of 5.4 and 3.4 lb/yd^3 (3.2 and 2.0 kg/m^3), which does not seem like much of a difference, can produce vastly different results. These two shots involved 25 and 5 lb (11.4 and 2.3 kg) of explosive per running foot (0.3 m) of 16- and 10-ft- (5- and 3-m-) deep trenches and 76 and 10 lb (34.5 and 4.5 kg) of explosive per hole, respectively. The larger shot cratered the rock and damaged pipe 21 ft (6.4 m) away, whereas the more optimally designed shot did not crater or damage pipe 9 ft (2.7 m) away. The drill factors for these two shots are 1.1 and 3.4 ft/yd^3 (1.3 m/m^3), respectively.

Direct regulation or specification of effects, rather than shot design, is the most effective control from a regulatory viewpoint because effects are so dependent on the details of shot geometry and initiation sequence. Such dependency renders control impossible by simple regulatory specification of two- or three-shot design parameters. For instance, consider control by specification of the maximum charge weight detonated per instant at given distances from the nearest structure. Even with such detailed specification, intended vibration limits at the structure may be exceeded because of poor choice in the location of holes and/or the relative times of initiation.

Present regulatory control limits in many countries are below the levels at which cosmetic cracking may appear. There are two principal reasons for such tight restrictions. First, regulatory limits are influenced heavily by human response to blast-induced vibration and noise. Since humans are approximately 10 times more sensitive than structures to vibration, low regulatory limits are understandable. Second, many regulations appear to have been adopted without the documented scientific experimentation necessary to determine the vibration levels that cause cracking.

Statistical Analysis of Data by Pre- and Postblast Inspection

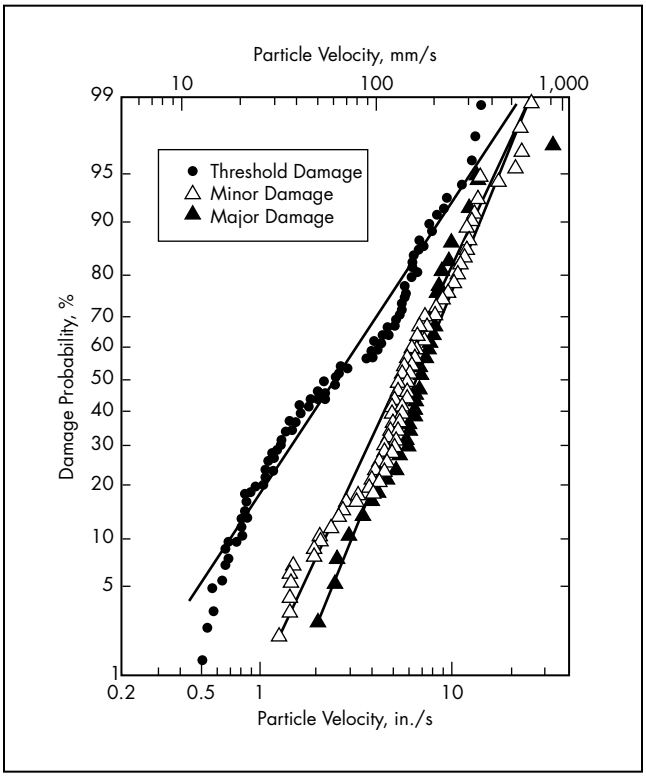
Unmeasurables in observation can be taken into account indirectly by considering the appearance of cosmetic cracks as a probabilistic event. As an aid in determining the effects of certain data sets on overall conclusions, the probabilities of cracking at various different particle-velocity levels have been calculated several times (Siskind et al. 1980b; Siskind 1981). These studies involve both immediate pre- and postblast inspection of walls in residential structures, many of which were old and distorted, and whose walls were covered with plaster. The definitions of observed cracking in each study are described previously in the "Range of Blast Effects" section.

Data from various sets of observations were analyzed with cracking points and the assumption that every cracking point excludes the possibility of noncracking at a higher particle velocity (Siskind et al. 1980b). If the probability of cracking is calculated as the percentage of points at lower levels of velocity, the result is the log-normal scaled plot of the probability of cracking vs. particle velocity in Figure 16.3-10, where threshold damage is the occurrence of hair-sized cosmetic cracks similar to those caused by natural expansions and contraction. This approach seems conservative as low particle-velocity observations do not count noncracking at higher levels.

According to Figure 16.3-10, there appears to be a lower limit of particle velocity of 0.5 in./s (12 mm/s) below which no cosmetic or threshold cracking (extension of hairline cracks) has been observed from blasting anywhere in the world. This observation includes the data with unusually low frequencies that were collected by Dvorak (1962). His data are those that tend to populate the lower region of the figure. High-frequency data (>40 Hz) show that a 5% probability of minor cracking does not occur until particle velocities reach 3 in./s (75 mm/s) (Siskind et al. 1980b).

The admissibility of Dvorak's data has been questioned because of the absence of time histories; some other studies, such as that by Langefors et al. (1958), are plagued by the same problem. To resolve this difficulty, only new USBM observations have been included in a recomputation of probabilities in Figure 16.3-11. The observations include low-frequency motions associated with surface mining. Again, there is a particle velocity, 0.79 in./s (20 mm/s), below which no blast-induced cracking was observed.

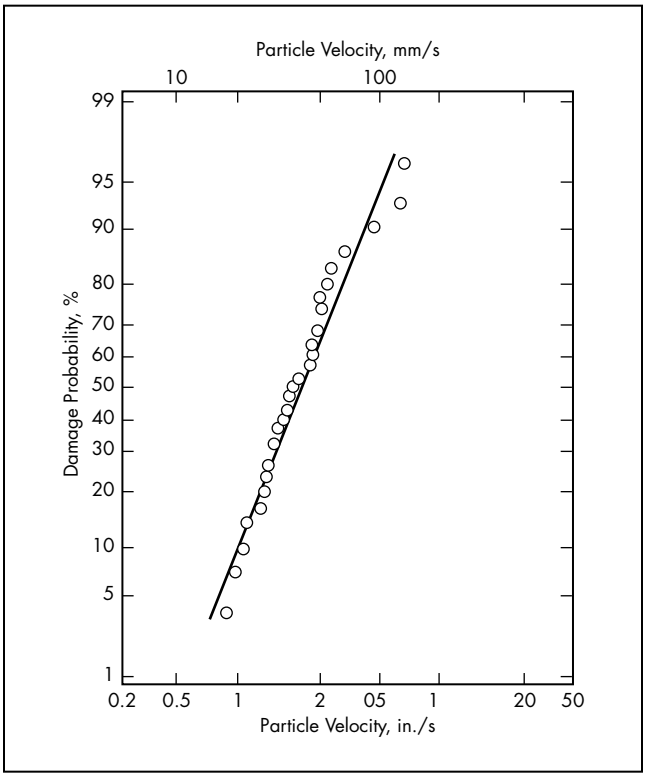
Comparison of Blast and Environmental Effects



Changes in crack width caused by ground motions of <1 in./s (25 mm/s) are smaller than those caused by the passage of weekly weather fronts (Dowding 1988). This conclusion was reached after measuring, for 8 months, the displacement response on a poorly built house located close to surface-coal-mining vibrations. Displacements were measured at 10 different wall positions that included cracked and uncracked wall coverings. Weather- and blast-induced crack displacements across the most dynamically responsive wall-covering cracks are compared in Figure 16.3-12. The continuous and highly cyclical curve is that of displacements produced by environmental changes. The small circles are the maximum zero-to-peak dynamic displacements recorded by the same gauge. Even though the maximum recorded particle velocity is as high as 0.95 in./s (24 mm/s), the maximum weather-induced displacements are three times higher than those produced by blasting. On other gauges, weather changes produced displacements that were 10 times higher than those produced by blasting. This crack response is typical of those for the more than 30 cracks in over 20 studies reviewed by Dowding (2008).

Special Considerations

Statistically determined control limits are too low for basement walls and engineered structures. They are based on the response of residential structures and on lower-limit cases involving cracking of aboveground plaster or gypsum wallboard coverings in older distorted structures.



Engineered Structures

Concrete is much stronger than plaster. Therefore, engineered structures constructed of concrete can withstand maximum particle velocities of at least 4 in./s (100 mm/s) without cracking (Crawford and Ward 1965). Furthermore, buried structures such as pipelines and tunnel linings are not free to respond as are aboveground residential structures whose response provides the data from which most limits are chosen. Therefore, underground structures are able to withstand even greater excitation motions (Dowding 1985).

Figure 16.3-10 Probability analysis of worldwide blast cracking data

Source: Siskind 1981.

Figure 16.3-11 Probability analysis of blast-induced threshold cracks observed by the USBM

Specific engineered structures should be ana1yzed in terms of the strain that can be withstood by critical elements and the strain should be measured. This approach is particularly appropriate for singular structures with isolated portions near the blast source, such as buried pipelines. Often the ground and pipe strains can be confirmed by directly measuring the strains on the buried pipes, as was done by the USBM (Siskind et al. 1994). Their measurements confirmed that welded steel pipelines can withstand ground motions considerably above the typical control limit of 50 mm/s. Oriard (2002) believes that even the high allowable peak particle velocities reported by Siskind et al. are conservative for welded steel pipelines. Recently, use of measured strains at critical locations within engineered structures has been adopted for blasting immediately beneath steel-frame structures. Strain gauges attached to the steel H-beam cores of the building columns confirmed that high peak particle velocities were not causing high strains.

Fatigue or Repeated Events

Since current regulatory limits are so low as to restrain blast-induced displacements below those caused by the passage of weekly weather fronts, the question of repeated events becomes moot. Weather by itself over the years produces greater repeated-event effects than does blasting.

A repeated-event experiment conducted at the USBM test house (Stagg et al. 1984) confirms that current regulatory controls for fatigue cracking are low enough. The test house was framed in wood and had paper-backed gypsum-board interior walls. When continuously vibrated at an equivalent ground particle velocity of 0.5 in./s (12 mm/s), no response

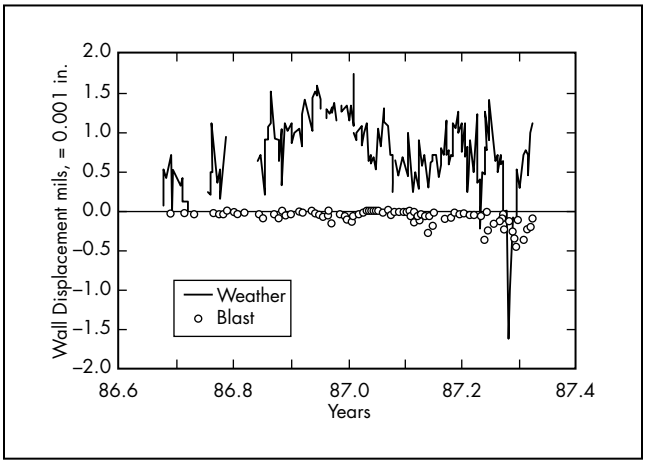

Figure 16.3-12 Displacements produced by weather-induced changes in humidity and temperature (continuous line) and by surface-coal-mine-induced ground motions (circles)

was observed until 52,000 cycles, when a taped joint between sheets of gypsum board cracked. These taped joints are the weakest and most compliant zones in a house with paper-backed gypsum-board walls.

Rock Mass Displacement and Cracking

Cracking rock immediately adjacent to a blast can be controlled by limiting particle velocities to 27 in./s (700 mm/s) in the volume of rock to be protected (Holmberg and Persson 1978).

Rock displacement by forces produced from delayed gas pressure cannot be controlled by specifying an allowable particle velocity. Fortunately, these displacements occur only very close to a blast, within 100 to 165 ft (30 to 50 m) and are associated with blocks that are unconstrained by other surrounding rock.

The sliding instability of individual rock blocks must be evaluated on a case-by-case basis. Each block must have an adequate factor of safety to prevent static failure (Dowding and Gilbert 1988). Since wavelengths of blast-induced shearing motions in rock might be 100–200 ft (roughly 30–60 m) for a 50-Hz wave, only blocks 23–46 ft (7–14 m) in size (~one-fourth the wavelength) can accelerate uniformly. Thus large slopes are unlikely to be destabilized by blasting where the peak particle velocity is high.

Frequency-Based Control with Dominant Frequency

Figure 16.3-13 shows the limit adopted by the OSM, based on a suggested but not rigorously validated proposal by the USBM (Siskind et al. 1980b). Corner 1 of the figure is the lowest particle velocity at which USBM personnel observed cosmetic cracking; corners 2 and 3 are unconfirmed. The dotted line shows the limit for safe construction blasting near engineered structures; the dashed line shows the limit for safe construction blasting in urban areas near older homes and historic buildings.

The dominant frequency that is consistent with Figure 16.3-13 is the frequency that is associated with peaks in the time history whose amplitudes are >50% of the peak or maximum particle velocity. The frequency of these peaks was calculated by the zero-crossing method, as shown in the inset for Figure 16.3-3. The frequency associated with the peak-particle-velocity pulse is a good first approximation and eliminates the need for sophisticated Fourier frequency analysis or response-spectrum analysis. Response-spectrum analyses are the most precise approach to account for the frequency effects of structural response and should be used in singular cases where exacting analysis is required.

Regulatory Compliance for Air Overpressure

Although broken glass is normally associated with excessive air-blast overpressures, limits in the United States are based on the wall response necessary to produce wall strains equivalent to those produced by surface-coal-mining-induced ground motions with a peak particle velocity of 0.75 in./s (19 mm/s). These limits are listed in Table 16.3-3. If a wall-strain level equivalent to that produced by a particle velocity of 1.0 in./s (25 mm/s) measured in the ground were chosen, the allowable overpressure would increase by 3 dB. Most cases of broken glass are reported to have been observed at air overpressures of 136–140 dB (as measured with a linear transducer). Wiggins (1969) reports that sonic-boom air overpressures of >140 dB were necessary to produce cosmetic cracking in military barracks and windows. This observation underscores the conservatism of the 133-dB regulatory limit for cosmetic cracking.

Because of the different sound-weighting scales used by monitoring instruments, the recommended levels in the table differ by instrument system. Since structures are most sensitive to low-frequency motions and the greatest air pressures occur at these inaudible frequencies, A-weighted scales cannot be used at all. Since C-weighted scales are least sensitive at low frequencies, their use requires the most restrictive limits.

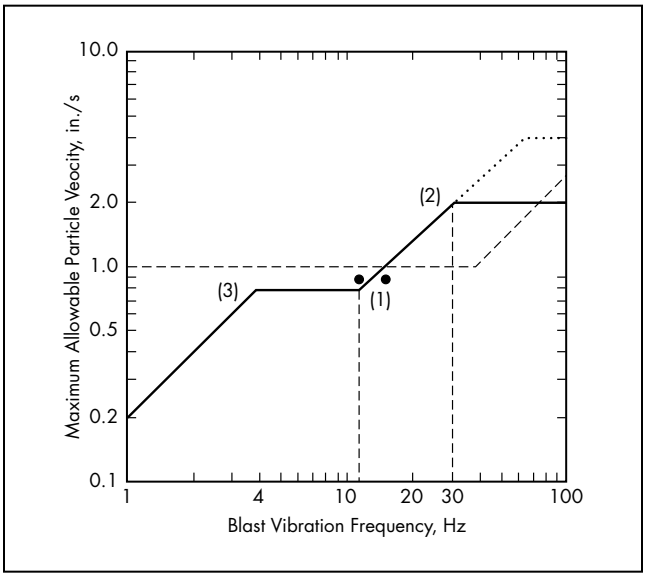

Figure 16.3-13 Frequency-based blast-vibration control limit to protect residential structures, modified from suggestion by USBM

Table 16.3-3 Air-overpressure control limits for various instrument lower-frequency limits

Lower-frequency limit, Hz (–3 dB)	Maximum level, dB
≤0.1-Hz flat response*	134 peak
≤2-Hz flat response	133 peak
≤6-Hz flat response	129 peak
C-weighted slow response*	105 peak dBC

DIGITAL-AGE IMPROVEMENTS IN BLAST CONTROL

Significant digital-age improvements in blast control have accrued from the use of electronic detonators and signature hole analysis.

Electronic Detonators

Electronic detonators contain a microprocessor that improves the precision of firing times by almost two orders of magnitude (Bartley et al. 2000). This increase now makes it possible to precisely control the firing time of each blasthole, even for shots with several hundred holes. Although electronic detonators are more expensive than pyrotechnic detonators, they offer a number of advantages because of their increased control of detonation times as well as increased safety and flexibility of timing.

The increase in firing-time precision is dramatic. Several decades ago, single batches of pyrotechnic detonators had variations (coefficient of variation or 1 standard deviation divided by the average) in delay times as high as 5% to 10% (Winzer et al. 1979); today these values are on the order of 2%–5% (Cunningham 2000). Although 5% may not be important for shots with a small number of holes (<30), it is important for a four-row, 100-hole shot, designed, for example, with surface delays of 17–25 ms between holes and 42 ms between rows. If a nonelectric system is used for this shot, then all of the downhole delays must be at least 500 ms to allow the surface signal

to traverse all of the holes and reach the last hole before the first hole detonates. Thus the last hole will fire between 475 and 525 ms 64% of the time, between 450 and 550 ms 95% of the time, and between 425 and 575 ms 99% of the time. Thus 64% of the delay times fall within ±1 coefficient of variation (5%) of the expected or average delay time of 500 ms. For every shot, there is a 5% possibility of a delay overlap with three (i.e., 50/17) of the previous holes. These increases in unintended external effects occur if overlap results in simultaneous detonations (less than about 8 ms apart), detonation of a rear-row hole before the front-row holes complete, or detonation of holes out of sequence along a row. Electronic detonators now eliminate these potential overlaps and associated increases in back break and peak particle velocity.

The downhole microprocessor in the electronic detonator allows complete freedom in programming firing times. It is now no longer necessary to carry an inventory of preprogrammed delays for all anticipated blast designs. This freedom allows designs to accommodate changes in inter-row and inter-hole delay times as a function of the changing free face at corners and other challenging shot geometries.

Electronic detonators not only reduce peak particle velocities, they also improve safety and in-hole diagnostics (Bartley and McClure 2003). They offer increased immunity to radio-frequency transmissions, electromagnetic interference, and stray current. They are completely testable and can be automated to test and disarm. Most important, in these days of threats of terrorism, they require a specific blasting machine as well as specific identification and password.

Signature-Hole Analysis

Production of synthetic seismograms (ground-motion time histories) by superposition of time-lagged waveforms is another product of the digital age. This superposition is popularly called *signature-hole analysis*, as it requires a waveform measured at the position of interest generated from a single (i.e., a signature) hole at the blast location. The time history recorded for the signature hole (which automatically accounts for the geological irregularities in the travel path) is superposed and time-lagged for each hole's designed detonation time (and travel path in more sophisticated versions) (Anderson 2008). Like electronic detonators, this analytical technique has benefited from the digital age, as it would not be possible without digital waveforms and computerized manipulation.

Signature-hole analysis provides a means to estimate the peak-particle-velocity waveform that results from a change in blast timing. Thus it enables estimates of both the resulting peak particle velocity and the frequency content to match frequency-dependent control limits. Scaled-distance relationships enable only the peak particle velocity, but not the frequency content, to be estimated. Regardless of the genesis of the changes in design, be it the need to improve fragmentation or ground motions or both, signature-hole analysis can be helpful in predicting the changes in amplitude and frequency of the ground-motion time history produced by blasting.

Signature-hole analysis has been the subject of both support and skepticism over the years. It was hampered in its early days by wide differences between design and actual delay firing times for pyrotechnic delays. Yet even its skeptics believe that, when applied correctly, it is a useful design tool. Increased precision of electronic detonators as described previously now eliminates mistiming as a cause of differences between values that are predicted by signature-hole analysis and values that are measured.

CHAPTER 16.4

Water and Sediment Control Systems

Christopher D. Lidstone and Abby Korte

INTEGRATING ENVIRONMENTAL COSTS

Watershed plans have been integrated into public policy in response to the complex requirements of water resources and land-use planning. The permitting of a new mine and the expansion of an existing mine both face public scrutiny, especially in relation to the effects of mining on the local watershed or groundwater basin. Geographic information system (GIS) databases, which are available on numerous public Web sites, typically identify the presence of a mine as a potential point source for pollution.

The mining industry is responsible for much of this perception because of its historic failure to address drainage pollution of all types and because of its historic failure to include environmental costs as part of its public stewardship of the land. In the United States, new sand and gravel operations are often first reviewed by local planning and zoning boards. These planning and zoning boards consist of volunteers or individuals serving by local appointment rather than technical experts or regulators experienced with mining and the impacts related to mining. It is this local board of citizens that first addresses a mine's potential to have an adverse impact on area water wells or nearby flood levels.

The quality and quantity of the surface water runoff that leaves a mine site is often the public's first indication of the presence of a mining operation and the environmental behavior of the corporate citizen. Unlike industrial pollution, which is often generated from an undesirable or unforeseen by-product of the manufacturing process and which is short lived, water pollution from mining can continue long after the mine is shut down and the mineral resource has been fully exhausted. Underground mining can impact groundwater by changing its flow direction, by mixing multiple groundwater sources, and by changing water quality through the physiochemical processes of oxidation and reduction. Runoff from inadequately controlled or poorly reclaimed surface mine disturbances can result in large volumes of sediment-laden waters exiting the mine site and delivering toxic and acid-forming substances to off-site drainages. The act of surface mining will disrupt vegetation, parent material (bedrock), and soil beds. As a surface drainage system trends towards geomorphic instability, excessive erosion will occur and deliver sediment and turbid water off-site.

Cost Benefit and Probability of Failure

The design and implementation of an adequate drainage system before, during, and after surface and underground mining operations is essential to minimize adverse and costly environmental impacts. In addition, the mining industry is faced with the challenge of designing hydrologic and hydraulic control under a myriad of climatic conditions worldwide. For example, surface mines in Sumatra, Indonesia, need to control 3 m (10 ft) of rainfall over a 6-month period during the wet season, while surface mines in western New South Wales, Australia, need to control 0.3 m (12 in.) of rainfall in 60 minutes. Both situations create hydrologic challenges, and one universal truth can be identified—the larger the rainfall volume or the greater the rainfall intensity, the larger and more costly the hydrologic control structure.

Life of the Structure

It can be said that all engineered systems are designed to fail; it is the probability of failure that governs the degree of environmental protection. Each mining company must make this design decision either in response to regulatory criteria or as a cost–benefit analysis made during the planning stages. The probability of failure relationship can be simply stated as

$$P = 1 - q^n$$

where

P = probability of failure
$q = 1 - (1/T_R)$, where T_R is the return period of the design storm
n = anticipated life of the structure

For the purposes of this handbook, the four classes of structures (Class A through Class D) shown in Table 16.4-1 should be considered.

Christopher D. Lidstone, President, Lidstone and Associates, Inc., Fort Collins, Colorado, USA
Abby Korte, Project Hydrologist, Lidstone and Associates, Inc., Fort Collins, Colorado, USA

Table 16.4-1 Design life of structures

Type and Life of Structure	Return Period of Design Storm, T_R
Class A: 10 years	25 years or less
Class B: 11 to 20 years	50 years or less
Class C: Greater than 20 years	100 years or less
Class D: Enhanced protection need	Greater than 100 years

Many temporary haul roads, with a design life of less than 10 years, would dictate the use of a Class A structure (e.g., culverts or diversions). Railroad access structures that will be present for the life of the mine may dictate the use of Class C or Class D structures. A tailings dam or a diversion around a tailings dam will certainly dictate the use of a Class D structure design, including a structure designed for a probable maximum flood (PMF).

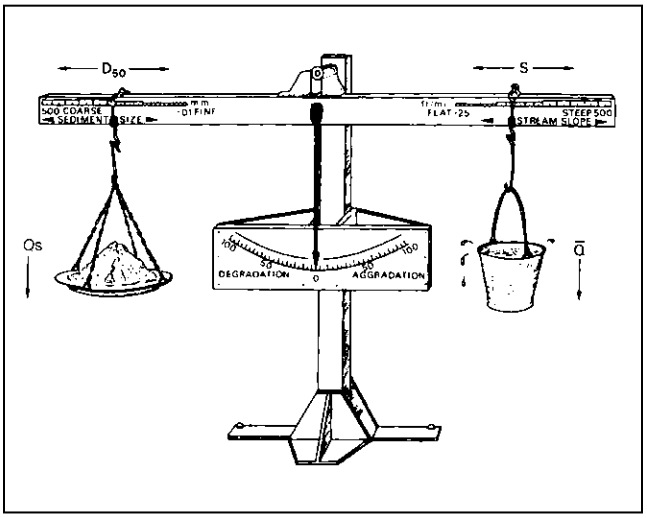
DESIGN CONSIDERATIONS RELATED TO MINING

Geomorphology

Surface drainage systems represent a delicate balance between supply and demand. There exists a delicate balance between the amount of material to be carried by a particular stream system and the amount of power available to move that material downstream. The relation can be presented as follows (Lane 1955):

$$QS \propto Q_s D_{50}$$

where



Q = discharge
S = channel slope
Q_s = sediment discharge
D_{50} = median grain size of the bed material

This equation shows that the discharge, Q, and channel slope, S, are proportional to the sediment discharge, Q_s. This relationship is presented graphically in Figure 16.4-1 and can be used to predict how a channel system might respond to changes in various parameters (sediment load, channel geometry, channel slope, discharge, etc.).

Whether constructing a diversion around a surface mineral mine or determining the appropriate setback distances for a floodplain sand and gravel mine, knowing how that system behaves geomorphically is critical. Historic aerial photo analysis can be a useful tool in determining a river system's channel migration zone and determining the risk of avulsive (versus accretionary) changes in the channel bank location. In addition, it is important to understand how a natural system behaves when designing a surface water diversion so as to avoid additional degradation or aggradation of the channel.

Groundwater Hydrology

It is critical for the engineer or mining company to put wells into the ground to evaluate both groundwater hydrology and chemistry before opening up the ground to extraction activities. Putting wells in the ground allows for the collection of data relating to groundwater levels, groundwater chemistry (oxidizing versus reducing environment), and the direction and rate of groundwater flow. If a proper evaluation of site conditions is not completed prior to the commencement of mining, the site can be inundated with more inflow than the pumping system can handle, resulting in flooding and possibly environmental excursions as mine personnel must handle higher than anticipated levels of "dirty" water.

Water and Sediment Management

Diversion and Interception of Undisturbed Runoff

It has been said that an ounce of prevention is worth a pound of cure. Treating disturbed sediment or nutrient-laden runoff from a mine site can be a complicated and costly endeavor. Diverting undisturbed runoff or upgradient groundwater around the mining operation via a constructed channel or drain will eliminate the need for postprocess water treatment. Diversions take on many design forms, depending on the quantity of runoff and the slope of the channel. Classically, as the quantity of runoff increases, there is a progression from bare earthen to grassed waterways to rock riprap channels. In the design of diversions, the development of a stable channel for the design storm appears to be the primary consideration. Often diversions can accommodate the large design storm event, but failure to consider potential sediment deposition from intermediate events and the subsequent loss of conveyance capacity sometimes leads to failure of the control structure.

If undisturbed runoff cannot be diverted around a mine site, it can sometimes be detained in one or a series of interceptor ponds. Interceptor ponds are designed to store and infiltrate all runoff associated with a given design storm, so that undisturbed runoff does not interact with land disturbances.

Treatment of Disturbed Land Runoff

In the event that surface runoff can be neither diverted around the mine site nor stored and infiltrated back into the groundwater via the use of interceptor ponds, then all runoff, which mixes with the mining process, must be treated to prevent the contamination of downstream water resources. One of the primary pollutants associated with surface mine operations is sediment. Because there are other chapters in this handbook dedicated to the treatment of acid mine drainage and various other chemical constituents, this chapter will deal exclusively with the removal of sediment from disturbed runoff.

Increased sediment inputs to stream systems can have a series of adverse ecological and economic impacts, ranging from increased sediment loading in reservoirs, degradation of fish-spawning habitat, and increased nutrient loading that can lead to eutrophication in stagnant water bodies.

The basis for sediment removal is settlement under quiescent flow conditions. Stokes' law describes the settling velocity of a spherical object in a viscous liquid as a result of the pull of gravity. The settling velocity of a small spherical particle (i.e., sediment) can be described by the following equation:

$$V_s = \frac{2(\rho_p - \rho_f)}{9\mu} g R^2$$

where

V_s = downward settling velocity, m/s
ρ_p = mass density of the particles, kg/m^3
ρ_f = mass density of the fluid, kg/m^3
μ = fluid's dynamic viscosity, Pa s
g = acceleration due to gravity, m/s^2
R = radius of the object, m

When the required sediment settling velocity is determined, a sediment detention pond can be designed such that turbid water is retained long enough for the design particle size to settle out of solution.

In some cases, the detention of turbid waters is not enough to remove clay-size particles, which are too small to be removed by settling. In these cases, the treatment of disturbed runoff by the use of flocculants may be necessary. Most flocculants are composed of heavy organic polymers with a strong positive charge that attracts the negatively charged clay particles in a "bundle," allowing them (collectively) to settle out faster than single particles might settle.

Flocculants tend to be cost prohibitive and are generally used only when at least one of the following conditions are present: there is a limitation on the amount of space and, therefore, time available to allow particulates to settle out; there is a particularly large proportion of the sediment load that is silt or clay in size; or the water quality of the receiving water body is of a pristine nature. If a flocculant is used, the most important component of the distribution system is to ensure that the flocculant is well mixed with the discharge.

SURFACE WATER HYDROLOGY

An accurate analysis of surface water hydrology and runoff processes is a critical first step in the design and management of water and sediment control systems. It is important not only for the water resources professional to determine whether the project cost, timing, and scope warrant the collection of surface water data, but also to recognize the limitations and errors associated with the collection and analysis of a time-limited data set. Often on-site data must be augmented with data from published sources. For any given project location and scope, there is no absolute best method. However, the only universal truism in surface water hydrology is that, if available, there is no substitution for locally collected data.

Selection of Analysis Method

Many methods are available for estimating design rainfall depths and for constructing synthetic rainfall distributions or a rainfall hyetograph. The construction of the rainfall hyetograph leads to the calculation and simulation of a runoff hydrograph. For the design of some surface water controls like culverts and some diversions, a peak runoff rate is sufficient. The design of storage components such as detention ponds and certain conveyance channels require the determination of the entire storm hyetograph and runoff hydrograph, as the design must take into account conveyance and residency time calculations.

Design Rainfall Event

The design rainfall event is typically mathematically generated from volume-duration-frequency data or intensity-duration-frequency data for a specific region or project location (Seybert 2006). The design rainfall event is often established by local permitting regulations and is the foundation of the runoff modeling and design calculations for hydraulic structures associated with surface mining operations. The most comprehensive source of rainfall data for the United States and its territories is provided by the Hydrometeorological Design Studies Center and the Office of Hydrological Development of the National Oceanic and Atmospheric Administration's National Weather Service through its Precipitation Frequency Data Server, which can be accessed through the Internet at www.weather.gov/ohd/hdsc/ (NOAA 2009). Through the listed Web site, one can access state-specific rainfall distribution data in the form of rainfall atlases (NWS 1961) and distribution tables (Arkell and Richards 1986). International organizations maintain similar rainfall information databases, and these can be researched in advance of mine planning. If it is important to know the temporal distribution of rainfall for a particular event, and real-time local data are unavailable. The Soil Conservation Service (SCS) and local agricultural services provide synthetic rainfall distribution curves (SCS 1973).

Peak Flow Determination

Rational Method

The rational method is the most commonly used technique for determining peak flow rates. The rational method formula is

$$Q_{PK} = CiAk$$

where

Q_{PK} = peak flow rate, m^3/s (ft^3/s)
C = dimensionless runoff coefficient
i = rainfall intensity, mm/h (in./h)
A = drainage area, ha (acres)
k = conversion factor equal to 0.00278 in metric units (1.008 in English units)

The dimensionless runoff coefficient, C, is designed to incorporate differences of rainfall interception/infiltration, surface detention, and/or antecedent moisture conditions. It is nearly impossible for a single factor to incorporate all of these. Therefore, more commonly, the C factor is based on land-use type and imperviousness. A simplified list of C factor values is shown in Table 16.4-2. The C factor can also be area weight averaged throughout the basin of study (Haan and Barfield 1978). The rational method is a simple peak flow calculation based on several assumptions. Included in the assumptions is that the rainfall occurs uniformly throughout the basin and that the rainfall frequency equals the runoff frequency. Typically, this can be successfully used for smaller basins. The method is well described in numerous publications, including Haan and Barfield (1978) and Simons, Li and Associates (1982b).

Table 16.4-2 Simplified table of rational Method *C* factors

Groundcover	Runoff Coefficient, *C*
Lawns	0.05–0.35
Forest	0.05–0.25
Cultivated land	0.08–0.41
Meadow	0.1–0.5
Parks, cemeteries	0.1–0.25
Unimproved areas	0.1–0.3
Pasture	0.12–0.62
Residential areas	0.3–0.75
Business areas	0.5–0.95
Industrial areas	0.5–0.9
Asphalt streets	0.7–0.95
Concrete streets	0.7–0.95
Roofs	0.75–0.95

SCS Curve Number Method

An alternative is the SCS curve number (SCS-CN) method, which was first published in the *National Engineering Handbook* (SCS 1982) in 1956 by the Soil Conservation Service, now known as the Natural Resources Conservation Service. The SCS-CN method was developed from extensive field investigations and has been revised several times. The SCS-CN formulas are as follows:

$$Q = \frac{(P - I_a)^2}{(P - I + S)}$$

$$I_a = 0.2S$$

$$S = \frac{1{,}000}{\text{CN}} - 10$$

where

Q = runoff, in.
P = precipitation, in.
I_a = initial abstraction, in.
S = potential maximum retention, in.
CN = curve number

Initial abstraction generally consists of interception losses, surface storage, and soil infiltration. Because of the dimensional incongruity of these formulae, there is no direct coefficient conversion between English and metric units, and each variable must be converted separately. This method requires the water resources professional to collect information pertaining to land use, hydrologic condition, and hydrologic soil type. A more detailed explanation of the development and use of the SCS-CN method is beyond the scope of this chapter, but many excellent texts and papers outline the methodology and provide the necessary tabular data (Seybert 2006).

Time of Concentration

The time of concentration, t_c, is the length of time it takes for precipitation to travel from the most remote part of a watershed to the point of interest, often the basin outlet. Several methods exist for estimating t_c, including, but not limited to, the SCS upland method and the kinematic wave method (Kirpich 1940; Ragan and Duru 1972). The Ragan and Duru equation is

$$t_c = \frac{C_1 (nL)^{0.6}}{(i_e^{0.4} S^{0.3})}$$

where

t_c = time of concentration, min
C_1 = a constant equal to 1.977 in metric units (0.928 in English units)
n = Manning's roughness coefficient
L = length, m (ft)
i_e = excess rainfall intensity, mm/h (in./h)
S = slope (vertical/horizontal), m/m (ft/ft)

This equation is only valid when the product of i_e and L is greater than 152 m (500 ft).

The Manning's roughness coefficient, n, can be assigned as a single unit for the reach of interest or can be composited to better represent a channel with varying degrees of resistance to flow. Several sources of information are available for Manning's n values, including books with photographs of channel sections with measured n values (Chow 1959; Acrement and Schneider 1984).

The Kirpich equation for estimating t_c is

$$t_c = C_2 L_1^{0.77} \left(\frac{L_1}{H}\right)^{0.385}$$

where

C_2 = a constant equal to 0.0195 in metric units (0.0078 in English units)
L_1 = maximum flow length, m (ft)
H = elevation difference between the hydraulically most remote point in the watershed and the point of interest, m (ft)

SURFACE WATER HYDRAULICS

Designing a diversion ditch or reclamation channel requires that the mining professional must have a good understanding of the hydraulic and sediment transport characteristics, as well as channel geometry and morphometric characteristics of the native system. Flow conditions in open channels are complex. The position of the free water surface and channel geometry can change with respect to time and space. Depth of flow, velocity, discharge, and slope of the channel bottom and water surface are interdependent.

The basic hydraulic theories that relate flow velocity, depth, discharge, and slope are as follows:

- Conservation of mass (continuity)
- Conservation of linear momentum
- Conservation of energy

Conservation of mass states that matter can neither be created nor destroyed. Based on this it can be concluded that flow discharge in each section of a river reach is identical. Conservation of momentum concludes that the summation of all external forces (pressure, body, and shear forces) acting on the fluid is equal to the rate of a flux of momentum through the boundary of the fluid. The law of conservation of energy (the first law of thermodynamics) states that energy can neither be created nor destroyed. For steady flow, the total energy (kinematic and potential energy) at any point in a stream is equal to the sum of the total energy at any downstream point and the loss of energy between the two points.

The continuity, momentum, and energy equations can be used to determine the elevation of the water surface in an open channel for a given discharge. For steady flow, the energy equation is written in the following form to compute the water surface profile:

$$\delta L = \frac{H_2 - H_1}{S_o - S_f}$$

where
δL = distance between sections 1 and 2, m (ft)
H = specific head, m (ft)
S_o = bed slope (vertical/horizontal), m/m (ft/ft)
S_f = friction or energy slope (vertical/horizontal), m/m (ft/ft)

The specific head, H, is defined as

$$H = \frac{V^2}{2g} + y$$

where
V = average velocity, m/s (ft/s)
g = acceleration due to gravity, m^3/s (ft^3/s)
y = flow depth, m (ft)

The energy slope, S_f, is the slope of the energy line representing the elevation of the total energy of flow. It is related to the velocity and depth by the following empirical relationship, which is known as Manning's equation:

$$Q = VA = \left(\frac{k}{n}\right) AR^{2/3} S^{1/2}$$

where
Q = flow rate, m^3/s (ft^3/s)
V = velocity, m/s (ft/s)
A = flow area, m^2 (ft^2)
k = conversion factor equal to 1.00 in metric units (1.486 in English units)
n = Manning's roughness coefficient
R = hydraulic radius, m (ft)
S = channel slope (vertical/horizontal), m/m (ft/ft)

R is calculated by the cross-sectional area of the channel divided by the wetted perimeter. Basic channel hydraulics is well summarized in Simons, Li and Associates (1982b).

SEDIMENT PRODUCTION

Soil Loss Equations

The Universal Soil Loss Equation (USLE) calculates sediment production via a combination of sheet and rill erosion and the associated runoff for the landscape profile. The soil loss is an average erosion rate for the landscape profile. Erosion can vary widely, even on a uniform slope, depending on slope position and configuration of the slope profile. USLE does not estimate the amount of sediment leaving a field or watershed but estimates soil movement at a particular site. The quantity of sediment eroded from a slope depends on the erosive power of rainfall, soil characteristics, slope length, and gradient, as well as type and amount of soil cover and conservation practices. These parameters have been combined into the USLE (Wischmeier and Smith 1978).

$$A = R \times K \times LS \times C \times P$$

where
A = soil loss, kg/ha (st/acre)
R = rainfall factor
K = soil erodibility, t/ha (st/acre) per unit R
LS = dimensionless length–slope factor that accounts for the actual length and slope compared to a standard slope of 9% and 22.1 m (72.6 ft) in length
C = a factor that accounts for the effectiveness of vegetative cover, mulches, etc.
P = a factor that accounts for the effectiveness of conservation practices such as terraces or fallow cover

Values for these parameters (i.e., R, LS, C, and P) may be found in many sources and have been modified for the mining industry (Chow 1959; Wischmeier and Smith 1978).

Contemporary to the USLE, the Revised Universal Soil Loss Equation (RUSLE) computes sheet and rill erosion and the associated runoff from untilled lands, as the original USLE was derived and intended for use in agricultural settings. RUSLE contains several updates and changes from USLE, including new and improved soil erodibility indexes for some areas, time-variant soil erodibility to reflect freeze–thaw cycles, new equations to account for slope length and steepness, and additional C and P factors to account for cover and conservation practices on untilled lands.

Regression Studies

In some cases, particularly when there are anthropogenic or human-related sources of sediment present, it is possible to pull real data on sediment contributions from previously conducted field research. In many cases, real data have been collected on sediment production rates from given land-use types, and regression (i.e., retrospective) analyses have been performed to model the rate of sediment production as a function of several landscape variables. For example, several studies have been completed quantifying sediment production from various unsealed road surfaces. One such study has quantified and modeled sediment production from all sources, focusing on forest roads in the southern Sierra Nevada, California, United States (Korte and MacDonald 2005).

Other Methods

In the international setting, predictive models developed in the United States may not be applicable. International mining efforts typically require the site-specific application of empirical methods and observations. Denudation rates can be calculated from observation of past mining practices. One technique that is uniformly applicable includes the volumetric measurement of accumulated sediment within a pond over a known period of time. In an effort to develop an appropriate empirical model, it is important for the mining professional to evaluate observed conditions within the watershed that delivered water and sediment to that pond.

HYDROLOGIC STRUCTURES

Hydrologic control structures are an integral part of any mining operation. Such structures are generally referred to in the context of surface mines and their associated disturbances, but are becoming increasingly more important for both underground and in-situ recovery (ISR) mining operations. All mining

operations include such surface disturbances associated with roads, buildings, power lines and substations, stockpile areas, loadout and water treatment facilities. Such facilities require water and sediment control during mining and reclamation at the end of mining. Surface mining operations are further complicated by the associated disruption of the existing topography to extract the ore or mineral commodity from the ground. Such operations will require a more sophisticated drainage control and a far more complicated final reclamation plan than underground or ISR operations.

To adequately control pollution, it is necessary to establish a complete drainage design plan for the entire permit area using sound engineering practices. It is often important to separate the hydrologic control plan on a temporal basis, that is, short term (1 to 5 years) and long term or "life of mine," depending on the size and dynamic nature of the operation. The short-term plan will include design details, engineering calculations, and likely all required construction permits from the various regulatory agencies. The long-term or life-of-mine plan is simply a concept plan, which will dictate the progression and type of hydrologic control features but will allow flexibility as mine production and mining methods inevitably change. This long-term plan is completed without actual engineering design or regulatory permitting.

In addressing the overall hydrologic control plan, it is essential that the design engineer recognize that the drainage basin or basins within the mining area are only part of a larger, more complex system. Mining within a portion of the drainage basin will elicit a complex response both upstream and downstream from the area of actual disturbance. The design engineer must consider the active mine controls and, even more importantly, the postmining restoration of this drainage system, such that the reclaimed land surface will properly function as part of a larger system. Hydrologic control structures are summarized in Table 16.4-3.

Table 16.4-3 Hydrologic control structures

Type of Structure	Design Life	Purpose of Structure
Diversion channels and ditches	Temporary or permanent	Divert undisturbed runoff around the mining operation in a stable fashion.
Culverts	Temporary	Divert runoff below mine access or haul road.
Sediment ponds	Temporary	Treat disturbed land runoff.
Interceptor ponds	Temporary or permanent	Prevent undisturbed runoff from entering a mine pit or mine area. Can serve as a stock pond or detention pond.
Small area sediment controls (best management practices)	Temporary	Treat disturbed land runoff from small acreage disturbance.
Dry wells	Temporary or permanent	Capture and treat disturbed land runoff.

Diversion Channels and Ditches

Diversions are used throughout mining to intercept and convey runoff. Typically they are used to convey runoff from undisturbed areas around active mining sites and preclude mixing of runoff waters and reduce the quantity of runoff requiring treatment. In some cases, diversions are necessary to maintain water flow for downstream water users, including farmers, recreation, wildlife, and fisheries. Because the construction of a diversion of an intermittent or perennial stream is generally a high capital-cost item, mine management must closely address the question of the proposed design life and determine value engineering. As the size of the drainage basin increases, it can be assumed that the means to stabilize each diversion will transition from a simple earthen cut/fill at a graded slope to a well-established vegetated channel to a channel stabilized with geotextile, concrete, or riprap. Drop structures are typically constructed at locations where the design or as-constructed channel gradient is too steep, resulting in excessive flow velocities and the need for channel protection (Jones and Lidstone 1996). A diversion structure that will remain in place after mining is completed must also incorporate geomorphic stability and may include aquatic habitat features (e.g., pools, riffles, large woody debris, and riparian vegetation).

The diversion hydrology is determined after the design life is established. Permanent diversions or life-of-mine features are typically designed for the 100-year discharge event, with additional capacity to accommodate freeboard. Regulatory programs may dictate the use of the PMF or some proportion of the PMF, where mine tailings or hazardous wastes are involved. The diversion hydraulics can be simplified using normal depth procedures (Manning's equation) or using more complicated software programs such as SEDCAD, from Civil Software Design LLC, and HEC-RAS and HEC-HMS, which were developed by the Hydrologic Engineering Center of the U.S. Army Corps of Engineers. For the purposes of this section, conveyance capacity of a diversion can be summarized by

$$Q = VA$$

where

Q = design discharge, m^3/s (ft^3/s)
V = velocity, m/s (ft/s)
A = cross-sectional area, m^2 (ft^2)

Design hydraulics can be simply calculated using Manning's equation as follows:

$$V = (1.49/n)R^{2/3}S^{1/2}$$

where

V = average velocity, m/s (ft/s)
n = roughness coefficient of the channel, which is empirically determined
$R = A/P$, or the cross-sectional area of the channel divided by the wetted perimeter, m (ft)
S = slope (vertical/horizontal) of the channel or hydraulic gradient, m/m (ft/ft)

The channel must be proportioned to carry the design runoff at average velocities less than or equal to the maximum permissible velocity. This is accomplished by applications of the Manning's formula with iterative adjustments in channel parameters until the maximum permissible velocity is achieved.

Numerous studies address the maximum permissible velocity of a channel, and the most commonly accepted is in Chow (1959). Channel type or channel lining must be established in the determination of maximum permissible velocity. Noncohesive (sand bed) channels are governed by initiation

of motion and upper limits of 0.6 to 0.9 m/s (2 to 3 ft/s). Well-vegetated channels can withstand velocities of 1.5 to 2.1 m/s (5 to 7 ft/s) before erosion will take place. Cohesive bed (clay) channels are typically not governed by the principles of initiation of motion but rather by tractive force as follows:

$$\tau_c = \gamma DS$$

where

τ_c = critical shear
γ = unit weight of water, which is 1,000 kg/m^3 (62.4 lb/ft^3)
D = flow depth, m (ft)
S = channel slope (vertical/horizontal) or hydraulic gradient, m/m (ft/ft)

Allowable shear is dependent on the strength characteristics of the clay, plasticity, and electrical conductivity or salinity. Typical critical shear, τ_c, limits range from 0.73 to 3.12 kg/m^2 (0.15 to 0.64 lb/ft^2).

Where erosion problems are anticipated in design, the engineer will need to employ hydrologic control structures such as riprap or gabion drop structures to reduce overall channel slope; riprap or geotextiles to protect the underlying soils from erosion; or interlocking concrete blocks to stabilize the problematic reach of the channel. Numerous publications assist in the design of such structures, including Haan and Barfield (1978); Simons, Li and Associates (1982a); Ferris (1996); and Jones and Lidstone (1996). The design and construction of a riprap drop structure or grade control is an important means to reduce the overall channel slope and thus the erosive energy within a stream channel or diversion.

Permanent diversions require forward planning and a dedication of design and construction resources. Such diversions, which are used for the reestablishment of a drainage system affected by surface mining, must perform adequately without the assured benefit of periodic maintenance. The designer must be familiar with the inherent stability of the upstream and downstream undisturbed watersheds, including channel geometry, channel slope, channel bed and bank materials, and geomorphic characteristics. Although the designer may not necessarily want to duplicate these natural conditions, in recognition that the act of mining has permanently changed the landform, such preexisting conditions will lend themselves to design concepts. Channel design should incorporate a pilot channel to convey the annual channel forming event, typically the 1.5- to 2-year flood event, and a floodplain that at a minimum can convey the 100-year/24-hour flood event. Channel meanders, pools, and riffles may be incorporated into the ultimate channel design. Implementation of final design must incorporate biological and riparian considerations. Typically, this includes the presence of randomly placed boulders, large woody debris, and bank stabilization with woody vegetation. Numerous publications can assist in the design of such permanent diversions (Simons, Li and Associates 1982b).

Diversion ditches are a smaller-scale diversion structure, but they have become increasingly important in areas disturbed by underground mines and ISR-type mining operations. Diversion ditches can protect a well field from overland flow, as well as protecting the face-up or main portal area from off-site erosion. The design event for such ditches are governed by the life of the structure to be protected or, in some cases, the length of time for the site to be successfully revegetated and become stable in its own right. The ditches control a small basin area and often deliver water to a culvert and ultimately to native, undisturbed receiving water. Similar to the drainages, adequate freeboard must be allowed, and the water should be passed via the diversion ditch in a nonerosive fashion.

Culverts

Culverts are used throughout mining to intercept and convey runoff under access roads, stockpile areas, and structures. The selection of a properly sized culvert is dependent on the life of the structure (design discharge), type of culvert, entrance configuration, pipe length and slope, headwater constraints (the available elevation above the top of pipe to pond water), and tail-water condition (the degree to which the downstream portion of the culvert is submerged). Design procedures have been somewhat simplified by the development of culvert-capacity charts or nomographs. Culvert capacity, Q, is governed by the following general equation:

$$Q = \frac{a\sqrt{2gH}}{\sqrt{1 + K_e + K_b} + K_c L}$$

where

a = cross-sectional area of the pipe, m^2 (ft^2)
g = gravitational acceleration, which is 10 m/s^2 (32 ft/s^2)
H = head loss through the pipe, m (ft)
K_b, K_c, and K_e = coefficients that reflect various head loss coefficients that are pipe dependent
L = length of the pipe, m (ft)

Most manufacturers provide design nomographs for their type of pipe, and the Federal Highway Administration (FHWA) presents an extensive culvert-design publication called HEC-5. Publicly available software, HY-8, can be downloaded from the FHWA Web site (FHWA 2009).

Several types and shapes of culverts are commonly used in modern mines. These include concrete pipe, reinforced concrete pipe, corrugated metal pipe, corrugated steel pipe, corrugated plastic pipe, and smooth-walled plastic pipe. Each pipe type has certain advantages in cost, transportability, loading characteristics, and durability. The shape of the culvert will often dictate its capacity and, given modern environmental concerns, its ability to allow sediment and fish to pass. Barrel culverts, which are often the most common, will typically maintain the highest velocities, but they can be a barrier to fish. Box culverts provide greater flow capacity, but can require more frequent maintenance and may not provide the depth of flow to allow fish passage. Arch culverts and, more preferably, bottomless arch culverts (i.e., those where there is neither a steel underbody nor an engineered lower section) can be used. Bottomless arch culverts can be founded on bedrock or on the natural alluvial material, which comprises the actual streambed. The use of such culverts can balance flow-capacity demands while allowing fish passage with a natural substrate. The development of a natural substrate within the floor of the culvert will allow the development of a low-flow channel for the movement of fish. However, such culverts can be sediment sinks, given that the floor of the culvert will often behave as a natural channel. The geomorphic position of bottomless arch culverts is a critical design consideration.

A fundamental mistake at many mine sites is the use of an undersized culvert or the placement of a culvert at too flat

a grade. Under no circumstances should a culvert less than 0.45 m (18 in.) in diameter be used. The ability of the culvert to pass sediment and debris must be considered in all designs. Where regular maintenance is available, the use of a trash rack can prevent culvert clogging. In an area of high sediment yield, too flat a culvert grade will result in plugging. In this case, culverts should be set at a minimum grade of 2%. Where erosion may occur at the inlet or outlet or if a road overtopping design must be considered, the placement of erosion protection is a critical design concern. A fundamental error in culvert design and placement is the purchase of too short a pipe length. Where erosion control is required at the inlet or outlet portion, the pipe must project a sufficient length to allow the adequate construction of erosion control. Usually this requires an additional 3 to 6 m (10 to 20 ft) of culvert length, depending on the burial depth and diameter of the culvert. This erosion control could be riprap, gabion structures, or a concrete headwall. Riprap is the most commonly used. Riprap should be placed on a slope no steeper than a 1.5:1 (horizontal/vertical) slope. So, if a 1.2-m- (4-ft-) diameter culvert is placed under a haul road with 0.6-m (2-ft) burial depth, then the culvert will need to project 2.7 m (9 ft) on the upstream and downstream sides. For a typical 7.4-m- (24-ft-) wide haul road, this would require the purchase of a 13-m- (42-ft-) long culvert. Tail-water protection is equally important to ensure that the culvert is not undermined by erosion or, in the case of overtopping flows, that adequate protection is available. The tail-water protection is generally loose riprap and should extend a minimum of 3 m (10 ft) beyond the end of the culvert.

Water and Sediment Control Ponds

Water and sediment control ponds have been used extensively by the mining industry for stormwater management and sediment control. For simplicity purposes, three basic types of ponds are used in mining: sediment ponds, interceptor ponds, and infiltration basins. Sediment ponds are used to reduce peak flow, trap sediment, and meet effluent limits (Ferris 1996). In many countries, mine discharge must meet certain governmental standards. In the United States, these standards are dictated by both state and federal programs under the guise of the National Pollutant Discharge Elimination System, Water Pollution Control Facility, and/or a general stormwater permit. The key distinction in treatment requirements is to determine whether or not the source water mixes with process water or has the potential for being contaminated by some other pollutant besides soil. In general practice, it is important to keep stormwater from commingling with the following: truck traffic (oil and grease), process or wash water, and chemical leachate sources.

For this reason, interceptor ponds may be constructed. Interceptor ponds are used to prevent runoff from entering the mining pit and impacting mining operations. Many mine operators will construct a pond on the upstream side of a mine pit to ensure that at least a portion of the native stormwater is captured prior to entering the mining operations. This water can then be diverted or pumped around the mining operation or can be left to evaporate or infiltrate away. The design capacities of such ponds are not dictated by regulatory or treatment requirements but are more likely based on mining economics. A larger pond (100-year/24-hour capacity) can provide the pit with a high degree (0.01 annual probability) of protection. A smaller pond will provide incrementally less protection. Interceptor ponds can also include small, elongated ponds, which are constructed on mine benches to capture groundwater and/or surface water. Such ponds will prevent stormwater from mixing with the mining operation, thereby eliminating the need for water treatment.

Finally, an infiltration basin is a depression in the earth that is designed to percolate the water to the subsurface. Such basins are designed on either highly pervious soils/rock, or alternatively, they may be overexcavated and filled with pervious rock. Infiltration basins are most common on aggregate mines, rock quarries, and placer mines where such pervious soils or fractured rock are most likely to occur. The advantage of such basins is that there will be a minimal water-handling requirement, and water treatment regulations typically do not apply.

Design Considerations

Sediment pond design must address placement or location standards, hydrology, sediment production from the upstream watershed, and the upstream watershed's efficiency to trap sediment. The location of this sediment pond within the watershed must consider the size and location of the mine-related disturbance, sizing criteria to ensure that the dam height and volumetric capacity will meet regulatory criteria, pond shape to ensure sediment trapping efficiency, and overall shape to allow sediment cleanout as required.

Sediment ponds are generally located downstream of the mining disturbance, so as to capture and treat disturbed land runoff. The mining engineer must compute design hydrology to permit the sizing of the structure and, as applicable, its embankment and spillway. Design hydrology is directly related to the discussion of the design life of the structure (see the "Life of the Structure" section earlier in this chapter). In the United States, design hydrology may be dictated by federal or state regulation. For example, a coal mining company in the United States must establish sediment control "so as to prevent to the extent possible additional contributions of suspended solids to stream flow, or runoff outside the permit area, but in no event shall contributions be in excess of requirements set by applicable State or Federal law" (30USC1265). Various state guidelines interpret sediment pond containment for the water and sediment yield for the 10-year/24-hour storm event. The volume associated with the design event is directly related to the position of the structure within the watershed and the runoff of the soils, as discussed earlier in the "Surface Water Hydrology" section. A larger water or sediment containment volume could translate into a larger embankment structure and may dictate a more complex permitting/design or construction process. Therefore, the selection of the embankment's location within the watershed (i.e., upstream contributing watershed) may be critical in an effort to avoid such complexities.

In the case of process water ponds, where the generation of sediment and dirty water is the result of material processing operations, basin or pond shape is critical. These ponds are often required to discharge, and as such they must meet discharge standards. The length-to-width ratio is important in that the longer the flow length, the greater the opportunity to deposit or settle suspended solids. Such ponds may incorporate baffles to increase flow length (settling time) and to allow periodic cleaning of the facility. Where sedimentation rates need to be accelerated and additional flow length cannot be achieved, flocculants can be added to water to enhance the sedimentation process.

Sediment pond design is well documented (Haan and Barfield 1978; Simons, Li and Associates 1982a; Ferris 1996).

Dams and Incised Structures

A variety of dam/impoundment types have been utilized for these structures, including embankment dams and excavated basins. The most common pond consists of a dam embankment that may range from 3.6 to 6 m (12 to 20 ft) in height and a collection basin. The dam height requirement of 6 m (20 ft) may be dictated by certain regulatory requirements. For example, the Mine Safety and Health Administration's Safety of Dam requirements will influence the determination of a sediment-pond dam height in the United States (30CFR 77.216; MSHA 1975). On an international basis, dam height consideration may be governed by local rules, but more importantly, dam height is governed by the talents of the designer and by quality control during construction. Large dams that exceed 6 m (20 ft) should be designed by an experienced engineer and will require foundation preparation, material selection and compaction control, among other requirements. The safest ponds are those with no embankment. Such pond basins are constructed as incised or below-grade basins. These basins can be of an unlimited depth and may include the mine pit itself. Such basins are not subject to rules and regulations dictating dam stability, but they can be subject to rules that require thorough drainage or passage of water for downstream users.

Inlet Structures

Inlet structures are an important design consideration in all sediment ponds. Such structures should be located to provide the hydraulically longest flow path between the inlet and outlet. This will help to reduce short-circuiting and provide a higher potential for mixing the inflow with the permanent pool, thereby reducing sediment concentration through dilution and providing a longer residence time needed for settling sediment.

Stabilizing the inlet structure is particularly important in an excavated basin where the sediment pond is incised below the elevation of the natural ground surface. In this case, the inlet structure conveys water from the natural stream's bed elevation to the bottom of the pond or to the elevation of the permanent pool. Without an effort to stabilize the inlet structure, erosion and excess generation of sediment will occur. Inlet structures can be stabilized by riprap, concrete, vegetation, or numerous erosion-control products.

Sediment Storage Capacity

Sediment storage can be addressed by numerous methods, including computer programs or a guideline such as *x*-acre-feet of storage per disturbed contributing watershed acreage (Ferris 1996). The most common method is an adaptation of the USLE or one of the numerous variations available in the literature, discussed previously in the "Sediment Production" section and later in the "Small-Area Sediment Controls" section. Depending on cleanout opportunities, each sediment pond should be designed to hold a minimum of 3 years of sediment accumulation.

Permanent-Pool Storage Capacity

The size of the permanent pool affects peak flow reduction, sediment trap efficiency, and effluent concentration. A permanent pool can be generated from groundwater inflow or surface water inflow where seasonal precipitation and runoff exceeds evaporation and infiltration. A permanent pool volume is calculated through the development of a water balance within the watershed and at the sediment pond site. A permanent pool can provide significant dilution opportunities; it will also result in less available storage and detention time for the influent waters.

Spillway Design

Spillway location, type, and size directly influence the performance of a sediment pond. Spillways consist of primary spillways, which are designed to allow smaller flows out of the impoundment, and emergency spillways, which are designed to pass a peak flow and to ensure the stability of the embankment. Most treatment-type reservoirs are designed with both a primary and an emergency spillway, so that treated water can be released on a regular basis while protecting the embankment. Detention-type reservoirs may only have an emergency spillway and are either dewatered by a pump or through evaporation and seepage.

Primary spillways are often gated culverts or pipes, which can be controlled to allow periodic discharge and draining of the reservoir. Where treatment is required, a drop inlet or riser may be attached to the culvert to remove water from the upper portion of the pond. All valve assemblies should be equipped so that they can be operated from above the surface of the water. All inlets should be protected by a screening device that prevents floating objects, brush, turtles, fish, and so forth from entering and clogging the pipe (Schwab et al. 1966). The design size and capacity of the primary spillway is dictated by dewatering needs and treatment time requirements. In some instances it may be dictated by downstream water users via regulated water rights or irrigation needs.

All sediment ponds and most interceptor ponds should have an emergency spillway. In the case of the incised pond or excavated basin, the emergency spillway is generally the downstream drainage channel. Typically, an incised pond has no embankment to protect. Good design practice, as well as environmental rules and regulations, dictate the design and construction of an emergency spillway to protect an embankment from overtopping and thus leading to ultimate failure. The emergency spillway will typically be sized for a peak runoff event greater than the actual design event for the pond. For example, if the pond is designed for storage of the 10-year/24-hour storm event, the emergency spillway should be designed to pass the 25-year/24-hour storm event at a minimum. If the design life of the structure is greater than 10 years, good engineering practices may dictate a more conservative design (e.g., 50-year/24-hour). The emergency spillway should be designed to be nonerosive at the design event. This may be accomplished with a vegetated spillway, or in some cases it can be stabilized by riprap, concrete, or numerous erosion-control products. This will be discussed in the following section. The emergency spillway should be constructed such that no flow will be conveyed against the embankment, so that the affected parts of the embankment are protected.

SMALL-AREA SEDIMENT CONTROLS

Small-area sediment controls or best management practices (BMPs) allow an area of land to be subdivided such that the volume of runoff coming from a given parcel is bifurcated and reduced. If the area of land draining to a single given point can be reduced, then the volume of surface runoff traveling to

that given point will be reduced and the erosion potential will thereby be mitigated.

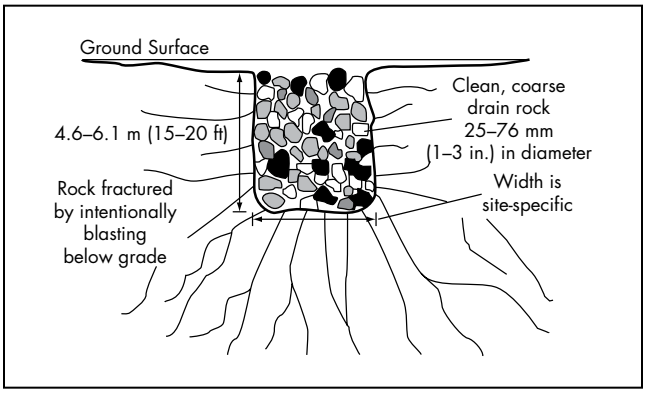
Best Management Practices

As is the case when designing hydrologic controls or control structures, the design life of the erosion-control structure is often the driving force when determining the type of material used for BMPs. In addition, the severity of the slope, runoff hydraulics, and potential for sediment production may also influence the determination of the type of BMP. Proper installation of erosion-control structures is critical because when overland flow has either bypassed or undermined the structure, failure is imminent. The mining professional must match the method to the site condition (i.e., straw bales may not be effective in a steep draw). In general, many of the discussed erosion-control structures (especially those designed to stabilize slopes and promote the development of vegetation) require very regular maintenance and have a short life span.

Dry Wells or French Drains

A dry well or French drain can be used to treat contaminated runoff and promote infiltration of surface water back into an aquifer. French drains are only effective at removing sediment from contaminated waters and are not designed to treat hazardous wastes. Both structures are passive, relying on gravity to pass runoff through a filter comprised of rock or gravel before it mixes with groundwater (Figure 16.4-2). These systems are often lined with filter fabric, and in general, the deeper the well or drain, the more effectively it can remove particulate pollution.

Revegetation



Steep, smooth, and nonvegetated slopes and spoil mounds are subject to high rates of water and wind erosion. High erosion rates decrease slope stability, result in the loss of valuable topsoil, and can be very costly to repair. Adding vegetation cover to an exposed soil surface can intercept and reduce raindrop impact and increase infiltration, which slows and redirects overland flow (Kleinman 1996). Several immediate revegetation establishment options exist, including drill seeding, hydroseeding, broadcast seeding, and transplanting entire live plants or plant cuttings. In addition, the placement of mulch can increase soil moisture, provide a temporary cover to reduce erosion risk, moderate soil temperature, and increase the likelihood of seed establishment (Kleinman 1996).

Natural and Biodegradable

Straw or hay bale check dams can be installed for temporary sediment or erosion control for one season or less. Straw or hay bale check dams are placed end to end on contour to reduce the run length of any exposed slope (Table 16.4-4). The most critical factor in proper installation of a straw bale check dam is the surface slope, which should be less than 20%. In addition to straw bale check dams, there are a variety of biodegradable matrix fabric structures that can be used both to protect steep slopes from erosion and to aid in the establishment of living vegetation (Barrett et al. 1998; North American Green 2009; RoLanka International 2009).

Artificial and Synthetic Materials

The most commonly used synthetic erosion-control product is sediment fencing. Sediment fences act as a dam, trapping sediment on the upslope side and allowing water to leave the site (Figure 16.4-3). They are effective in retaining suspended solids coarser than 0.02 mm (0.00079 in.). They are simple to construct, relatively inexpensive, and easily moved as development proceeds.

MECHANICAL TREATMENT (SEDIMENT SEPARATORS)

The mining industry has utilized mechanical treatment for sediment removal or sediment separation for decades. Mechanical separators can be incorporated into the mineral-processing stream (placer or aggregate mines, process mills) or can be used solely for environmental purposes. For the purposes of this chapter, only environmental use of this equipment will be discussed. The principal advantage of mechanical separators is their ability to effectively remove sediment from water where space or time is limited. With the addition of flocculants, these separators can generally meet discharge effluent standards relatively quickly without requiring several acres of treatment ponds. Mechanical separators will also reduce cleanout costs because sediment traps and particulate removal is integrated within the equipment process stream.

Mechanical separators can include a swirl concentrator or inertial separator and will intercept sediment-laden flow. The swirl concentrator separates sediment from the incoming flow through the centrifugal force generated by the inherent inertia of the flow (Warner and Dysart 1983). In many ways they operate in the same way as centrifugal cyclones used in mineral processing. Effluent with a high sediment load is transmitted to a small sediment trap, while the clearer flow is discharged directly to a stream or receiving water. The inertial separator is designed to retain incoming sediment in a tank between a series of V-cut bottom-slotted troughs (Sterling and Warner 1984). The sediment-laden influent is transferred from influent troughs into the tank, and clearer flow is withdrawn by deep troughs (Warner 1992). The concept behind these mechanical separators has been transferred to stormwater

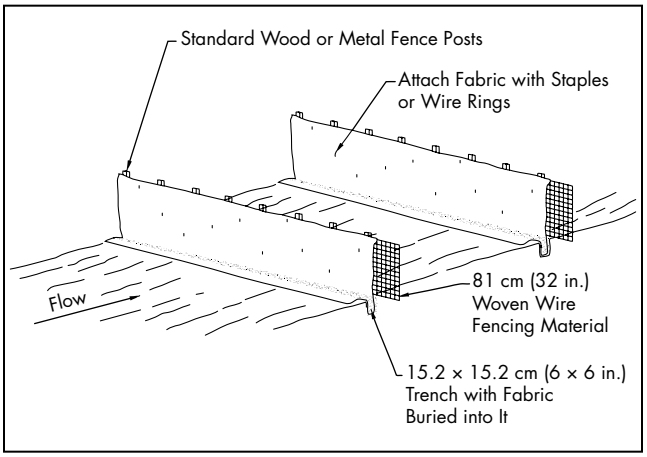

Figure 16.4-3 Sediment fence installation details

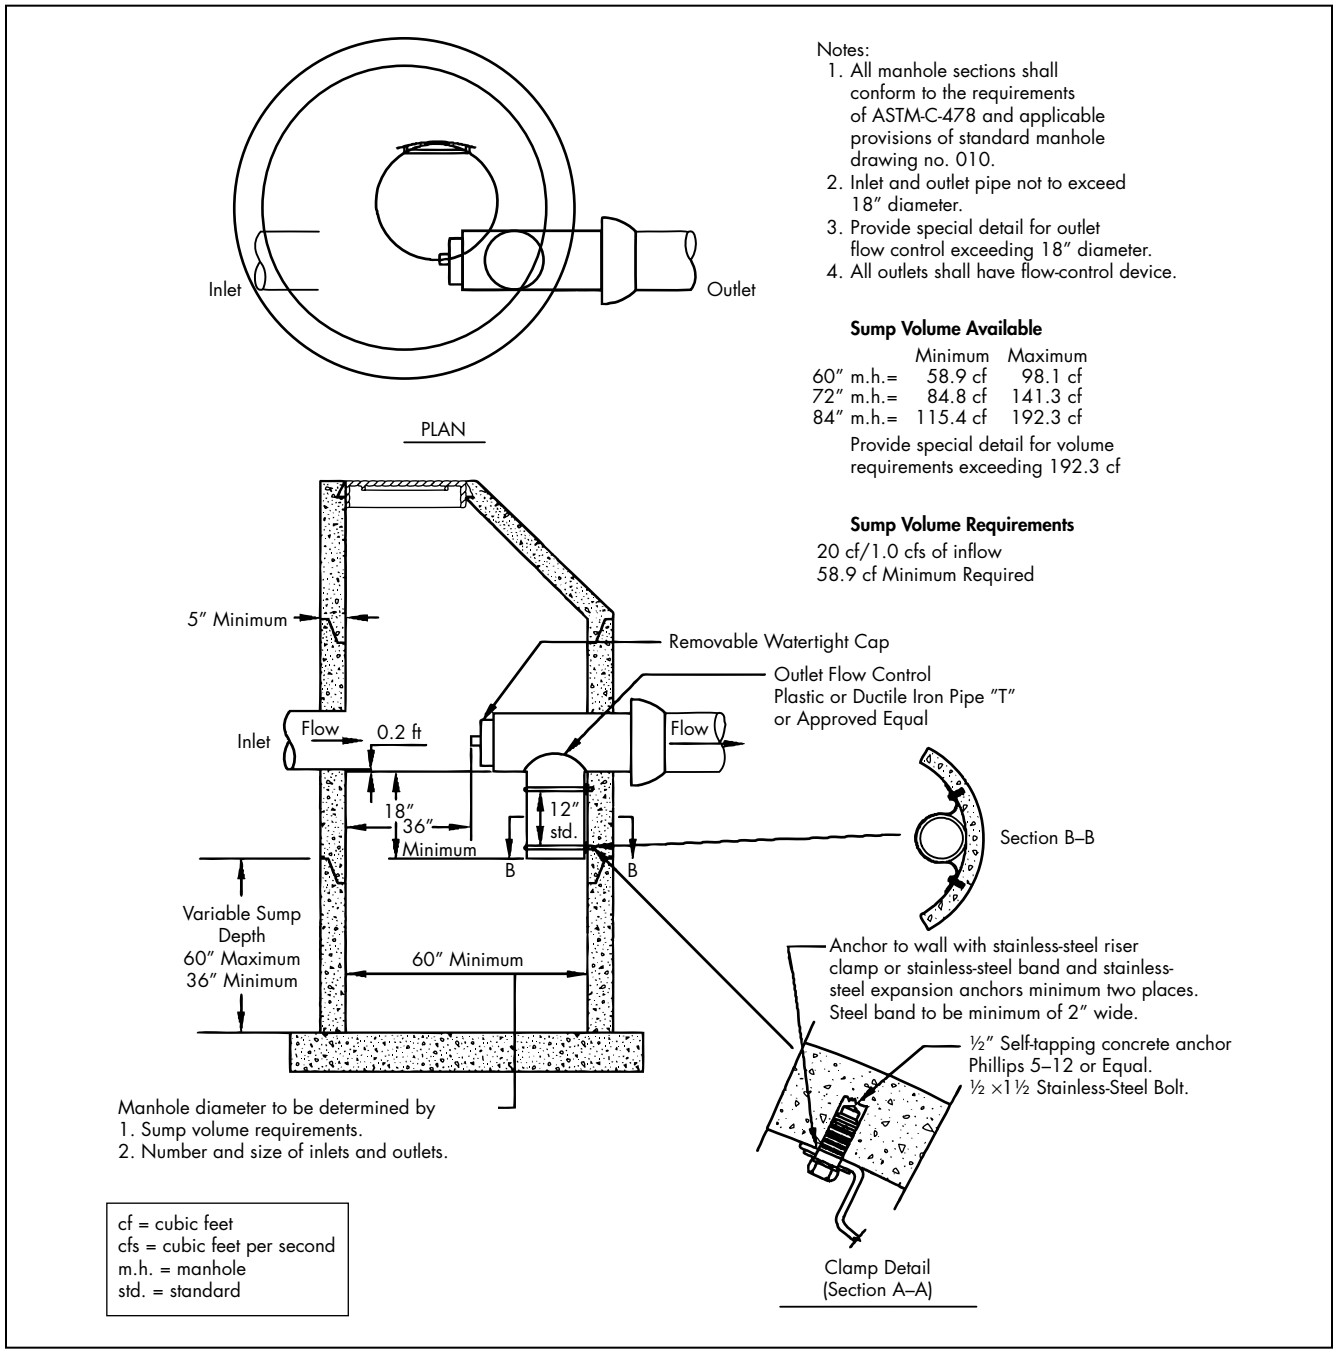
control agencies and has manifested as design guidelines for BMPs in the control of sediment-laden runoff. An example of this is presented in the Washington County (Oregon, United States) Clean Water Services design and construction standards, one of which is presented as Figure 16.4-4.

The large-scale use of mechanical separation in the mining industry may include hydrocyclone separators, which are prevalent in the gold mining industry, and water clarifiers, which are utilized extensively in the aggregate industry. Both systems allow operators to take a dirty stream of water and produce clean water immediately, concentrating the fines or solids to a thick state. Hydrocyclones are based on the centrifuge principal, where the particles are spun against the outside wall of the separator and gravitate toward the bottom and are collected in the sedimentation tank. A water clarifier is a similarly self-contained unit but uses a flocculant-driven process with a combination of settlement time and available space. It includes a dry polymer feed system, a hydraulic package, control panels, and a mud-discharge pump system. As the sediment is removed from the water, it is pumped as slurry out of the clarifier to its interim or final resting space. The clean water is pumped back into the process stream or to the receiving water. Hydrocyclones and clarifiers can typically handle greater flow volumes of up to 252 L/s (4,000 gpm) and greater sediment concentrations (up to 20% solids).

GROUNDWATER HYDROLOGY

Both surface and underground mines must develop a strategy to handle groundwater both for water quantity and quality. If the volume of intercepted groundwater exceeds an operation's ability to pump, flooding of the mine operations will result. If groundwater commingles with the mining operation, contamination of this water by the operation may ensue. Such contamination may result from interaction with equipment and haul traffic (oil, grease, sediment) or from an interaction with a by-product of mining, which could include the leaching of metals as the groundwater moves from a reduced to an oxidized state. Excess groundwater must be handled in a similar fashion as excess surface water and must be treated in advance of discharge.

The purpose of this section is to outline a strategy for designing a groundwater monitoring program that provides useful information throughout the life of the mining operation. Like surface water, if groundwater is successfully intercepted and diverted around the mining operation, the need for treatment is eliminated. Unlike surface water, groundwater interception requires extensive subsurface capital construction, which may include slurry walls, grout curtains, or a dewatering well field.



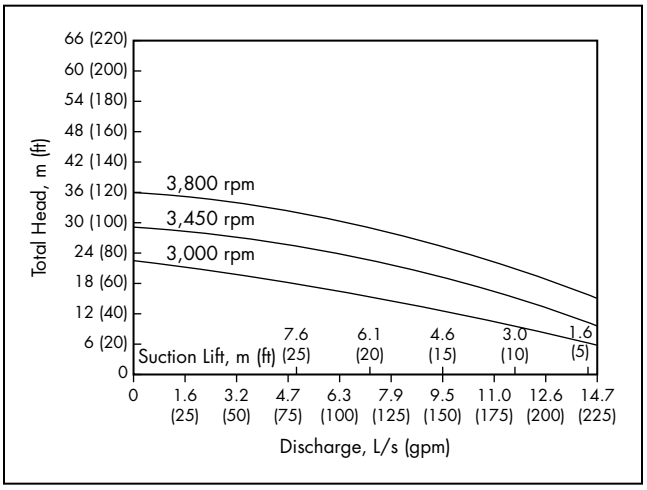
Predictions of Groundwater Inflow

Predictions of groundwater inflow require a detailed knowledge of the geologic framework, including structure, stratigraphy, and a definition of the aquifer properties. Such properties typically include an understanding of hydrologic boundaries (recharge and discharge), an aquifer's potentiometric surface, the presence of aquitards (low-permeability strata) and aquicludes (very low permeability strata), and areas of aquifer communication. Supporting data can be derived from the geologic exploration program, which may include drill-hole logs, geotechnical studies, geophysical logs, geological cross sections, monitor wells, and structure contour maps. Aquifer hydraulic characteristics must be derived from actual pump tests, which have been conducted on or near the mine property.

Aquifer Testing

Aquifer tests should be used to determine transmissivity, storage coefficient, hydrologic boundaries, leakage, aquifer homogeneity, and isotropy. For example, an aquifer pump test can be used to determine these groundwater properties in accordance with methods described by Theis (1935), Cooper and Jacob (1946), Boulton (1954), and Lohman (1979). The location and number of aquifer tests should be sufficient to characterize the different aquifers or the variability within the aquifer in the vicinity of the mine. The purpose of the data collection effort will dictate the degree of investment. For example, an in-situ mine requires an extensive network of wells and aquifer tests to not only define the hydrologic unit from which resource extraction is taking place but also to define the overlying and underlying aquifer and confining units. A coal or metal mine may require an aquifer testing program to establish baseline data and to ensure that the mine workings remain dry during and in some cases following the extraction process. Geochemical change, where groundwater passes through spent mine workings, is a long-term surface and underground mining concern.

Aquifer tests include single-well and multiple-well tests. A single-well test can allow the specialist to establish permeability or transmissivity of an aquifer on a local scale. A multiple-well test can allow for the calculation of storativity, as well as provide data for the degree of communication between a production zone and its overlying and underlying counterparts. A typical aquifer test includes the placement and testing of a pump in the pumping well and monitoring water level changes in that well and any other well in the immediate area. Well completion and aquifer testing are well presented in the literature (Sterrett 2007). The length of an aquifer test may change depending on its relative importance in the design process. A short-term test (1 to 4 hours) typically provides information in the immediate area of the well bore. An intermediate-length test (4 to 24 hours) provides good information relative to the aquifer in general. A long-term test (24 hours to 30 days) provides excellent information relative to the aquifer, aquifer sustainability, and area boundary conditions. A good guideline is that the longer the test, the greater the aquifer area tested. When designing an extensive underground mine operation, dependent on dewatering, a long-term multiple-well test is



Source: Clean Water Services 2009.

Figure 16.4-4 Stormwater manhole and sediment separator

recommended. It is important to collect and maintain meteorological data throughout the course of the test.

Methods to Handle Groundwater Inflow

Groundwater can be handled before mine interaction, on interception by the mine, or after it passes through the mine. On a water quality and treatment basis, it is far better to handle groundwater before it interacts with the mine or mine workings. This can be done simply using a dewatering well field, or it can be done using slightly more complex and far more permanent slurry walls or a grout curtain. A dewatering well field requires closely spaced wells that are pumped continuously, and the respective cone of depression of each well will overlap and ensure that no groundwater passes through the well field. This is an effective means of controlling groundwater flow, but it requires nearly constant operation and maintenance. The advantages are its relatively low capital cost, its system design flexibility, and its short-term effectiveness. The disadvantages are the operational costs of keeping pumps and well screens operational, the electrical costs, and the need to move the system as the mine operation advances.

Source: Warner 1992.

Figure 16.4-5 Pump characteristic curves for engine-driven pump

A far more effective and long-term method is the construction of a grout curtain, which includes the drilling of exploration boreholes into a lower confining layer and emplacement (injection) of a concrete grout or, in limited cases, a freezing agent such as liquid nitrogen. Drill-hole spacing must be adequate to ensure the overlapping of the grout to guarantee an impermeable seal. In the case of the concrete grout curtain, its advantage is its relative permanent characteristic such that after the mine closes, groundwater will continue to be diverted around the mining operation, thereby avoiding the long-term geochemical impacts. The disadvantages are the initial capital cost and its overall ineffectiveness in some fractured aquifer systems.

A recent advancement in groundwater interception for mining is the use of slurry walls. This technique is far more effective than a grout wall in that it is constructed as a continuous trench that is backfilled with a bentonite/sand mix. Slurry walls are keyed into a lower confining layer, but may be limited by equipment reach and depth. Recent advances in slurry-wall construction allow depths up to 24 m (70 ft). The advantages of slurry walls are their relatively lower capital cost compared to grout walls and their relatively permanent behavior, even after the mine closes, so that groundwater will continue to be diverted around the mining operation. The disadvantages of such slurry walls are that they are limited to relatively shallow applications and they require a nearby source of clean sand. They are particularly effective in sand and gravel mining near or adjacent to the floodplain of a river.

When groundwater enters the mine operation, it must be collected in a sump (at a low spot within the mine workings) and removed from the mine operation by mechanical means. This is generally accomplished with a pump or a series of pumps. Pump and pipeline redundancy is absolutely critical if there is a pump or pipeline failure. Another critical concern is electrical failure and protection of the dewatering controls. Backup generators should be available at all mine sites, and the system of controls should be protected from a rising water level and/or placed at a location that is above the water table if all pumps were shut off (i.e., the recovered potentiometric surface).

Ideally, groundwater should be intercepted before it has an opportunity to be contaminated by mine equipment or oxidized waste rock. For this reason, sumps can be constructed on highwall benches or at the leading edge of an underground mine. If the groundwater is unaffected, it can be pumped directly to the surface streams. If it is affected, it must be handled in the same fashion as surface water and treated through sediment or treatment ponds. In most cases, additional treatment for mobilized metals will be required beyond pure sediment control, and this may include, but not be limited to, the addition of lime (pH control), organic matter (chelation), "bugs" (sulfate-reducing agents), or barium chloride (radium control).

Pumps

Pumps are widely used throughout the mining industry for dewatering underground mine operations and active pits, and for predraining areas adjacent to the pit prior to excavation (Warner 1992). Having the ability to control the presence of groundwater or surface water can alleviate numerous production problems and provide safer working conditions.

Centrifugal Pump

The basic components of a centrifugal pump are the inlet, the eye of the rotating impeller, the curved impeller vanes, the volute (i.e., casing), and the discharge connection. A centrifugal pump is a simple device with the only moving part being the impeller, which is attached to the shaft of a motor or engine. Assuming that the suction pipe and pump housing (volute) is filled with water to the level of the impeller eye (i.e., it is primed), then as the impellers rotate, a partial vacuum is created that allows atmospheric pressure to lift more water into the pump housing. The water, which enters the inlet opening at the eye of the impeller, is set in rotation by the impeller and creates centrifugal force, resulting in pressure at the outer perimeter of the impeller. Water moves outward from the impeller at a high velocity and pressure into an expanding volute and is then discharged.

Calculating Dynamic Head

The essential information needed to properly select a pump is the required flow rate in liters per second (gallons per minute) and the total dynamic head in meters (feet). Flow rate is dependent primarily on operational factors such as the anticipated rate of flow into a pit or underground mine. Determination of the total dynamic head requires consideration of the suction lift; the elevation difference between the pump and the discharge point; the pressure requirements, if any, at the discharge outlet; the friction along the pipes and fittings; and the velocity head.

Representative pump characteristic curves are illustrated in Figure 16.4-5. The curves show the relationship between the discharge and the total dynamic head. Also shown along the x-axis is the suction lift or net positive suction head. The discharge points along the x-axis indicate the maximum flows that the pump is capable of delivering at designated suction lifts.

Pump Troubleshooting

A properly designed and installed pump will reduce potential operational problems. A vacuum gauge, installed a minimum of one pipe diameter from the pump inlet, can solve the majority of problems. A high gauge reading indicates a partially blocked suction line, whereas a low reading often indicates air leakage through fittings on the suction side. A vacuum gauge can easily detect common problems, such as a nonprimed pump; too high a dynamic lift; excessive air in the water due

to the intake being near the water surface; air leakage in the inlet pipe, fittings, or stuffing box; or the strainer, foot valve, or suction pipe that is too small or restricted by debris. If a discharge pressure gauge reads too low, the pump may not be primed, the revolutions per minute may be too low, the total dynamic head may be too high, the impeller may be rotating in the wrong direction, there may be excessive air in the water, there may be mechanical defects, and so forth. Excess pump vibration may indicate a misalignment, worn bearings, a bent shaft, or that an obstruction has lodged in one side of the impeller.

COMPUTER MODELS AND REFERENCES

Utilization of computer applications and software can offer readily available professional assistance to the mining engineer. Simulation models and software are very important tools that are used to evaluate both surface and groundwater hydrology as well as sediment and erosion processes. Much of this software is publicly available and can be downloaded for free or at a nominal charge. Table 16.4-5 identifies some of the currently available software that has been successfully used by the environmental professional, with a certain bias toward publicly available and free software. An excellent reference (including downloadable technology transfer) for design manuals and software used by the mining industry is the U.S. Department of the Interior, Office of Surface Mining Web site (DOI 2009).

A variety of software programs exist that allow the mining professional to evaluate both existing and proposed conditions. Not only are the modeling programs valuable on their own, but they can also be interfaced or joined with AutoCAD design software by Autodesk or with GIS software by ESRI.

CHAPTER 16.5

Mitigating Acid Rock Drainage

Rens Verburg

INTRODUCTION

Sustainable mining requires the prevention, mitigation, management, and control of mining impacts on the environment. Acid rock drainage (ARD) continues to be one of the most serious and visible environmental issues facing the mining industry because it is often the transport medium for a range of pollutants, which may affect on-site and off-site water resources, and associated human and ecological receptors. The impacts of ARD on near and distant water resources and receptors can also be long term and persist after mine closure. Therefore, ARD prevention, mitigation, and treatment are important components of overall mine water management over the entire life of a mining operation.

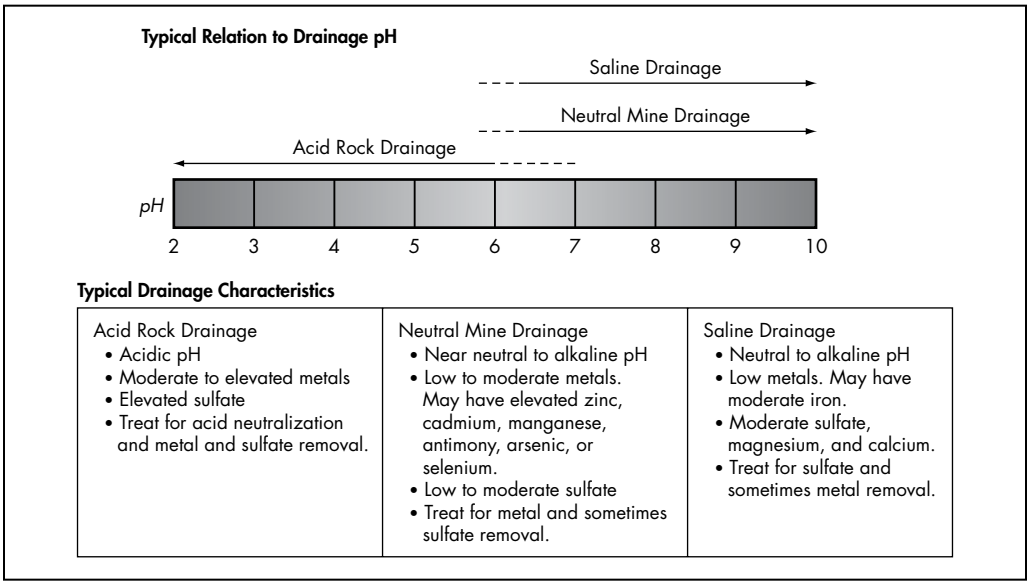
This chapter addresses the prediction, prevention, and treatment of ARD. A comprehensive approach to ARD management reduces the environmental risks and subsequent costs for the mining industry and governments, reduces adverse environmental impacts, and promotes public support for mining. The extent and particular elements of the ARD management approach that should be implemented at a certain operation will vary based on many site-specific factors, not limited to the project's potential to generate ARD.

Acid rock drainage is formed by the natural oxidation of sulfide minerals when exposed to air and water. Activities that involve the excavation of rock with sulfide minerals, such as metal and coal mining, accelerate the process. ARD results from a series of reactions and stages that typically proceed from near-neutral to more acidic pH conditions. When sufficient base minerals are present to neutralize the ARD, neutral mine drainage or saline drainage may result from the oxidation process. Neutral mine drainage (NMD) is characterized by elevated metals in solution at approximately neutral pH, whereas saline drainage (SD) contains high levels of sulfate at neutral pH without significant dissolved metal concentrations. Figure 16.5-1 illustrates the various types of drainage schematically.

A risk-based planning and design approach forms the basis for prevention and mitigation. This approach is applied throughout the mine life cycle but primarily in the assessment and design phases. The risk-based process aims to quantify the long-term impacts of alternatives and to use this knowledge to select the option that has the most desirable combination of attributes (e.g., protectiveness, regulatory acceptance, community approval, cost). Mitigation measures implemented as part of an effective control strategy should require minimal active intervention and management.

Proper mine characterization, drainage-quality prediction, and mine waste management can prevent ARD formation in most cases and minimize ARD formation in all cases. Prevention of ARD must commence at exploration and continue throughout the mine life cycle. Ongoing ARD planning and management is critical to the successful prevention of ARD.

Stopping ARD formation, once initiated, may be challenging because it is a process that, left unimpeded, will continue (and may accelerate) until one or more of the reactants (sulfide minerals, oxygen, water) are exhausted or excluded from reaction. The ARD formation process can continue to produce impacted drainage for decades or centuries after mining has ceased, as is illustrated by the portal in Spain shown in Figure 16.5-2, which dates from the Roman era.



The cost of ARD remediation at orphaned mines in North America alone has been estimated in the tens of billions of U.S. dollars. Individual mines can face postclosure liabilities of tens to hundreds of million dollars for ARD remediation and treatment if the sulfide oxidation process is not properly managed during the mine's life.

This chapter draws heavily from and follows the general structure of the *Global Acid Rock Drainage Guide* (*GARD Guide*), a state-of-practice summary of the best practices and technologies. It was developed under the auspices of the International Network for Acid Prevention (INAP) to assist ARD stakeholders, such as mine operators, regulators, communities, and consultants, with addressing issues related to sulfide mineral oxidation (INAP 2009). Readers are encouraged to make use of the *GARD Guide* and its references for further detail on the subjects covered in this chapter.

FORMATION OF ACID ROCK DRAINAGE

The process of sulfide oxidation and formation of ARD is very complex and involves a multitude of chemical and biological processes that can vary significantly depending on

environmental, geological, and climate conditions (Nordstrom and Alpers 1999). Sulfide minerals in ore deposits are formed under reducing conditions in the absence of oxygen. When exposed to atmospheric oxygen or oxygenated waters due to mining, mineral processing, excavation, or other earth-moving processes, sulfide minerals can become unstable and oxidize.

Figure 16.5-3 presents a simplified model that describes the oxidation of pyrite, the sulfide mineral responsible for the majority of ARD (Stumm and Morgan 1981). The reactions shown are schematic and may not represent the exact mechanisms or reaction stoichiometry, but the illustration is a useful visual aid for understanding sulfide oxidation.

The chemical reaction representing pyrite oxidation (Reaction 1 in Figure 16.5-3) requires three basic ingredients: pyrite, oxygen, and water. This reaction can occur either abiotically or biotically (i.e., mediated through microorganisms). In the latter case, bacteria such as *Acidithiobacillus ferrooxidans*, which derive their metabolic energy from oxidizing ferrous to ferric iron, can accelerate the oxidation reaction rate by many orders of magnitude relative to abiotic rates (Nordstrom 2003). In addition to direct oxidation, pyrite can also be dissolved and then oxidized (Reaction 1a).

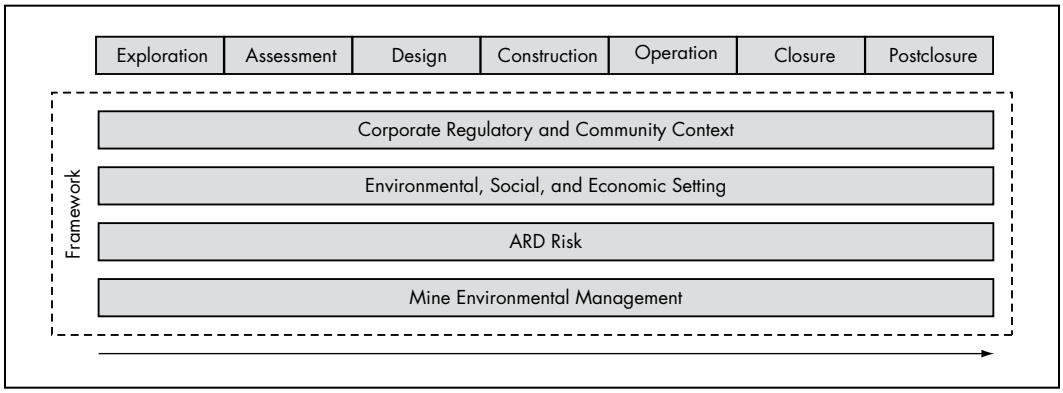
Under the majority of circumstances, atmospheric oxygen acts as the oxidant. However, aqueous ferric iron can oxidize pyrite as well according to Reaction 2. This reaction is

Source: INAP 2009.

Figure 16.5-4 Stages in the formation of ARD

considerably faster (two to three orders of magnitude) than the reaction with oxygen, and generates substantially more acidity per mole of pyrite oxidized. However, this reaction is limited to conditions in which significant amounts of dissolved ferric iron occur (i.e., acidic conditions: pH 4.5 and lower). Oxidation of ferrous iron by oxygen (Reaction 3) is required to generate and replenish ferric iron, and acidic conditions are required for the latter to remain in solution and participate in the ARD production process. As indicated by this reaction, oxygen is needed to generate ferric iron from ferrous iron. Also, the bacteria that may catalyze this reaction (primarily members of the *Acidithiobacillus* genus) demand oxygen for aerobic cellular respiration. Therefore, some nominal amount of oxygen is needed for this process to be effective, even when catalyzed by bacteria, although the oxygen requirement is considerably less than for abiotic oxidation.

A process of environmental importance related to ARD generation pertains to the fate of ferrous iron resulting from Reaction 1. Ferrous iron can be removed from solution under slightly acidic to alkaline conditions through oxidation and subsequent hydrolysis and the formation of a relatively insoluble iron (hydr)oxide (Reaction 4). When Reactions 1 and 4 are combined, as is generally the case when conditions are not acidic (i.e., pH > 4.5), oxidation of pyrite produces twice the amount of acidity relative to Reaction 1 as follows:



$$FeS_2 + 15/4O_2 + 7/2H_2O = Fe(OH)_3 + 2SO_4^{2-} + 4H^+$$

which is the overall reaction most commonly used to describe pyrite oxidation.

Although pyrite is by far the dominant sulfide responsible for the generation of acidity, different ore deposits contain different types of sulfide minerals. Not all of these sulfide minerals generate acidity when being oxidized. As a general rule, iron sulfides (pyrite, marcasite, pyrrhotite), sulfides with molar metal/sulfur ratios less than 1, and sulfosalts (e.g., enargite) generate acid when they react with oxygen and water. Sulfides with metal/sulfur ratios equal to 1 (e.g., sphalerite, galena, chalcopyrite) tend not to produce acidity when oxygen is the oxidant. Therefore, the acid generation potential of an ore deposit or mine waste generally depends on the amount of iron sulfide present. However, when aqueous ferric iron is the oxidant, all sulfides are capable of generating acidity.

Neutralization reactions also play a key role in determining the compositional characteristics of drainage originating from sulfide oxidation. As for sulfide minerals, the reactivity, and accordingly the effectiveness with which neutralizing minerals are able to buffer any acid being generated, can vary widely. Most carbonate minerals are capable of dissolving rapidly, making them effective acid consumers. However, hydrolysis of dissolved Fe or Mn following dissolution of their respective carbonates and subsequent precipitation of a secondary mineral may generate acidity. Although generally more common than carbonate phases, aluminosilicate minerals tend to be less reactive, and their buffering may only succeed in stabilizing the pH when rather acidic conditions have been achieved. Calcium–magnesium silicates have been known to buffer mine effluents at neutral pH when sulfide oxidation rates were very low (Jambor 2003).

The combination of acid generation and acid neutralization reactions typically leads to a stepwise development of ARD (Figure 16.5-4). Over time, pH decreases along a series of pH plateaus governed by the buffering of a range of mineral assemblages. The lag time to acid generation is a very important consideration in ARD prevention. It is far more effective (and generally far less costly in the long term) to control ARD generation during its early stages. The lag time also has significant ramifications for interpretation of test results. Because the first stage of ARD generation may last for a very long time, even for materials that will eventually be highly acid generating, it is critical to recognize the stage of oxidation when predicting ARD potential. The early results

Source: INAP 2009.

Figure 16.5-5 Conceptual ARD management framework

of geochemical testing, therefore, may not be representative of long-term environmental stability and associated discharge quality. However, early test results provide valuable data to assess future conditions such as consumption rates of available neutralizing minerals.

A common corollary of sulfide oxidation is metal leaching (ML), leading to the frequent use of the acronyms *ARD/ML* or *ML/ARD* to describe the nature of acidic mine discharges more accurately. Major and trace metals in ARD, NMD, and SD originate from the oxidizing sulfides and dissolving acid-consuming minerals. In the case of ARD, Fe and Al are usually the principal major dissolved metals, while trace metals such as Cu, Pb, Zn, Cd, Mn, Co, and Ni can also achieve elevated concentrations. In mine discharges with a more circumneutral character, trace metal concentrations tend to be lower as the result of formation of secondary mineral phases and increased sorption. However, certain parameters remain in solution as the pH increases, in particular the metalloids As, Se, and Sb, as well as other trace metals (e.g., Cd, Cr, Mn, Mo, and Zn).

FRAMEWORK FOR ACID ROCK DRAINAGE MANAGEMENT

The issues and approaches to ARD prevention and management are the same around the world. However, the specific techniques used for ARD prediction, interpretation of ARD test results, and ARD management may differ depending on the local, regional, or country context and are adapted to climate, topography, and other site conditions.

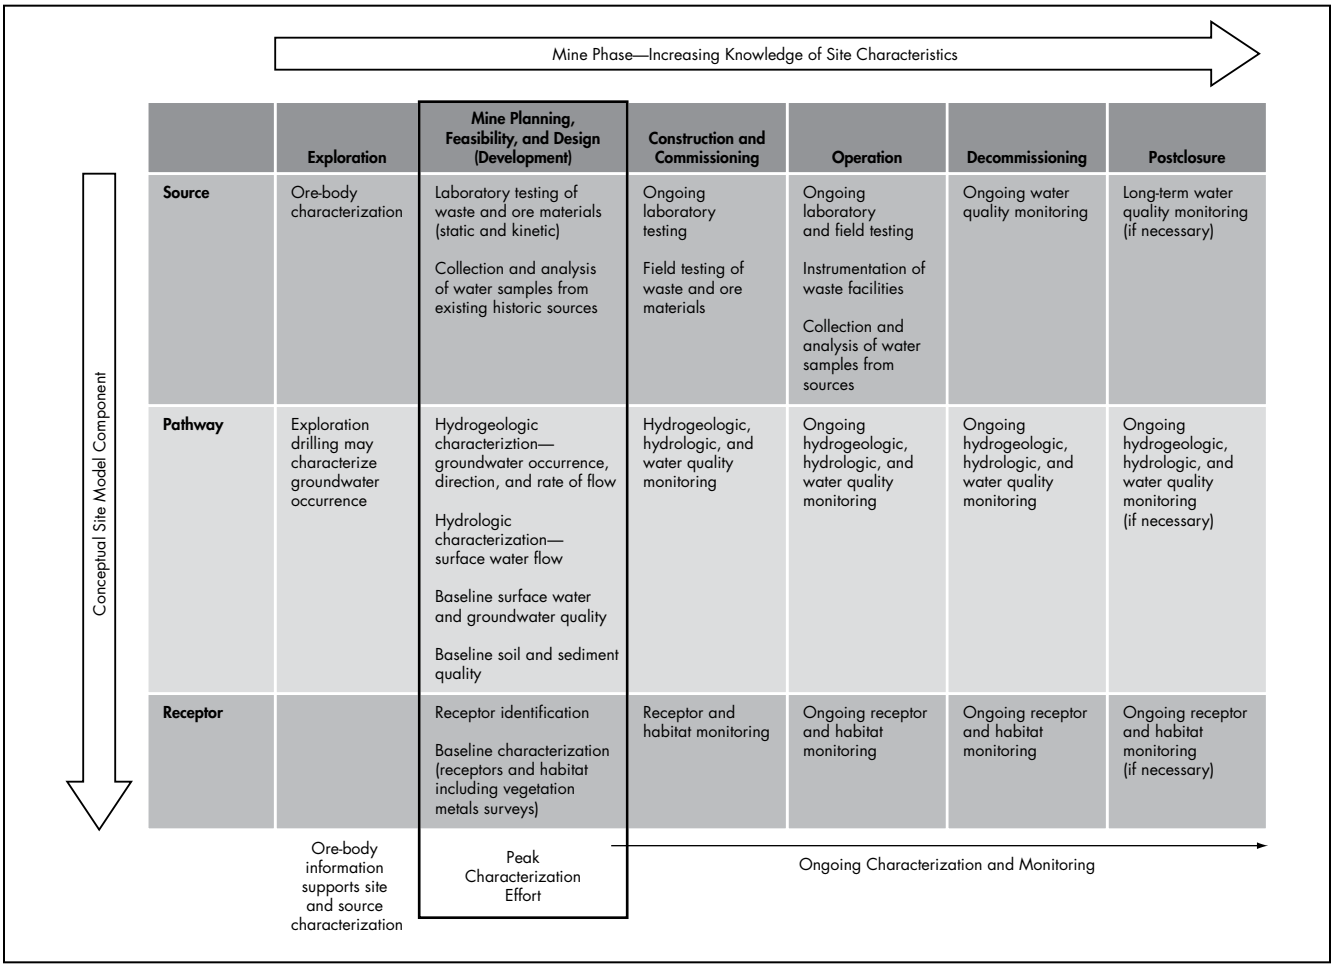
Therefore, despite the global similarities of ARD issues, there is no "one size fits all" approach to address ARD management. The setting of each mine is unique and requires a carefully considered assessment to find a management strategy within the broader corporate, regulatory, and community framework that applies to the project in question. The site-specific setting comprises the social, economic, and environmental situation within which the mine is located; the framework comprises the applicable corporate, regulatory norms and standards and community-specific requirements and expectations. This framework applies over the complete life cycle of the mine and is illustrated conceptually in Figure 16.5-5.

All mining companies, regardless of size, need to comply with the national legislation and regulations pertaining to ARD for the countries within which they operate. It is considered good corporate practice to adhere to global ARD guidance as well; in many cases, such adherence is a condition of funding.

Many mining companies have established clear corporate guidelines that represent the company's view of the priorities to be addressed and their interpretation of generally accepted best practice related to ARD. Caution is needed to ensure that all specifics of the country's regulations are met, as corporate ARD guidelines cannot be a substitute for country regulations.

Mining companies operate within the constraints of a "social license" that, ideally, is based on a broad consensus from all stakeholders. This consensus tends to cover a broad range of social, economic, environmental, and governance elements (sustainable development). ARD plays an important part in the mine's social license because it tends to be one of the more visible environmental consequences of mining.

The costs of closure and postclosure management of ARD are increasingly recognized as a fundamental component of all proposed and operating mining operations. Some form of financial assurance is now required in many jurisdictions.



Characterization

The generation, release, transport, and attenuation of ARD are intricate processes governed by a combination of physical, chemical, and biological factors. Whether ARD becomes an environmental concern depends largely on the characteristics of the sources, pathways, and receptors involved. Characterization of these aspects is therefore crucial to the prediction, prevention, and management of ARD.

Environmental characterization programs are designed to collect sufficient data to answer the following questions:

1. Is ARD likely to occur?
2. What are the sources of ARD?
3. How much ARD will be generated and when?
4. What are the significant pathways that transport contaminants to the receiving environment?
5. What human and ecological receptors have contact with the receiving environment?
6. What level of risk would the anticipated concentrations of contaminants in the receiving environment pose to the receptors?
7. What can be done to prevent or mitigate/manage ARD?

The geologic and mineralogical characteristics of the ore body and host rock are the principal controls on the type of drainage that will be generated as a result of mining. Subsequently, the site climatic and hydrologic/hydrogeologic characteristics define how mine drainage and its constituents

Source: INAP 2009.

Figure 16.5-6 Overview of ARD characterization program by mine phase

are transported through the receiving environment to receptors. To evaluate these issues, expertise from multiple disciplines is required, including geology, mineralogy, hydrology, hydrogeology, geochemistry, (micro)biology, meteorology, and engineering.

The geologic characteristics of mineral deposits exert important and predictable controls on the environmental signature of mineralized areas (Plumlee 1999). Therefore, a preliminary assessment of the ARD potential should be made based on a review of geologic data collected during exploration. Baseline characterization of metal concentrations in various environmental media (i.e., water, soils, vegetation, animal tissue) may also provide an indication of ARD potential and serves to document the potential for naturally elevated metal concentrations.

During mine development and operation, the initial assessment of ARD potential is refined through detailed characterization data on the environmental stability of the waste and ore materials. The magnitude and location of mine discharges to the environment also are identified during mine development. Meteorological, hydrological, and hydrogeological investigations are conducted to characterize the amount and direction of water movement within the mine watershed(s) to evaluate transport pathways for constituents of interest. Identification of potential human and ecological receptors within the watershed boundary requires expertise in field biology and public health.

Over the mine life, the focus of the ARD characterization program evolves from establishing baseline conditions to predicting drainage release and transport and to monitoring of the environmental conditions, receptors, and impacts. Despite inherent differences at mine sites (e.g., based on commodity type, climate, mine phase, regulatory framework), the general approach to site characterization is similar.

Figures 16.5-6 and 16.5-7 present the chronology of an ARD characterization program and identify the data collection activities typically executed during each mine phase. The bulk of the characterization effort occurs prior to mining during the mine planning, assessment, and design (sometimes collectively referred to as the development phase). In addition, potential environmental impacts are identified and appropriate prevention and mitigation measures, intended to minimize environmental impacts and human and ecological risk, are incorporated. During the commissioning/construction and operation phases, a transition from site characterization to monitoring occurs, which is continued throughout the decommissioning/closure and postclosure phases. Ongoing monitoring helps refine the understanding of the site, which allows for adjustment of remedial measures, in turn resulting in reduced closure costs and improved risk management.

Mine Phase—Increasing Knowledge of Source Material Characterization

Waste or Facility Type—Potential ARD/NMD/SD Sources

	Exploration	Mine Planning, (Pre-) Feasibility and Design	Construction and Commissioning	Operation	Decommissioning	Postclosure (Care and Maintenance)
Waste Rock	Drill core descriptions and assay data (petrology and mineralogy) Block model (quantity of ore and waste) Review of any historical data	Laboratory testing of drill core samples—sample selection targets waste*	Ongoing laboratory testing of drill core or development rock samples* Field leach testing (barrels, test pads)	Ongoing laboratory testing* Ongoing field leach testing Collection and analysis of runoff and seepage samples from waste rock facility	Collection and analysis of runoff and seepage samples from waste rock facility	Collection and analysis of runoff and seepage samples from waste rock facility (if necessary)
Tailings		Laboratory testing of pilot plant tailings* Analysis of pilot testing supernatant	Ongoing laboratory testing of pilot-plant tailings*	Ongoing laboratory testing of tailings discharge* Collection and analysis of supernatant and seepage samples from tailings storage facility	Collection and analysis of supernatant and seepage samples from tailings storage facility	Collection and analysis of supernatant and seepage samples from tailings storage facility (if necessary)
Ore		Laboratory testing of drill core samples*		Ongoing laboratory testing*	If ore stockpiles exist, collection and analysis of runoff and seepage samples	
Pit		Laboratory testing of drill core samples—sample selection targets pit walls*		Field scale leach testing (e.g., wall washing) Collection and analysis of water samples (i.e., runoff, sumps)	Collection and analysis of pit water and pit inflow(s) water samples	Collection and analysis of pit water samples (if necessary)
Underground Workings		Laboratory testing of drill core samples—sample selection targets mine walls*		Collection and analysis of water samples (i.e., sumps, dewatering wells)	Collection and analysis of mine pool water samples	Collection and analysis of mine pool water samples (if necessary)

Prediction

One of the main objectives of site characterization is prediction of ARD potential and drainage chemistry. Because prediction is directly linked to mine planning, in particular with regard to water and mine waste management, the characterization effort needs to be phased in step with overall project planning. Early characterization tends to be generic and generally avoids presumptions about the future engineering/mine design, whereas later characterization and modeling must consider and be integrated with the specifics of engineering/mine design. Iteration may be required as evaluation of the ARD potential may result in the realization that a reassessment of the overall mine plan is needed. Integration of the characterization and prediction effort into the mine operation is a key element for successful ARD management.

Accurate prediction of future mine discharges requires an understanding of the sampling, testing, and analytical procedures used, consideration of the future physical and geochemical conditions, and the identity, location, and reactivity of the contributing minerals. All mine sites are unique for reasons related to geology, geochemistry, climate, commodity, processing method, regulations, and stakeholders. Prediction programs therefore need to be tailored to the mine in question. Also, the objectives of a prediction program can be variable. For instance, they can include definition of water treatment requirements, selection of mitigation methods, assessment of water quality impact, or determination of reclamation bond amounts.

Predictions of drainage quality are made in a qualitative and quantitative sense. Qualitative predictions are focused on assessing whether acidic conditions might develop in mine wastes, with the corresponding release of metals and acidity to mine drainage. Where qualitative predictions indicate a high probability of ARD generation, attention turns to review of alternatives to prevent ARD, and the prediction program is refocused to assist in the design and evaluation of these alternatives.

Significant advances in the understanding of ARD have been made over the last several decades, with parallel advances in mine water quality prediction and use of prevention techniques. However, quantitative mine water quality prediction can be challenging because of the wide array of the reactions involved and potentially very long time periods over

which these reactions take place. Despite these uncertainties, quantitative predictions that have been developed using realistic assumptions (while recognizing associated limitations) have proven to be of significant value for identification of ARD management options and assessment of potential environmental impacts.

Prediction of mine water quality generally is based on one or more of the following:

- Test leachability of waste materials in the laboratory
- Test leachability of waste materials under field conditions
- Geological, hydrological, chemical, and mineralogical characterization of waste materials
- Geochemical and other modeling

Analog operating or historic sites are also valuable in ARD prediction, especially those that have been thoroughly characterized and monitored. The development of geo-environmental models is one of the more prominent examples of the "analog" methodology. Geo-environmental models, which are constructs that interpret the environmental characteristics of an ore deposit in a geologic context, provide a very useful way to interpret and summarize the environmental signatures of mining and mineral deposits in a systematic geologic framework; they can be applied to anticipate potential environmental problems at future mines, operating mines, and orphan sites (Plumlee et al. 1999). A generic overall approach for ARD prediction is illustrated in Figure 16.5-8.

Prevention and Mitigation

The fundamental principle of ARD prevention is to apply a planning and design process to prevent, inhibit, retard, or stop the hydrological, chemical, physical, or microbiological processes that result in the impacts to water resources. Prevention should occur at, or as close to, the point where the deterioration in water quality originates (i.e., source reduction), or through implementation of measures to prevent or retard the transport of the ARD to the water resource (i.e., recycling, treatment, and/or secure disposal). This principle is universally applicable but methods of implementation are site specific.

Prevention is a proactive strategy that obviates the need for the reactive approach to mitigation. For an existing case of ARD that is adversely impacting the environment, mitigation will usually be the initial course of action. Despite this initial action, subsequent preventive measures are often considered with the objective of reducing future contaminant loadings, thus reducing the ongoing need for mitigation controls. Integration of the prevention and mitigation effort into the mine operation is a key element for successful ARD management.

Prior to identification or evaluation of prevention and mitigation measures, the strategic objectives must be identified. That process should consider assessment of the following:

- Quantifiable risks to ecological systems, human health, and other receptors
- Site-specific discharge water quality criteria
- Capital, operating, and maintenance costs of mitigation or preventive measures
- Logistics of long-term operations and maintenance
- Required longevity and anticipated failure modes

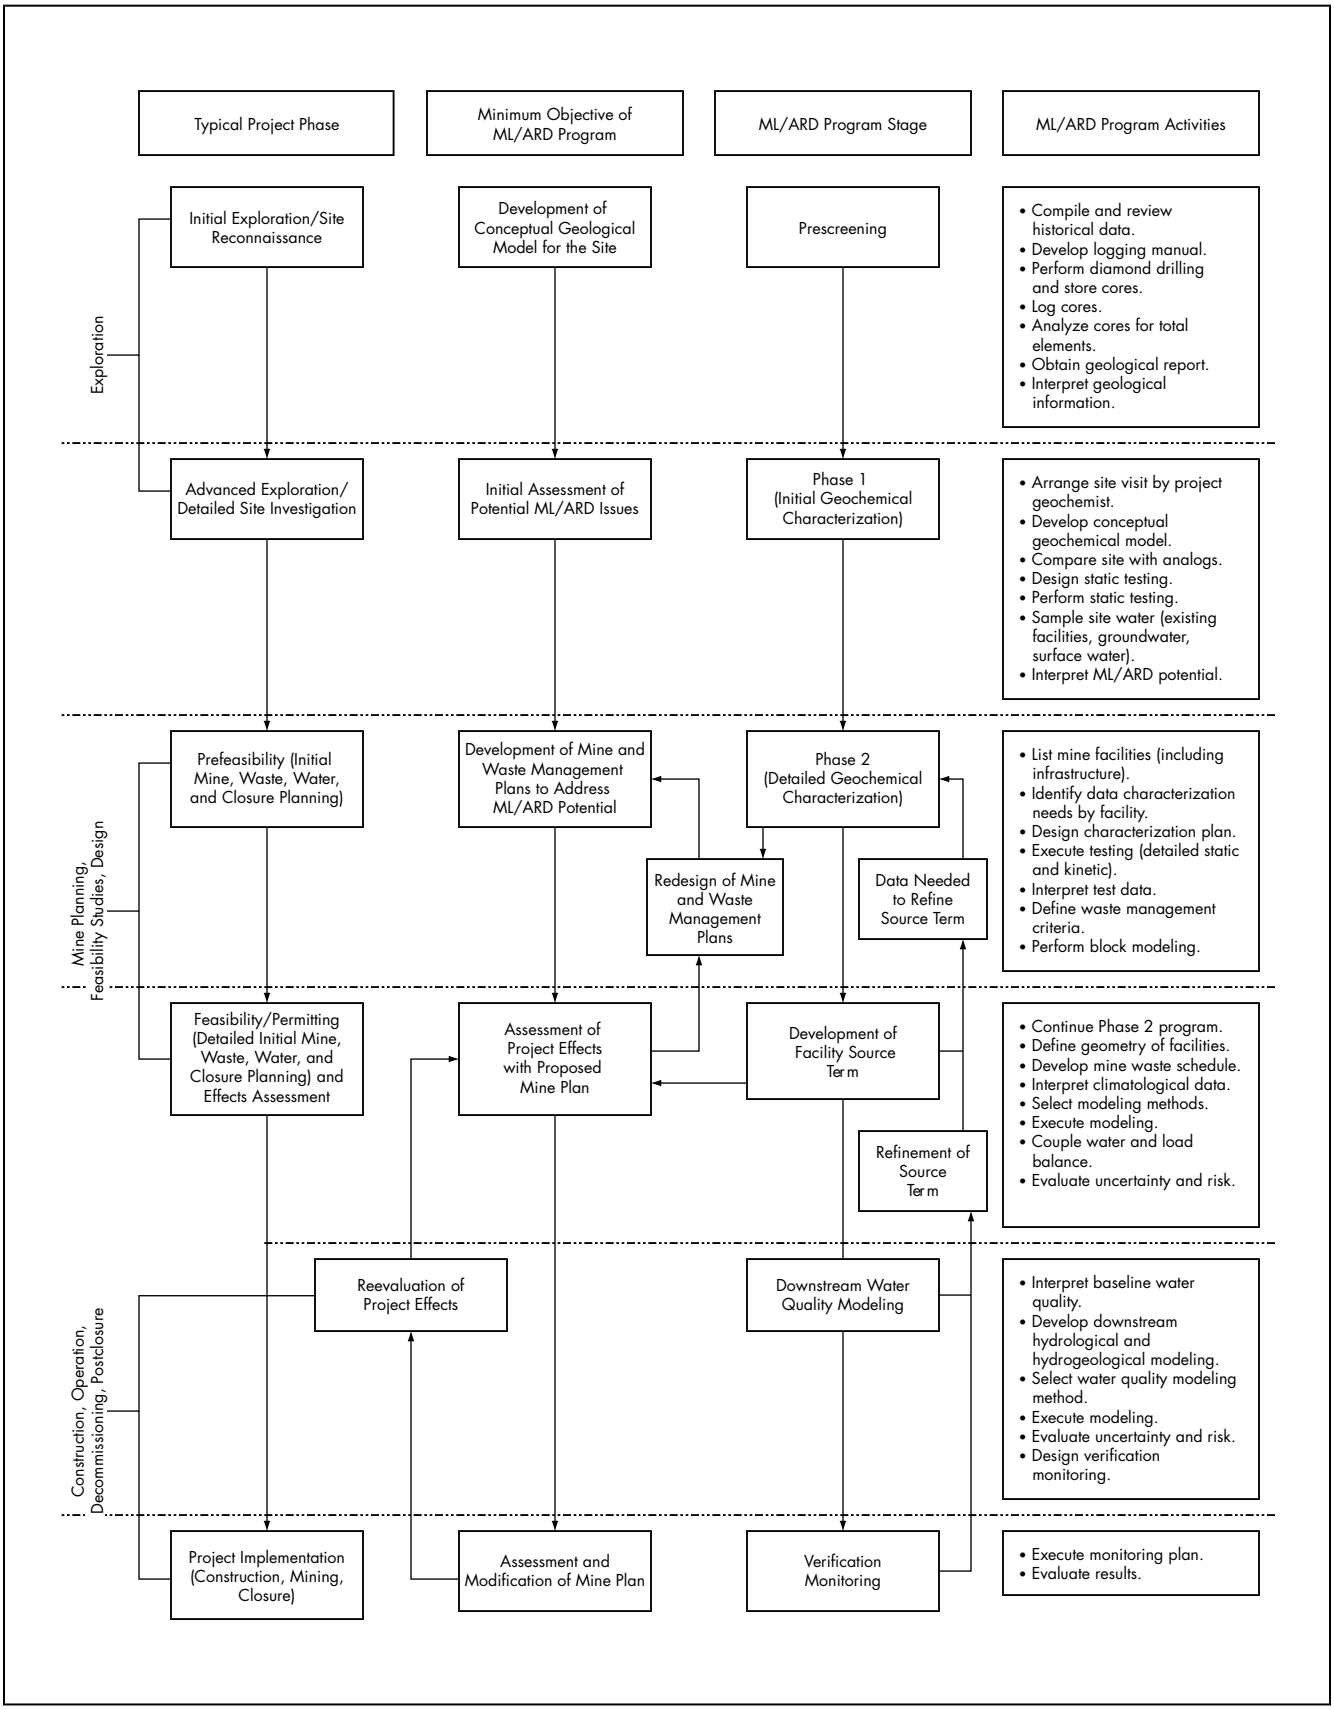
Prevention is the key to avoiding costly mitigation. The primary objective is to apply methods that minimize sulfide reaction rates, metal leaching, and the subsequent migration of weathering products that result from sulfide oxidation. Such methods involve the following:

- Minimizing oxygen supply
- Minimizing water infiltration and leaching
- Reducing, removing, or isolating sulfide minerals
- Controlling pore water solution pH
- Controlling bacteria and biogeochemical processes

Factors influencing selection of the above methods include the following:

- Geochemistry of source materials and the potential of source materials to produce ARD
- Type and physical characteristics of the source, including water flow and oxygen transport
- Mine development stage (more options are available at early stages)
- Phase of oxidation (more options are available at early stages when pH is still near neutral and oxidation products have not significantly accumulated)
- Time period for which the control measure is required to be effective
- Site conditions (i.e., location, topography and available mining voids, climate, geology, hydrology and hydrogeology, availability of materials and vegetation)
- Water quality criteria for discharge
- Risk acceptance by company and other stakeholders

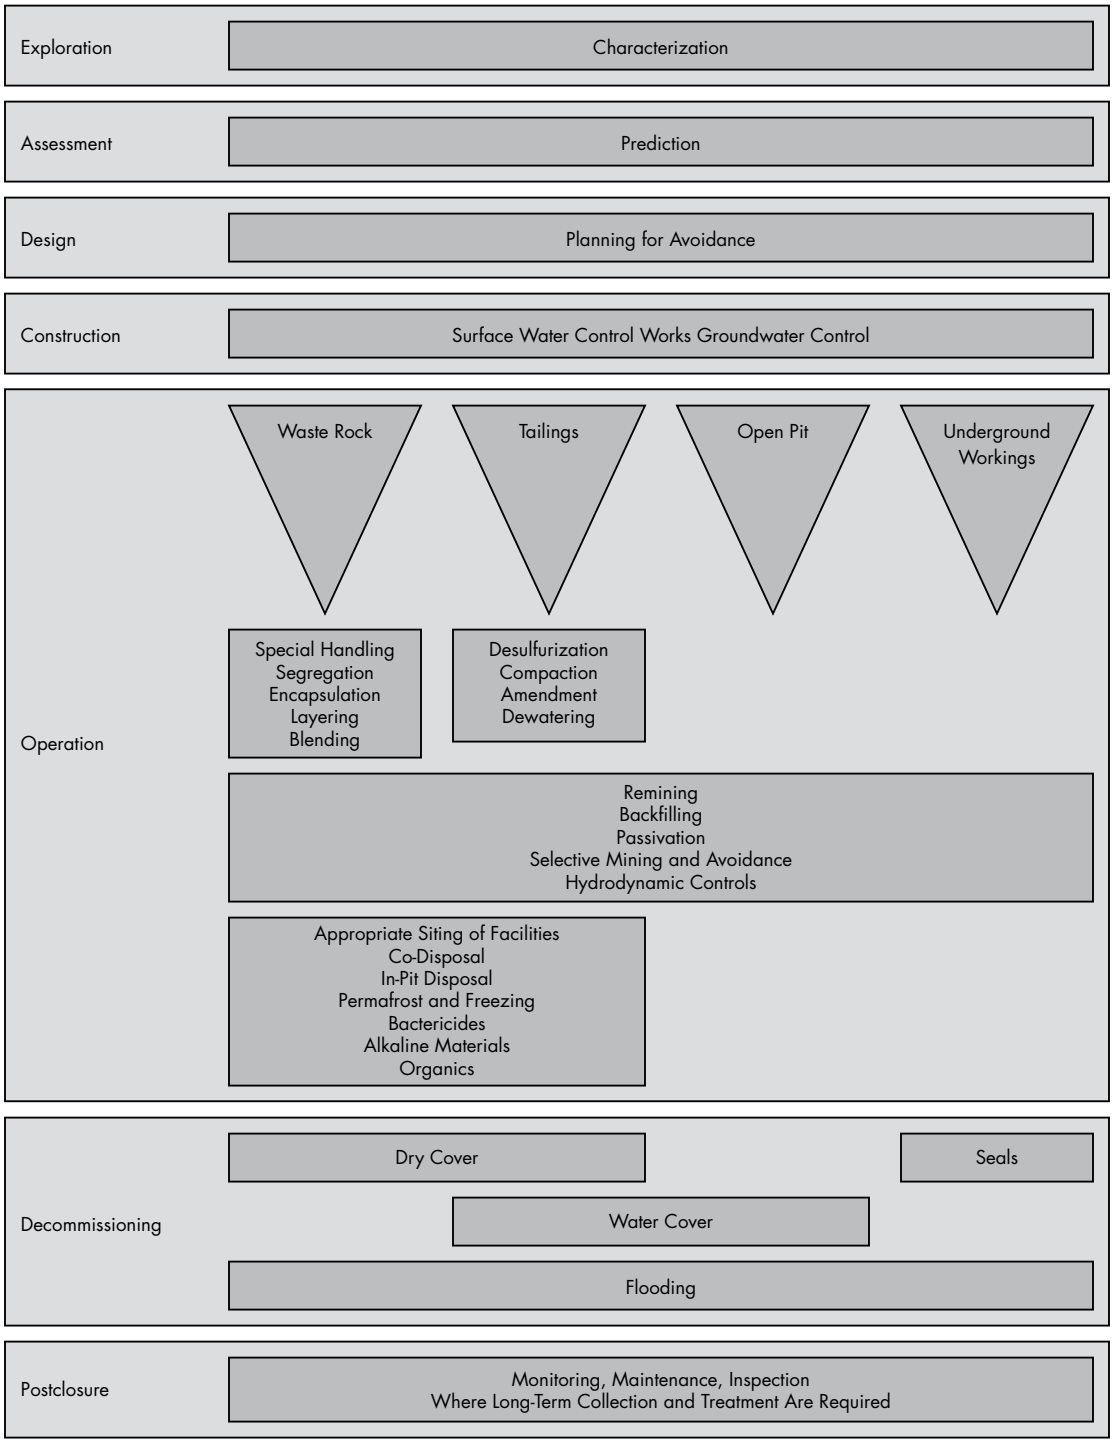
More than one measure, or a combination of measures, may be required to achieve the desired objective.



Typical objectives for ARD control are to satisfy environmental criteria using the most cost-effective technique. Technology selection should consider predictions for discharge water chemistry, advantages and disadvantages of treatment options, risk to receptors, and the regulatory context related to mine discharges. Figure 16.5-9 provides a generic overview of the most common ARD prevention and mitigation measures available during the various stages of the mine life cycle.

Treatment

The objectives of mine drainage treatment are varied. Recovery and reuse of mine water within the mining operations may be desirable or required for processing of ores and minerals, conveyance of materials, operational use (dust suppression, mine cooling, irrigation of rehabilitated land), and so forth. Mine drainage treatment, in this case, is aimed at modifying the water quality, so that it is fit for the intended use on or off the mine site.

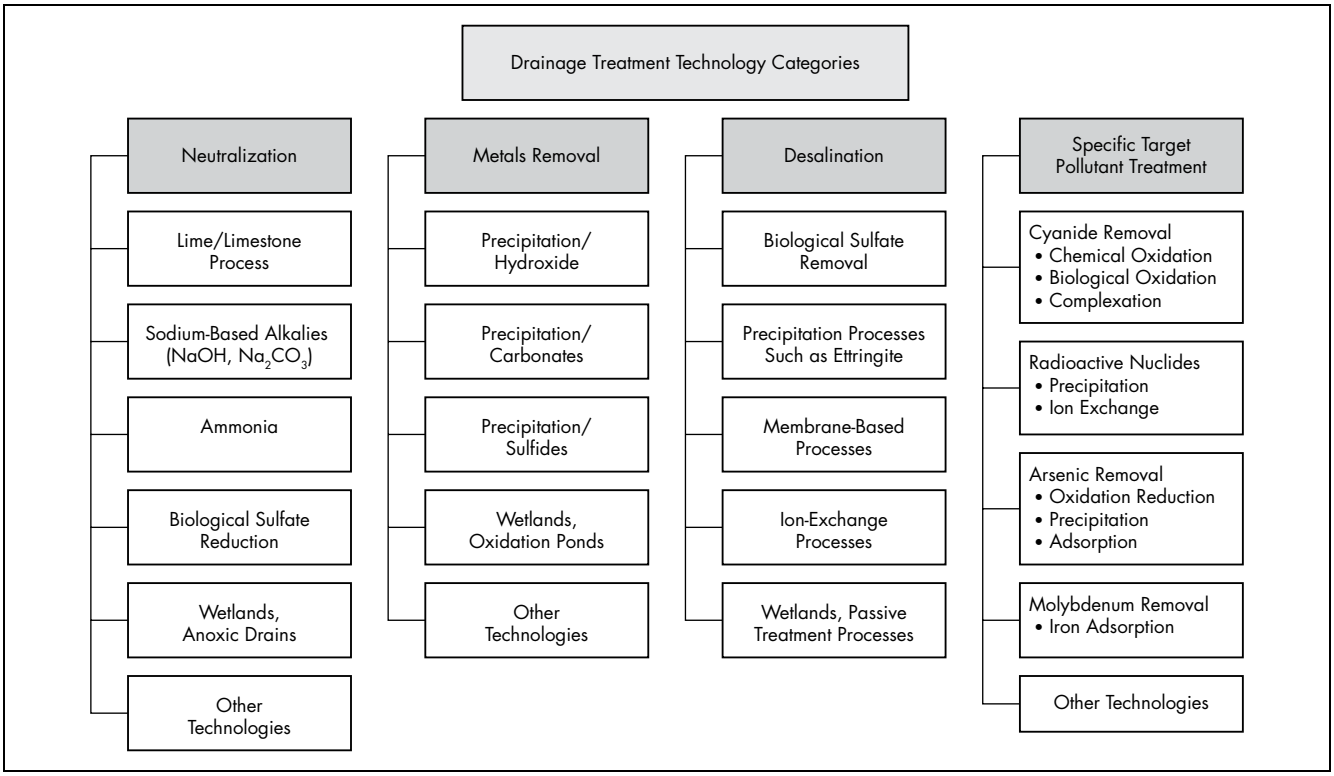


A more public objective of mine water treatment is the protection of human and ecological health in cases where people or ecological receptors may come in contact with the impacted mine water through indirect or direct use of on-site and off-site water resources. Water treatment then aims to remove the pollutants contained in mine drainage to prevent or mitigate environmental impacts.

In the majority of jurisdictions, any discharge of mine drainage into a public stream or aquifer must be approved by the relevant regulatory authorities; regulatory requirements stipulate a certain mine water discharge quality or associated discharge pollutant loads. Although discharge quality standards may not be available for many developing countries in which mining occurs, internationally acceptable environmental quality standards generally still apply as stipulated by project financiers and mining company policies.

Source: INAP 2009.

Figure 16.5-8 Generic overview of ARD prediction approach



Source: INAP 2009.

Figure 16.5-9 Generic overview of ARD prevention and mitigation measures

The approach to selection of a mine drainage treatment method is premised on a thorough understanding of the integrated mine water system and circuits and the specific objective(s) to be achieved. The approach adopted for mine drainage treatment will be influenced by a number of considerations.

Prior to selecting the treatment process, a clear statement and understanding of the objectives of treatment should be prepared. Mine drainage treatment must always be evaluated and implemented within the context of the integrated mine water system. Treatment will have an impact on the flow and quality profile in the water system; hence, a treatment system is selected based on mine water flow, water quality, cost, and water use(s) and receptors.

Characterization of the mine drainage in terms of flow and chemical characteristics should include consideration

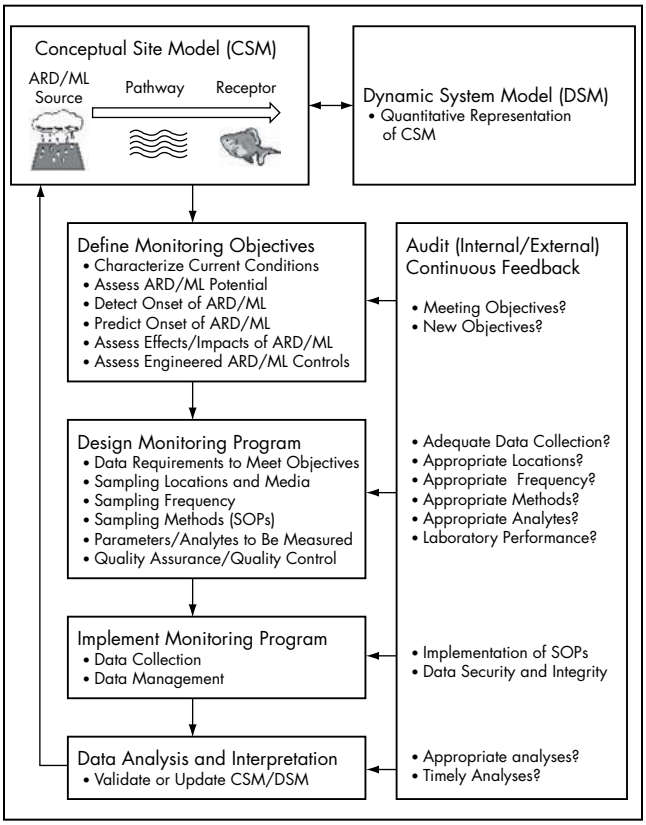
Source: INAP 2009.

Figure 16.5-10 Generic overview of ARD treatment alternatives

of temporal and seasonal changes. Flow data are especially important, as this information is required to size any treatment system properly. Of particular importance are extreme precipitation and snowmelt events that require adequate sizing of collection ponds and related piping and ditches. The key chemical properties of mine drainage relate to acidity/alkalinity, sulfate content, salinity, metal content, and the presence of specific compounds associated with specific mining operations, such as cyanide, ammonia, nitrate, arsenic, selenium, molybdenum, and radionuclides. There are also a number of mine drainage constituents (e.g., hardness, sulfate, silica), which may not be of regulatory or environmental concern in all jurisdictions but that could affect the selection of the preferred water treatment technology. Handling and disposal of treatment plant waste and residues such as sludges and brines and their chemical characteristics must also be factored into any treatment decisions.

A mine drainage treatment facility must have the flexibility to deal with increasing/decreasing water flows, changing water qualities, and regulatory requirements over the life of mine. This may dictate phased implementation and modular design and construction. Additionally, the postclosure phase may place specific constraints on the continued operation and maintenance of a treatment facility.

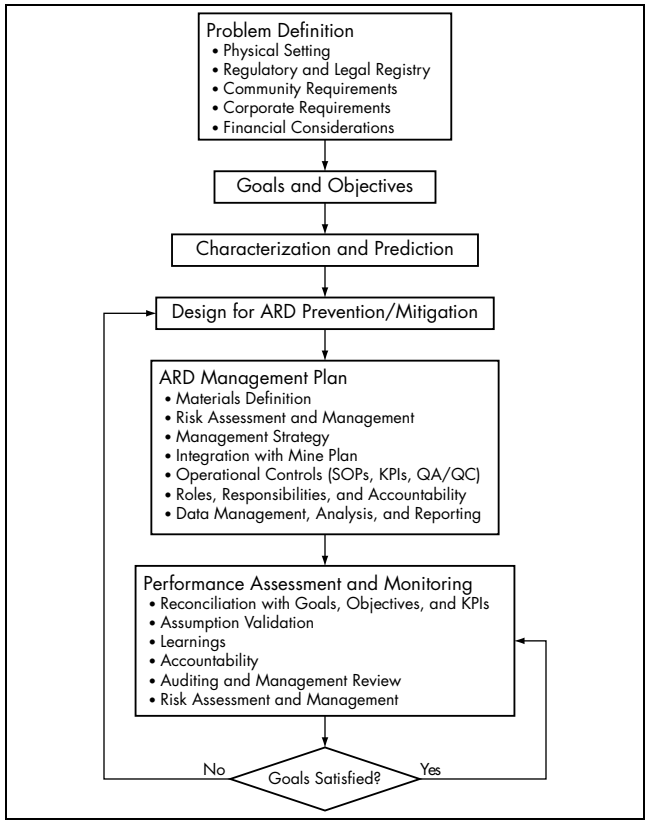
A variety of practical considerations related to mine site features will influence the construction, operation, and maintenance of a mine drainage treatment facility:



- Mine layout and topography
- Space
- Climate
- Sources of mine drainage feeding the treatment facility
- Nature and location of treated water receptors

Various ARD treatment alternatives are presented in Figure 16.5-10.

Monitoring



Monitoring is the process of routinely, systematically, and purposefully gathering information for use in management decision making. Mine site monitoring aims to identify and characterize any environmental changes from mining activities to assess conditions on the site and potential impacts to receptors both on- and off-site. Monitoring consists of both observation (e.g., recording information about the environment) and investigation (e.g., studies such as toxicity tests where environmental conditions are controlled). Monitoring is critical in decision making related to ARD management, for instance through assessing the effectiveness of mitigation measures and the subsequent implementation of adjustments to mitigation measures as required.

Development of an ARD monitoring program starts with a review of the mine plan, the geographical location, and the geological setting. The mine plan provides information on the location and magnitude of surface and subsurface disturbances, ore processing and milling procedures, waste disposal areas, effluent discharge locations, groundwater withdrawals, and surface water diversions. This information is used to identify potential sources of ARD, potential pathways for release of ARD to the receiving environment, receptors that may be impacted by these releases, and potential mitigation that may be required. Because the spatial extent of a monitoring

Source: INAP 2009.

Figure 16.5-11 Development of an ARD monitoring program

Source: INAP 2009.

Figure 16.5-12 Flow chart for ARD performance assessment and management review

program must include all these components, a watershed approach to ARD monitoring (including groundwater) is often required. Monitoring occurs at all stages of project development, from preoperational through postclosure. However, over the life of a mine, the objectives, components, and intensity of the monitoring activities will change. The development and components of a generic ARD monitoring program are presented in Figure 16.5-11.

Management and Performance Assessment

The management of ARD and the assessment of its performance are usually described within the site environmental management plan or in a site-specific ARD management plan. The ARD management plan represents the integration of the concepts and technologies described earlier in this chapter. It also references the engineering design processes and operational management systems employed by mining companies.

The need for a formal ARD management plan is usually triggered by the results of an ARD characterization and prediction program or the results of site monitoring. The development, implementation, assessment, and continuous improvement of an ARD management plan are ongoing processes throughout the life of a mine, which will typically follow the sequence of steps illustrated in Figure 16.5-12.

As shown in Figure 16.5-12, the development of an ARD management plan starts with establishment of clear goals and objectives, such as preventing ARD or achieving compliance with specific water quality criteria. This includes consideration of the physical setting, regulatory and legal registry, community and corporate requirements, and financial considerations. Characterization and prediction programs identify the potential magnitude of the ARD issue and provide the basis for the selection and design of appropriate ARD prevention and mitigation technologies. The design process includes an iterative series of steps in which ARD control technologies are assessed and then combined into a robust system of management and controls (i.e., the ARD management plan) for the specific site. The initial mine design may be used to develop the ARD management plan needed for an environmental assessment. The final design is usually developed in parallel with project permitting.

The ARD management plan identifies the materials and mine wastes that require special management. Risk assessment and management are included in the plan to refine strategies and implementation steps. To be effective, the ARD management plan must be fully integrated with the mine plan. Operational controls such as standard operating procedures (SOPs), key performance indicators (KPIs), and quality assurance/quality control (QA/QC) programs are established to guide its implementation. The ARD management plan identifies roles, responsibilities, and accountabilities for mine operating staff. Data management, analysis, and reporting schemes are included to track progress of the plan.

In the next step, monitoring is conducted to compare field performance against the design goals and objectives of the management plan. Assumptions made in the characterization and prediction programs and design of the prevention/

mitigation measures are tested and revised or validated. *Learnings,* or lessons learned during monitoring and assessment, are evaluated and incorporated into the plan as part of continuous improvement. Accountability for implementing the management plan is checked to ensure that those responsible are meeting the requirements stipulated in the plan. Internal and external reviews or audits should be conducted to gauge performance of personnel, management systems, and technical components to provide additional perspectives on the implementation of the ARD management plan. Review by site and corporate management of the entire plan is necessary to ensure that the plan continues to adhere to site and corporate policies. Finally, results are assessed against the goals. If the objectives are met, performance assessment and monitoring continues throughout the mine life with periodic rechecks against the goals. If the objectives are not met, then redesign and reevaluation of the management plan and performance assessment and monitoring systems for ARD prevention/mitigation are required. This additional effort might also require further characterization and ARD prediction.

The process described in Figure 16.5-12 results in continuous improvement of the ARD management plan and its implementation, and accommodates possible modifications in the mine plan. If the initial ARD management plan is robust, it can be more readily adapted to mine plan changes.

Implementing the ARD management plan relies on a hierarchy of management tools. Corporate policies help define corporate or site standards, which lead to SOPs and KPIs that are specific to the site and guide operators in implementing the ARD management plan. Where corporate policies or standards do not exist, projects and operations should rely on industry best practice.

Communication and Consultation

The level of knowledge of ARD generation and mitigation has increased dramatically over the last few decades within the mining industry, academia, and regulatory agencies. However, for this knowledge to be meaningful to the wide range of stakeholders generally involved with a mining project, it needs to be translated into a format that can be readily understood. This communication should convey the predictions of future drainage quality and the effectiveness of mitigation plans, their degree of uncertainty, and contingency measures to address that uncertainty. An open dialogue on what is known, and what can be predicted with varying levels of confidence, helps build understanding and trust, and ultimately results in a better ARD management plan.

Communicating and consulting with stakeholders about ARD issues is essential to the company's social license to operate. Because of the generally highly visible nature of ARD, skilled people are needed to communicate effectively, and the involvement of representatives from all relevant technical disciplines may be required.

SUMMARY

A thorough evaluation of ARD potential should be conducted prior to mining and continued throughout the life of the mine. Consistent with sustainability principles, strategies for dealing with ARD should focus on prevention or minimization, rather than control or treatment. These strategies are formulated within an ARD management plan, to be developed in the early phases of the project together with monitoring requirements to assess its performance. Integration of the ARD management plan with the mine operation plan is critical to the success of ARD prevention or mitigation. ARD management practices continue to evolve but tend to be site specific and require special expertise.

CHAPTER 16.6

Waste Disposal and Contamination Management

Richard K. Borden

INTRODUCTION

Wastes generated by mining and mineral processing operations can have profound environmental impacts on land, water, and air resources if improperly managed. Mining and mineral processing generate large volumes of mineral waste, such as tailings and waste rock. At large mines the mass of mineral waste generated can commonly be measured in the tens of millions to billions of tons. Similarly, the surface area that must be disturbed for mineral waste disposal is often measured in the tens to thousands of hectares and may account for the majority of disturbance. If the mineral waste is also chemically reactive, the potential environmental impacts and the complexity of waste management increase dramatically.

Public concerns during project permitting are commonly centered on potential exposure risks and water quality impacts from chemically reactive mineral wastes and can result in project delays and costly permitting requirements. If mishandled, chemically reactive mineral waste can degrade water quality for centuries, creating large environmental and financial liabilities. Waste-related perpetual water management and treatment can account for more than half of the total closure cost at some mines. Fortunately, significant advances in mineral waste characterization and management have been made over the past several decades. Proactive mineral waste management can significantly reduce the intensity, footprint, and duration of environmental impacts. Companies that practice proactive management can reduce their financial liabilities, improve their reputations, and become miners of choice, helping ensure access to new mining opportunities.

Mining and processing operations also can generate significant volumes of nonmineral waste. Common hazardous and industrial wastes include solvents, used oil, oily debris, spent reagents, coolants, greases, batteries, and used paint. These wastes typically are sent to off-site recycling, treatment, or disposal facilities. Other nonhazardous wastes such as construction debris, packing materials, general office waste, and used tires may be recycled, sent to an off-site municipal landfill, or placed in permitted on-site landfills. Both hazardous waste and materials such as gasoline, strong acids, and some reagents must be carefully managed on-site to comply with legal requirements, protect worker health and safety, and avoid spills. Areas that have been impacted by historic hazardous material spills and releases may have contaminated soils and groundwater that can threaten human health or the environment. Active management or remediation of contaminated sites is commonly required at older mining operations.

MINERAL WASTE

The most common mineral wastes include overburden and waste rock, tailings, spent heap leach ore, block cave rubble, and slag. Waste rock, overburden, and interburden are unmineralized or weakly mineralized rock and unconsolidated sediments that must be removed to access the underlying ore. Waste rock is typically a poorly sorted mixture of clay, silt, sand, gravel, and boulder-sized material. The most common disposal method for waste rock is placement within dumps and stockpiles, although in-pit disposal is common in strip mines. Tailings are the fine-grained waste that remains after the minerals or elements of economic interest have been removed from the ore. Rejects from coal-washing facilities, fines generated by bauxite and iron ore washing, and red mud generated by aluminum refining also have many of the same physical characteristics and management requirements as tailings. Tailings are composed of the gangue minerals in the ore and residual minerals of economic interest that were not recovered, along with process water and any reagents that were added during the milling and beneficiation processes. Tailings are usually disposed of in specially engineered repositories that are capable of containing the fine-grained and often saturated tailings mass without risk of geotechnical failure.

Spent heap leach ore is the residual rock that is left after the elements of economic interest have been removed by leaching. It may have the same physical characteristics as waste rock or it may have undergone additional crushing, grinding, and/or agglomeration steps. Chemically, the spent heap leach ore has usually been altered by the addition of strongly acidic, saline, and/or basic leach solutions and the addition of reagents such as cyanide. Spent ore will also contain residual leach solution held within its pores, even after the initial drain down has been completed. In most circumstances

Richard K. Borden, Principal Advisor Environment, Rio Tinto, South Jordan, Utah, USA

spent ore is left in place on the heap leach pad after closure, but sometimes it may be actively cycled on and off the pads.

The block cave underground mining method can create a large mass of highly fractured and disturbed rubble overlying the underground workings. This rubble can have many of the same physical and chemical characteristics as waste rock, even though it has been generated in situ. Slag is the glassy waste residue generated by the smelting of metallic ores, typically at much lower volumes than other categories of mineral wastes.

Mineral waste disposal can be responsible for much of the environmental impact caused by mining. Potential impacts that must be assessed, minimized, and mitigated during mine design, operation, and closure include the following:

- **Direct land disturbance.** Construction of out-of-pit mineral waste storage facilities will typically require burial of the premining surface, its soils, and ecosystems beneath tens to hundreds of meters of waste. The surface area impacted by waste disposal is commonly larger than the disturbance required to access the ore body via open pits and underground workings.
- **Geotechnical instability.** Unless properly designed, thick waste piles may be prone to geotechnical instability and failure. Instability may range from excessive surface erosion to large deep-seated slope failures. Geotechnical risks are generally highest for tailings and other fine-grained waste materials that are saturated when deposited. Geotechnical issues and requirements related to waste management are detailed in Chapters 8.10 and 8.11.
- **Erosion and sediment release.** Erosive wastes are prone to the formation of gullies and other erosion features. The release of sediment at much higher rates than surrounding natural landforms can have negative impacts on downgradient surface water bodies and aquatic ecosystems.
- **Visual impacts.** Large-scale mineral waste transport and placement can significantly modify the landscape, creating landforms that are taller than the surrounding topography, truncating valleys and drainage lines, and creating unnatural uniform planar landforms that do not blend in with the surrounding natural topography. Mineral wastes may inhibit vegetation establishment, creating surfaces that look different from the surrounding undisturbed lands. Visual impacts are likely to be a particular concern near population centers and recreational or protected areas.
- **Direct exposure risks and phytotoxicity.** As detailed in the next section, chemically reactive mineral waste may pose direct chemical exposure risks to people, plants, and animals that live on or near the waste. The pH, salinity, or metals content of the waste can also inhibit vegetation establishment and prevent successful rehabilitation of waste surfaces.
- **Water quality degradation.** Chemically reactive mineral wastes can degrade the quality of water that runs off of or seeps through the waste material. Unless properly managed, this can cause degradation of surface and groundwater quality, impacts to aquatic ecosystems, and loss of the beneficial use of water resources far from the point of initial waste placement.
- **Dust release.** Wind erosion and dust release can degrade air quality because of increases in suspended particulate matter. If the dust is derived from chemically reactive waste, wind transport may disperse potential contaminants over a broad area.

Chemically Reactive Mineral Waste

Chemically reactive mineral waste has chemical or mineral constituents that could now or in the future create an environmental hazard above and beyond the risks posed by inert dust in air or inert total suspended solids in water. Several types of chemical hazards are associated with mineral waste and are discussed in the following paragraphs.

Acid Rock Drainage

The oxidation of naturally occurring sulfide minerals such as pyrite and chalcopyrite releases acidity, metals, and sulfate. Sulfide-bearing mineral waste can generate drainage with low pH, high salinity, and high metals concentrations, and can prevent the establishment of vegetation. Acid rock drainage (ARD) is most commonly associated with ore deposits that formed as a result of sulfide mineralization such as precious (gold, silver) and base metal (copper, nickel, lead, zinc) ore bodies. However, ARD is possible at any ore body or associated country rock that formed or exists under reducing conditions such as those typically found below the premining water table. For example, ARD has also been observed at coal, diamond, iron ore, and uranium mines. Operations that use acid for processing (such as uranium or copper heap leach operations) may also create acidic solutions and wastes with properties similar to ARD. ARD represents the most significant and most common chemical hazard posed by mineral waste and is discussed in more detail in Chapter 16.5 Good overviews of ARD chemistry, prediction, and management are provided in the *Global Acid Rock Drainage Guide* (INAP 2009) and the Mine Environment Neutral Drainage Program manuals (MEND 2001).

Metals Soluble or Bioavailable at Neutral pH

Many elements are soluble at neutral pH and can leach from mineral waste at concentrations that may be of environmental concern. Once in solution, these elements may be toxic to aquatic life or may make the water unfit for use as drinking, irrigation, or stock water. Many of these elements are also bioavailable at neutral pH and can inhibit vegetation establishment or pose direct exposure risks to animals and people via uptake by vegetation growing on the waste or incidental ingestion. These elements may include boron, cadmium, cobalt, chromium, fluoride, mercury, manganese, molybdenum, nickel, selenium, thallium, and zinc (Smith and Huyck 1999). Neutral drainage problems may be associated with many types of ore bodies and processes but are particularly common at sulfide-bearing ore bodies, which also contain significant neutralization potential. In this case the acidity released by sulfide oxidation is neutralized in situ, but the metals released from the sulfide minerals are soluble at neutral pH and can be mobilized out of the waste material.

Salinity and Sodicity

Some mineral wastes contain readily soluble salts, which can impact water quality and inhibit vegetation establishment. Major ions typically associated with salinity impacts include sodium, magnesium, potassium, calcium, chloride, sulfate, carbonate, and bicarbonate (Richards 1954). Elevated salinity can cause environmental impacts through general osmotic effects or specific ion effects. Saline soils can inhibit vegetation establishment, and solute loading to surface water can degrade water quality, harming aquatic life and ecosystems. Saline soils with a high proportion of exchangeable sodium

relative to calcium, potassium, and magnesium are defined as sodic soils. Sodic soils and wastes can have poor soil structure, are prone to erosion, and have poor drainage. Salt loading can make water unfit for use as drinking, stock, or irrigation water. Salinity guidelines for soils and water are usually expressed in terms of total dissolved solids concentration or electrical conductivity. However, water quality guidelines for specific major ions such as sulfate have also been promulgated in many jurisdictions. Many sectors of the mining industry may have salinity issues, including coal, borax, salt, potash, and any sulfide-bearing ore bodies. Operations that use seawater in the process can create tailings salinity issues. The evapoconcentration of zero-discharge or low-discharge water bodies and process circuits such as pit lakes and tailings impoundments may also result in high salinity.

Radionuclides

Radionuclides such as uranium, thorium, radium, and radon can pose exposure risks because of toxicity and/or radiological hazards. The release of uranium and its daughter products are an issue at uranium mines. However, radionuclides may also pose hazards at heavy mineral, coal, and rare earth ore bodies and at ore bodies associated with granitic rocks. Radon exposure may be a particular concern at some underground mining operations in granitic terrains.

Cyanide and Other Reagents

Cyanide is most commonly used in the mining industry to extract gold from ore and can also be used at low concentrations as a flotation reagent. As such it may be present in spent heap leach ore and tailings. Because of the toxicity of cyanide, airborne and aqueous releases to the environment are highly regulated in most jurisdictions. A good overview of cyanide geochemistry and environmental behavior is provided by Smith and Mudder (1999). Best practice for management of cyanide and cyanide-bearing wastes is provided by the International Cyanide Management Institute (ICMI 2009a, 2009b). Many other organic and inorganic reagents may be used in the flotation process or other ore-processing techniques. These reagents are commonly highly diluted within the resultant processing mineral waste but under some circumstances could pose risks to the environment and human health.

Nitrogen Compounds

Nitrogen compounds (ammonium, nitrate, and nitrite) are most commonly associated with incomplete combustion of blasting agents at hard-rock mines and can be present in both waste rock and tailings. Nitrate is also a common cyanide degradation product. Ammonium is also commonly used in uranium processing and is likely to be present in some uranium tailings. Nitrogen compounds have the potential to be directly toxic to aquatic life and can degrade water quality so that it cannot be used as drinking or stock water. The release of nitrogen and/or other nutrients such as phosphorus can cause algal blooms and eutrophication of surface water bodies.

Naturally Occurring Asbestos and Other Mineral Dust Health Issues

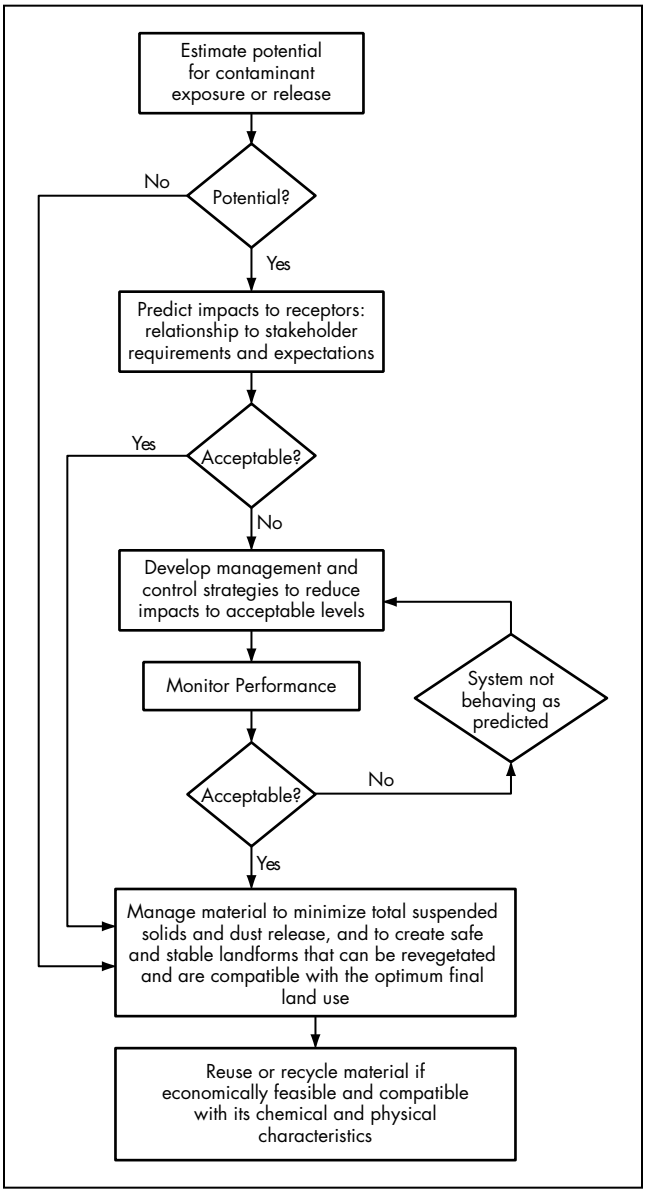
Although little commercial asbestos mining is still performed, asbestiform minerals may be present at low concentrations (as naturally occurring accessory or gangue minerals) in other types of ore bodies. These may include vermiculite, talc, and enriched banded iron formation ore bodies, and ore bodies associated with skarns, carbonatite intrusions, ultramafic igneous rocks, mafic alkaline intrusions, serpentinite, and metamorphosed carbonates (Virta 2002). Gangue asbestos in waste rock and tailings can pose airborne exposure risks to workers and nearby communities. Worker exposure to silica minerals, amorphous silica, and other fine mineral dusts can pose health risks. A good summary of the potential health effects of mineral dusts is provided by Ross (1999).

High pH

Many jurisdictions specify a maximum discharge limit of 8.5 to 9.0 for pH to protect aquatic ecosystems and drinking water resources. Aluminum refining generates bauxite residues (red mud), which typically have pH values of greater than 12. Alkaline leaching operations for the recovery of uranium, gold, and other commodities may also generate mineral waste with a high pH.

Spontaneous Combustion

Spontaneous combustion may pose a risk at operations that disturb or expose carbonaceous and/or highly reactive sulfide-bearing waste. Oxidation of the material may release heat faster than can be dissipated, until temperatures become high enough to trigger combustion of the waste. This is most likely to occur at coal mines but may also be a risk at operations that disturb carbonaceous and/or reactive pyritic shale.



Compared to inert waste, the presence of chemically reactive mineral waste can significantly increase the complexity and cost of waste management. Successful management of chemically reactive mineral waste requires a thorough understanding of pertinent regulations, well-designed characterization programs, careful site selection, good facility design, and rigorous ongoing management and monitoring (Figure 16.6-1).

Waste Characterization and Impact Prediction

When developing a waste characterization program, operations must identify and understand the physical and chemical characteristics and hazards of all mineral wastes that will be disturbed, exposed, produced, or imported over the life of the operation. The characterization program must be rigorous enough to provide reliable predictions of the long-term physical and chemical behavior of the waste. Ultimately, the program will be used to select appropriate management strategies that comply with pertinent regulations for each waste type; ensure that all repositories are physically and chemically safe and stable; and allow for successful rehabilitation and closure.

Physical hazards include materials that are highly erodable and may be prone to shallow or deep-seated geotechnical failure under local conditions. Very blocky or poorly graded coarse-grained materials may also inhibit vegetation establishment. The potential existence of each of the chemical hazards described in the previous section must be assessed. The characterization work should be implemented in a phased approach, beginning with a broad-based sampling program combined with simple laboratory tests, followed by more complex testing if required. Initial testing should be designed to determine if a potential problem exists, while later testing may be focused on defining geologic distribution, release rates, and ecological or health effects.

For most geochemical hazards, laboratory analysis typically progresses from

Courtesy of Rio Tinto.

Figure 16.6-1 Overarching management strategy for chemically reactive mineral waste

- Total element analyses, paste pH and conductivity, and short-term static leach tests; through
- Longer-term kinetic or sequential leach tests, mineralogical analysis, and ecotoxicity tests; to
- Field scale tests and trials.

For example, a typical phased testing program for ARD may begin with simple total sulfur analyses performed on a suite of well-distributed samples that represent all major lithologies, alteration types, ore grades, and waste types. If all samples contain very low sulfur values, then the risks posed by ARD are likely negligible, and more complex testing is unlikely to be required. At most sites, ARD risks are likely to be negligible if all total sulfur values are less than 0.1%, but under some geologic and environmental conditions, material with total sulfur values as low as 0.05% may require special management (e.g., if the waste contains negligible neutralization potential and is located in a sensitive environment with little buffering capacity).

If materials that pose an ARD risk are identified by the preliminary testing, increased sampling density coupled with more detailed acid–base accounting, net acid generation testing, and mineralogical analysis should be implemented to further define the geochemical behavior of the material under surface weathering conditions. Acid–base accounting compares the acid-generating potential of the rock sample (as measured by sulfide sulfur) against its acid-neutralization potential (most commonly related to the calcium and magnesium carbonate content of the sample). Rock that contains excess neutralization potential will theoretically maintain a neutral pH as it weathers, even if it contains abundant sulfide minerals. Because of the uncertainties created by differential reaction kinetics, leaching rates, and mineral distribution in the rock, a commonly used screening criterion assumes that rocks with excess neutralization potential may still be acid generating unless the neutralization potential is at least twice the acid potential (Price et al. 1997).

Long-term kinetic leach tests should be carried out on selected samples if contact water quality and contaminant release rates need to be predicted. Kinetic leach testing should be performed in a manner consistent with the conditions to which the material will be exposed (e.g., will it be deposited above the water table or under water?). The assessment must also consider the effects of processing and deposition on the materials (e.g., will sulfides become concentrated during processing?). More detail on ARD characterization and prediction is presented in Chapter 16.5.

Preliminary physical analysis commonly consists of standard laboratory classification tests such as

- Grain size distribution and unified soils classification,
- Plasticity (Atterberg limits),
- Estimated placement density, and
- Moisture content.

More sophisticated tests may be required to assess weathering, strength, permeability, and erosion potential. Similarly, revegetation tests for mineral wastes may progress from

- Nutrient analyses and grain size distribution, to
- Greenhouse trials, to
- Field revegetation test plots and plant tissue sampling (to determine metals uptake).

Materials characterization data should be integrated with mine plans, waste inventories, and environmental baseline data such as climatic setting, hydrology, hydrogeology, and receiving environment sensitivity to develop an integrated conceptual understanding of how contaminants may be released, migrate, and impact receiving environments, biota, and people. Transport and migration pathways to be considered include direct runoff, wind erosion and dispersion, infiltration and water discharge from the facility's toe, and infiltration and migration to groundwater. Receiving environments and resources that may be impacted include surrounding terrestrial ecosystems; nearby communities; downstream aquatic ecosystems; groundwater-dependent ecosystems; and surface and groundwater resources used for drinking, stock, and/or irrigation water.

It is usually useful and often important to develop a conceptual model that provides a unified overview of how the

waste behaves in the environment and how it may impact key receptors. Although a model may be as simple as a schematic diagram, flow chart, or summary text, in some cases, it will need to be supplemented with numerical computer models to predict geochemical, hydrogeologic, and geotechnical behavior. Conceptual and numeric models should be validated and periodically updated in response to changes in operations and new monitoring and characterization data.

Site Selection and Disposal Area Footprint

Waste disposal facilities should be located in areas that minimize environmental impacts and long-term environmental liabilities. The selection process should include a review of site regulatory requirements, baseline conditions, and environmental considerations (see Chapter 16.1), environmental consequences, and the direct surface impacts caused by disposal. In general, the following factors should be considered when selecting locations for waste disposal facilities (modified from Rio Tinto 2008a):

- Only place waste within legally permitted areas.
- When practicable, preferentially place waste within inactive open pits, underground workings, or existing disturbed areas. This not only minimizes direct land disturbance but may allow rehabilitation of open pits that otherwise could not be returned to productive postmining use and can provide significant benefits for the management of some chemically reactive mineral waste.
- Avoid permanent disruption of drainage systems.
- Tie waste repositories into the surrounding topography to maintain natural, free-draining landforms and to reduce visual impacts.
- Avoid placement on land with high biodiversity or ecosystem services values.
- Avoid placement in areas with significant archaeological or social value.
- Avoid placement in close proximity to local communities.
- Preferentially place chemically reactive wastes in drainage basins that already contain reactive waste (thereby avoiding placement in undisturbed drainages).
- Limit the footprint of chemically reactive mineral waste to the maximum extent practicable. This will limit the volume of precipitation that may ultimately contact the waste, mobilizing contaminants and degrading water quality. It will also limit the surface area that may ultimately need to be covered or capped, often at significant cost.
- Avoid placement in areas with poor foundation conditions due to topography, underlying geology, or hydrology.
- Avoid placement of chemically reactive mineral waste over significant aquifers or groundwater recharge zones. Preferentially place waste over aquitards and aquicludes and in areas where hydrogeologic containment can be demonstrated.
- When the choice is available, such as in some mountainous terrains, preferentially place chemically reactive waste in areas with significantly dryer climates.
- Balance economic considerations such as haul profiles, potential resource sterilization, and pumping costs with environmental, social, and closure considerations.
- Avoid placement in or near perennial surface water bodies or in large ephemeral drainage lines when practicable, unless this represents the preferred environmental alternative.

Uncontrolled river or shallow marine disposal, which could allow rapid transport of the mineral waste away from the point of initial placement, should almost always be avoided. This does not necessarily apply to the return of mining-related inert dredge spoils into the river or shallow marine environments from which they were derived. River flow, wave action, and long-shore currents can transport wastes far from the point of initial discharge, making it difficult to control where the wastes are ultimately deposited. Aquatic environments can also be severely damaged by the smothering of benthic organisms, degradation of water quality, metals uptake by organisms contacting the waste, and increases in turbidity, which inhibits photosynthesis. However, controlled deposition into lakes and the deep marine environment may represent a preferred environmental alternative under some circumstances. For example, lake disposal may be preferred if

- ARD or geotechnical stability concerns need to be managed;
- It is restricted to well-defined, permanent deposition areas;
- Disturbance of sensitive terrestrial habitats needs to be avoided; and
- Placement can be controlled so that significant fisheries, high-biodiversity freshwater habitats, and down-gradient water resources are protected.

Deep marine mineral waste disposal should generally be considered only if the waste can be discharged and deposited below the maximum euphotic, upwelling, and mixed-layer depths in the surrounding ocean. The actual maximum depths of these three zones must be determined though detailed field studies. Coral reefs, kelp forests, and almost all other high-biodiversity marine environments are restricted to the euphotic zone (where light penetration allows photosynthesis), which typically extends to maximum depths of anywhere from 30 to 200 m in the ocean. Within this marine zone, productivity, fishery resources, ecosystem services, and biodiversity are highest, and waste can be routinely transported by wave action and currents. In most cases, deep marine disposal involves pretreatment, discharge from a pipe more than 100 m deep, and final tailings deposition in water greater than 1,000 m deep.

Waste Management Strategy and Facility Environmental Design

The design and engineering of waste disposal facilities should take into account local legal requirements; the physical, chemical, and mineralogical properties of the waste; and the environmental setting of the disposal area, including considerations of climate, water balance, underlying geology, hydrogeology and foundation conditions, potential seismic events, and nearby receiving environments and communities. Priority should be given to the proactive management of chemical hazards so that exposure risks are controlled and long-term liabilities such as perpetual water treatment are minimized. The selection of appropriate management strategies typically begins by comparing the impacts as predicted by conceptual or numeric models to environmental compliance and performance objectives. If needed, a strategy is selected to reduce the potential impacts and ensure that all compliance and performance objectives will be met during start-up, operation, and closure.

The selected strategy does not have to completely prevent any solute or contaminant release but must ensure that release rates meet regulatory requirements and are low enough

to be assimilated by the receiving environment without causing harm to people, ecosystems, organisms, or resources. Numerous geochemical prevention and control strategies are available for consideration (Table 16.6-1). Based on the chemical hazard, waste characteristics, and environmental setting, many of the control strategies listed in Table 16.6-1 will be impractical or impossible to implement at a specific site. Final selection among the remaining viable control strategies should be based on a rigorous comparison of the potential options (or combination of options) and giving preference to strategies that

- Will consistently meet or exceed local regulatory or permit requirements;
- Pose the lowest risk of short- or long-term failure;
- Can be realistically implemented under actual field conditions (the simpler the better);
- Are compatible with life-of-mine and short-term mine plans including short-, intermediate, and long-term material balances;
- Are proactive preventive measures rather than reactive remedial measures;
- Minimize postclosure liabilities and most closely approach a "walk away" solution at closure; and
- Meet the surface discharge limits, groundwater quality requirements, air quality standards, and/or receiving environment objectives in the most cost-effective manner.

Not all strategies listed in Table 16.6-1 are applicable to each chemical hazard. Strategies that depend on subaqueous disposal to limit oxygen flux into the waste are extremely effective when attempting to control ARD, sulfate-dominated salinity, and metals release related to sulfide oxidation. The maximum concentration of dissolved oxygen in surface water is approximately 30 times less than in the atmosphere. More importantly, the diffusive transfer of oxygen in water is on the order of 10,000 times slower than in air, whether the water is fully oxygenated or not (MEND 2001). Subaqueous disposal in a nonerosive landform, such as a flooded inactive open pit or underground workings, usually represents the most effective and secure disposal option for sulfide-bearing mineral waste. However, subaqueous disposal is not appropriate for waste-containing metals and salts that are already in a soluble form, because the constituents will go into solution where they can be easily transported out of the waste. Subaqueous disposal may also not be appropriate for oxidized wastes, which may contain metals that are stable under oxidizing conditions but which would be mobilized under reducing conditions. Almost any kind of nonerosive inert cover will control dust release for hazards associated with naturally occurring asbestos and other contaminants that may be entrained in the dust. However, to minimize contaminant seepage from a waste repository, a cover must be designed to limit infiltration of precipitation or surface water into the waste.

Figure 16.6-2 provides an example of an integrated mineral waste management strategy at the Rio Tinto Barneys Canyon gold mine in the western United States. About 5% of the 150 Mt of waste rock produced at the mine was unoxidized, enriched in some metals, contained abundant pyrite, and was prone to ARD generation. Proactive control of this potential ARD source required implementation of several of the strategies from Table 16.6-1.

- **Selective handling:** Based on field inspection of color and periodic confirmatory sampling, the unoxidized sulfide-bearing rock was segregated from the benign oxide rock so that it could be specially handled.
- **In-pit disposal and selective waste placement:** The sulfide-bearing rock was placed in two small repositories: one an inactive open pit and another an area already used for oxide waste rock disposal. The repositories both had a small footprint (limiting incident precipitation), were located on previously disturbed land, were not in contact with significant drainage lines or springs, and were located away from property boundaries and groundwater resources.
- **Waste removal and consolidation:** Some sulfide-bearing, low-grade ore stockpiles were also moved into the repositories after it was decided that the material would not be processed.
- **Recontouring to promote runoff:** The repositories were constructed to tie into surrounding native hillsides and to have a final slope of at least 10°. This configuration minimizes run-on and promotes runoff during heavy precipitation events.
- **Infiltration limiting covers:** The mine is located in a semiarid climate, so a store-and-release infiltration limiting cover was constructed on the repositories. Evapotranspiration was maximized by construction of a 4-m-thick cover with good moisture retention properties and planting a mixture of deep-rooting native perennial grasses, forbs, and shrubs to maximize plant water usage. Both repository surfaces were also sloped to the south to maximize sun exposure, growing season, and evapotranspiration.

Store-and-release cover systems, which seek to limit water contact with the underlying mineral waste, are seldom viable in regions with high rainfall, particularly with distinct wet and dry seasons. When managing sulfide-bearing wastes in humid climates, it is commonly better to try and minimize oxidation of the waste by ensuring it remains saturated in perpetuity or is capped with a fine-grained, compacted cover that remains near saturation. Figure 16.6-3, the Rio Tinto Ridgeway gold mine in the eastern United States, is an example of a typical flooded, chemically reactive mineral waste repository designed to limit oxygen ingress into the waste.

Waste storage facilities should be designed and constructed so that postclosure environmental impacts and financial liabilities are minimized. For example, landforms can be constructed to minimize costly recontouring and earthmoving requirements at closure. In many jurisdictions, maximum allowable final slopes for landforms constructed of mineral waste can be no steeper than 2:1 or 3:1 (horizontal/vertical). Rehabilitation costs can be significantly decreased by benching final outer waste rock dump faces in short stair-stepped lifts to match the required final slope angle. Constructing final lifts out of benign waste material—whose physical and chemical properties can support vegetation, will not pose direct exposure risks, will not degrade water quality, and is not prone to erosion—can prevent the need to import costly cover material to meet these objectives at closure. Constructing waste disposal facilities in a manner that allows progressive rehabilitation can also allow operations to minimize the footprint of unreclaimed land at closure. Progressive rehabilitation and

Table 16.6-1 Common management strategies for chemically reactive mineral waste

Strategy	Features
	Proactive Preventive Measures
Selective mining	Early identification of rock masses that pose the greatest geochemical risk allows the mine plan to be designed to avoid exposing or disturbing these materials. The additional handling, closure, and water treatment costs associated with acid-generating or other chemically reactive materials should be included in any economic analysis when determining ore reserves and cutoff grades, open-pit geometry, and the layout of underground workings. Early characterization of relatively benign rock masses is also needed so that materials that could be used for clean fill, construction activities, encapsulation, mixing, or covering are identified and can be incorporated into the mine plan as appropriate.
Improved recoveries	Improving recovery rates during the beneficiation process means that less sulfide ore minerals (such as chalcopyrite and bornite) remain in the resultant tailings or spent ore, where they produce no economic benefit, can contribute to acid potential, and may increase metals concentrations in the waste. Similarly, improving leaching and recovery rates of elements with economic value can lower their concentration in leached tailings and spent heap leach ore where they may be potential contaminants.
Lowering cutoff grade	Anytime cutoff grade can be lowered, the volume of waste rock produced will be reduced. Because the highest-grade waste material is converted to ore when cutoff grades are lowered, this process commonly removes rock with the highest potential contaminant concentrations from waste rock production.
Reagent selection and management	Potential environmental impacts caused by reagents added during ore processing can be minimized by selecting less toxic but equally effective reagents or ensuring reagents such as cyanide are added at, but not above, rates that are optimum for processing. Ensuring that blasting techniques are optimized so that blasting agents are efficiently used can lessen the risks posed by residual nitrogen compounds in waste rock and tailings.
Chemical treatment of tailings	Tailings can be treated before they are discharged to waste repositories. For example, acid-leached tailings can be neutralized to raise the pH and lower metals solubility; rinsing and cyanide destruction can be used to reduce the hazard posed by cyanide leached materials; and red mud generated from aluminum refining can be neutralized with seawater addition.
Selective waste placement	Waste repositories should be designed so that transport pathways that may allow contaminants to migrate out of the waste are minimized. Issues that should be considered include avoiding placement of reactive wastes in areas where they may contact surface water flows or in areas where groundwater discharges to the surface, over highly permeable near-surface aquifers, over or immediately up-gradient of sensitive environments (such as lands with high biodiversity value) or facility boundaries, in unstable or highly erosive landforms, and in watersheds or in areas that have not already been impacted by previous chemically reactive mine waste disposal; and minimizing the ultimate footprint of the chemically reactive waste disposal areas.
Up-gradient water diversion	In locations where surface or groundwater comes into contact with chemically reactive waste materials or wall rock, it is beneficial to capture the clean up-gradient water before it contacts the reactive material. This will reduce the likelihood of contaminants being mobilized and will protect water quality from being degraded. A surface water control plan should be developed as part of the mine plan for all disturbed areas.
Selective handling/encapsulation	Chemically reactive mineral waste may be selectively handled and surrounded with benign waste to limit the contact of runoff water, infiltration, and groundwater; reduce direct plant uptake and animal exposure; reduce the risk posed by wind erosion; provide a growth media over phytotoxic waste; provide alkalinity to underlying acidic waste; or limit the access of oxygen to sulfidic waste. Benign materials can also be used for foundations in areas where water may perch at the base of the waste or in areas where groundwater may discharge into the base of the waste pile via seeps and springs.

(continues)

Table 16.6-1 Common management strategies for chemically reactive mineral waste (continued)

Strategy	Features
In-pit or underground disposal	This method is viable where mined-out pits or underground workings of sufficient size are available. With effective mine planning, the early closure of one of a series of pits or workings may allow for the effective disposal of chemically reactive wastes. Depending on the wall-rock permeability and the location of the water table, waste placed in open pits may need to be encapsulated. For pits and underground workings located below the postmining water table, this disposal method may be used in conjunction with subaqueous disposal to prevent sulfide oxidation but may not be appropriate for wastes containing soluble contaminants. Backfilling open pits above the postmining water table can also be used to prevent evapo-concentration and the creation of hypersaline conditions in arid or semiarid climates and the formation of pit lakes that may provide a direct exposure pathway to terrestrial animals.
Subaqueous disposal	The placement of acid- generating wastes below the water table or in a permanent surface water body and the permanent flooding of underground workings or pits will greatly limit the flux of oxygen into sulfide-bearing materials. This can lower the rate of acid generation and metals release by several orders of magnitude. This technique is most effective when flooding or covering is accomplished rapidly—before the material has time to oxidize. Subaqueous disposal is generally not a viable control option for wastes containing contaminants that are already in a soluble form and whose rate of release is not dependent on the supply of oxygen.
Blending/mixing	The blending and mixing of acid-generating wastes with net neutralizing materials may be used to ensure that bulk neutral pH conditions are maintained within the waste mass as a whole, either in perpetuity or for a sufficiently long period to allow another long-term management technique to be implemented. This control technique may be difficult to implement because of preferential flow paths established within the waste, armoring of neutralizing rock surfaces, and acidified pockets that are likely to form within the waste column. Proper implementation of the technique requires good ore and waste characterization and control, coupled with sequential mining and good dispatch control to ensure that acid-generating and acid-neutralizing wastes are intimately mixed at the appropriate ratios.
Enhanced tailings consolidation	Techniques that enhance tailings consolidation such as the construction of underdrains, ensuring subaerial placement, controlling the rate of rise, active removal of pore water with extraction bores, or initial placement as thickened, dry stacked, or paste tailings will create a more stable material with lower permeability. If solutes within the pore water pose an environmental risk, enhanced consolidation will also reduce the total contaminant mass and lower the potential flux of contaminants that could discharge from the tailings.
Codisposal	Materials with different physical characteristics may be mixed for codisposal to enhance stability and resistance to erosion or to reduce permeability. This technique may be applied to the codisposal of tailings with waste rock. The mixing of tailings and waste rock may create a well-graded material that typically has lower hydraulic conductivity and higher water storage capacity, and is relatively resistant to erosion. The geochemical compatibility and the physical behavior of the mixtures require careful evaluation. Techniques to deposit whole tailings (such as dry stacking, paste, or thickened tailings) that are not strongly segregated into coarse and fine fractions, or segregated into sulfide-depleted and sulfide-enriched fractions, may also provide lower hydraulic conductivity, maintain saturation and, if the parent material is net neutralizing, may prevent the creation of net acid-generating zones within the tailings.
Sulfide flotation	Gangue sulfides such as pyrite may be separated from the bulk of the tailings in order to reduce the tailings' acid potential and ensure they are net neutralizing. The relatively small volume of concentrated waste sulfide can then be specially handled to minimize its environmental risks. Metals that are associated with the sulfides may also be preferentially removed from the tailings by this technique.

Table 16.6-1 Common management strategies for chemically reactive mineral waste (continued)

Strategy	Features
Compaction during placement	Chemically reactive waste rock or overlying benign material may be compacted during placement to lower the hydraulic conductivity of the material and limit the potential flux of water through the compacted layer. Compaction may also aid in the establishment of capillary breaks and/or perched water tables associated with the compacted layers, which will inhibit the flux of oxygen. Although engineered compacted layers should usually be specially constructed, some compaction of the waste can also be accomplished by dumping in shorter lifts to enhance the compaction that occurs naturally as mine vehicles travel over the surface.
Liners	Liners can be constructed under reactive mineral wastes to allow capture of contact water that would normally discharge to the surface or to groundwater. Liners can be simple and relatively inexpensive or complex and expensive, depending on the required performance criteria (generally the allowable design leakage rate). Complex liners are generally required for heap leach pads containing very hazardous leach solutions. For mineral wastes, complex liners are usually only practicable for use with small volumes of very reactive mineral waste. If hydrogeologic containment can be demonstrated because of underlying aquicludes, aquitards, and/or strong upward vertical gradients, then liner systems may not be needed, or less complex systems may be adequate.
Temporary synthetic covers	Synthetic covers such as high-density polyethylene (HDPE) sheeting may be used to temporarily cover reactive mineral wastes or ore stockpiles. This isolates the material from precipitation and greatly limits the volume of contact water that may discharge from the material. This is generally not a viable long-term strategy to limit water contact because the synthetic cover will degrade with time, but it can be used on a short-term basis until the ore is processed or the final closure strategy for the mineral waste is implemented. However, when temporary covers are removed, sulfide oxidation products and other soluble constituents may dissolve and produce a large spike in contaminant release.
Micro-encapsulation (passivation)	This process involves the coating of mine wastes or pit walls with products that encapsulate sulfide surfaces and inhibit oxidation reactions. The mechanism involves mixing the reagents with waste or spraying pit walls with treatment solutions. Treatments that are being investigated include phosphate, amorphous silica, polymer, and potassium permanganate application. Encouraging bioshrouding of sulfide minerals by promoting the growth of microbe biofilms with nutrient addition is also under investigation. However, these techniques are likely to be costly on a per-ton basis; the potential exists for environmental problems associated with the use of some reagents; retroactive treatment of large waste storage facilities is unlikely to be successful; and the long-term viability of the techniques has not been proven at an operational scale.
Bactericide application	Abiotic sulfide oxidation rates are typically several times slower than biologically controlled oxidation rates. Bactericides such as thiocyanate that inhibit the growth of sulfide-oxidizing microorganisms can substantially slow ARD generation rates. However, these techniques are likely to be costly on a per-ton basis; the potential exists for environmental problems associated with the use of some reagents; retroactive treatment of large waste storage facilities is unlikely to be successful; and the long-term viability of the techniques has not been proven at an operational scale.
Incorporation of organic matter and/or nutrients	Incorporation of organic matter or nutrients into wastes can promote the establishment of reducing conditions within the waste material (inhibiting sulfide oxidation and promoting sulfide formation) and may reduce metals solubility by providing sorption sites. Organic matter and nutrients can also promote the establishment of sulfate-reducing bacteria, potentially removing dissolved sulfate and metals from pore waters. Such systems may not be appropriate for use with some oxidized wastes because reductive dissolution of iron or manganese oxides may release adsorbed trace metals such as arsenic.
Accelerated sulfide oxidation	In specially designed heap leach pads, it may be possible to accelerate sulfide oxidation processes, depleting all the reactive gangue sulfide minerals before closure. This would help reduce the risk of long-term contaminant release from the mineral waste. This technique would likely only be viable for copper heap leach pads and other operations that are already designed to maximize the oxidation of sulfide ore minerals. However, costs are likely to be high and the viability of this option has not been proven at an operational scale.

Table 16.6-1 Common management strategies for chemically reactive mineral waste (continued)

Strategy	Features
	Reactive Remedial Measures
Recontouring to promote runoff and inhibit infiltration	Waste surfaces can be recontoured to prevent precipitation from pooling and infiltrating at low points on the surface and/or to allow precipitation to be more efficiently shed from the surface. The surface can be contoured to naturally shed precipitation via runoff, or low points can be established from which runoff is collected and piped off the surface.
Direct revegetation	Some waste surfaces may be directly revegetated after minor physical or chemical modification, such as ripping to reduce compaction, addition of alkaline materials to increase the pH to near neutral, or the addition of organic matter. The establishment of vegetation can reduce erosion, significantly increase evapotranspiration, and reduce the amount of water that infiltrates the underlying waste material. Direct revegetation may allow many of the benefits of a store-and-release cover to be realized without the need to import large volumes of cover material.
General purpose covers	Covers can be constructed over reactive wastes using inert mineral waste, imported fill, or soil to reduce infiltration, preserve runoff water quality, allow vegetation to become established on phytotoxic wastes, limit plant uptake of bioavailable metals in the underlying waste, limit wind transport of reactive wastes, limit direct exposure pathways for animals and humans to metals and radionuclides in the underlying wastes, limit oxygen ingress into the underlying mineral waste, and/or provide alkalinity to the underlying waste.
Alkaline covers	Under certain climatic and geochemical conditions it may be beneficial to construct covers with relatively reactive carbonate material. The carbonate can provide alkalinity to the underlying waste via infiltrating precipitation to control ARD from weakly acid-generating wastes or to increase the thickness of the underlying neutralized waste layer, allowing plants to root more deeply.
Infiltration or oxygen-limiting covers	Two general types of covers to limit oxygen and/or water ingress may be constructed on top of existing mineral waste: (1) low-permeability covers to limit the flux of oxygen and water into the underlying waste or (2) store-and-release covers that limit the amount of water that may infiltrate the underlying waste. In general, low-permeability covers are best suited to wet climates, and store-and-release covers are best suited to dry climates (where evaporation is at least twice precipitation). Low-permeability covers that inhibit the entry of oxygen, using natural materials such as compacted clay, generally require that nearly saturated conditions be maintained within the cover at all times. Low-permeability covers are often subjected to natural processes that may cause degradation in performance over time such as biointrusion by plants and animals and increasing permeability because of natural freeze/thaw and wetting/drying cycles. It is important for compacted layers to be protected from these processes by a thick overlying cover layer. The performance of most store-and-release cover systems is strongly dependent on the thickness and texture of the cover material (i.e., high-moisture storage capacity and low susceptibility to cracking), as well as the density, rooting characteristics, and species composition of vegetation that is established on the cover to maximize evapotranspiration rates.
Infiltration or oxygen-limiting covers (continues)	Covers can be simple, thin, and relatively cheap or complex, thick, and relatively expensive depending on the required performance criteria (generally the design allowable flux of water or oxygen through the cover and into the underlying reactive mineral waste). Covers designed to limit infiltration may also include capillary breaks to inhibit vertical water movement.
Rinsing	Rinsing can be used to flush soluble constituents from mineral wastes such as spent heap leach ore. Generally, several pore volumes must be exchanged to reduce concentrations to acceptable levels. If all the potential contaminants are not present in a readily soluble form, then rinsing is unlikely to be viable. For example, rinsing would not be a viable alternative for sulfide-bearing wastes until almost all of the sulfides have been oxidized.

(continues)

Table 16.6-1 Common management strategies for chemically reactive mineral waste (continued)

Strategy	Features
Flooding	The permanent flooding of existing wastes, open pits, and workings can limit the access of oxygen to the waste material and greatly restrict the rate of sulfide oxidation. Ideally, flooding should occur as soon as possible after the waste material is exposed. Waste materials that have undergone long periods of subaerial storage prior to flooding may contain abundant soluble sulfide oxidation products that may be released when the material is initially contacted by water. It may be necessary to add neutralizing agents to weathered materials that have acidified before they are flooded or to add alkalinity to the flooding waters. Flooding is generally not a viable control strategy unless contamination release rates are dependent on the flux of oxygen into the waste. Large fluctuations in water level so that wastes are periodically exposed and resubmerged must be avoided.
Down-gradient collection and treatment of contact water	This is required for sites where contaminated water is already being released or where it cannot be avoided and involves the capture of impacted surface and groundwater for treatment and disposal. Potential collection and recovery systems may include gravity flow into catchment ponds, drains, and trenches, as well as pumping from pits, underground workings, and extraction wells. Management options include active water treatment such as the addition of alkaline materials or the use of reverse osmosis, internal mixing, and dilution with controlled release to receiving water bodies, evaporative disposal, reuse in the process, reactive barriers, settling ponds, and wetlands treatment for polishing.
In-pit water treatment	The water chemistry of pit lakes may be manipulated in situ to promote physical or chemical conditions and biological processes that improve or maintain water quality. Some examples include controlling the depth of flooding to completely cover acid-generating wall-rock zones, to prevent water from contacting chemically reactive zones, or to create lakes that are unlikely to turn over; the direct addition of alkaline materials to maintain a neutral pH and inhibit sulfide oxidation below the water surface; the addition of nutrients to promote biological activity that removes metals from the water column and helps establish anaerobic conditions at depth; and the addition of sorbing agents such as iron to remove dissolved metals from solution.
Demonstrating hydrogeologic containment	For open pits that intersect the water table in arid and semiarid climates it may be possible to demonstrate hydrogeologic containment of solutes and contaminated water within the pit. Evaporative losses from the pit lake may be sufficient to maintain radial groundwater flow toward the pit in perpetuity. Containment can be enhanced by reducing the volume of runoff water that reaches the pit floor or by pumping and treating enough pit water to keep the lake level below water levels in the surrounding bedrock. Contaminated groundwater underlying waste rock dumps and tailings impoundments located within the zone of groundwater capture of the open pit may also be permanently contained. In some arid climates it may be possible to preferentially direct contaminated surface water into the pit for disposal by evaporation.
Waste removal and consolidation	In some cases it may be beneficial to move tailings and waste rock from one location to another if they are broadly dispersed or located in a particularly sensitive location. The selective removal and consolidation of highly reactive wastes into a smaller footprint may allow for better mitigation, containment, and control of the waste.

Source: Adapted from Rio Tinto 2008b.

revegetation of tailings impoundments can be particularly important to prevent dust generation from inactive tailings surfaces as they dry out. Other closure requirements and considerations that are pertinent to mineral waste disposal facilities design and construction are detailed in Chapter 16.7.

Ongoing Management and Monitoring

After a mineral waste management strategy is selected and waste storage facilities have been designed, they must be constructed and successfully managed on an ongoing, long-term basis. If benign and chemically reactive wastes are to be segregated and specially handled, the complexity of mine planning and management is increased. Waste management strategies need to be fully integrated into mine plans and truck control and dispatch systems. Strategies and costs should also be fully integrated into any economic models used by mine planners. Standard operating procedures need to be developed to ensure that different types of waste are identified, hauled to the correct location, and then placed and managed appropriately. Successful field implementation of strategies and designs will typically require cooperation between environmental personnel, senior management, geologists, short- and long-term mine planners, field supervisors, equipment operators, and surveyors. At many operations, development of a formal mineral waste management plan may be justified. These plans typically include a brief description of management objectives and strategies, waste storage facility design criteria, detailed field procedures, clear assignment of responsibility for different tasks and actions, and ongoing sampling and monitoring requirements.

Monitoring is required to ensure successful implementation of the mineral waste management plan and to ensure that the strategy is leading to the intended results. Physical monitoring programs for waste disposal facilities typically will include at a minimum

- Regular visual inspections of surface structures and facilities such as spillways, piping, dykes, ditches, and other water management systems;
- Regular visual inspections for signs of excessive surface erosion and shallow or deep-seated failure on the outer slopes of waste repositories; and
- Monitoring of water levels and pore pressure within embankments and the waste.

Programs to monitor the geochemical behavior of waste disposal facilities will typically include

- Periodic sampling of runoff water and water discharging from the facility's toe in order to monitor flow volumes, solute concentrations, and the solute mass that is being released from the waste;
- Periodic sampling of down-gradient monitoring wells and surface water bodies to ensure that seepage from the waste is not adversely impacting receiving environment water quality; and
- Periodic assessment of revegetation success such as total cover, species composition, and plant health.

If needed, more specialized monitoring data may be collected, including

- Paste pH, conductivity, and leach testing of soils forming on the surface of the waste or on covers constructed over the waste;

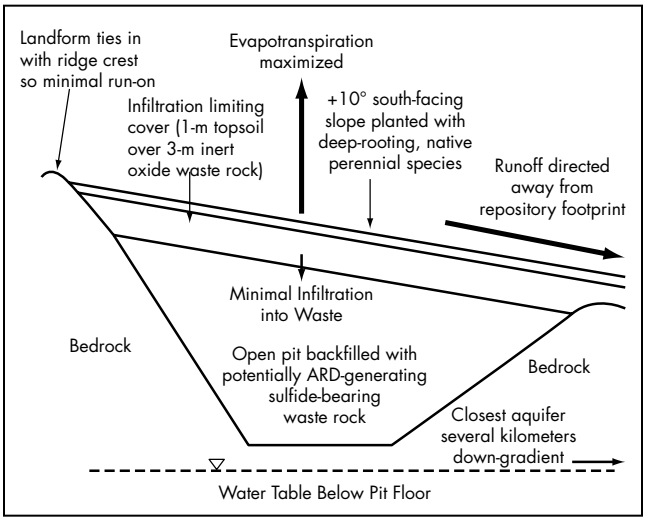

Figure 16.6-2 Example of a chemically reactive mineral waste repository in a semiarid climate

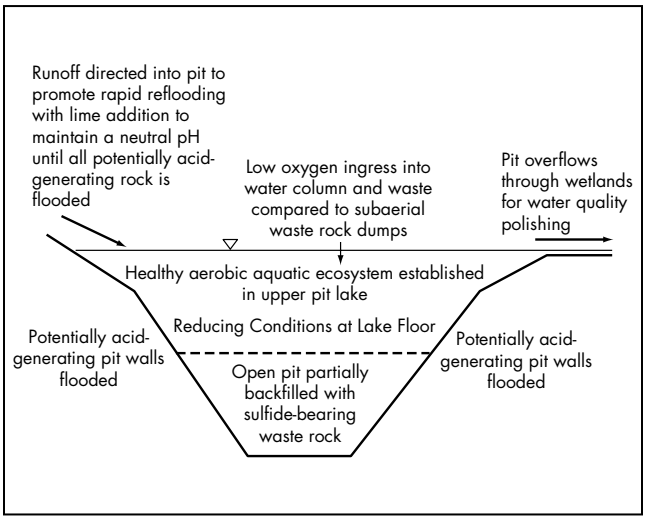

Figure 16.6-3 Example of a chemically reactive mineral waste repository in a humid climate

- Tissue sampling and metals analysis for plants growing on the waste;
- Monitoring of infiltration rates into the waste;
- Internal monitoring of the waste disposal facility for pertinent parameters such as temperature, oxygen content, moisture content, and pore water chemistry;
- Radiological measurements at the surface of the facility; and
- Monitoring of ecosystem health.

Monitoring data should be reviewed regularly, and historical trends should be examined so the longer-term chemical behavior of the mineral waste can be assessed. Time series of monitoring data should be maintained so that long-term changes in water quality, flow rate, or other key parameters can be tracked and significant changes can be identified. Significant unexpected changes should trigger a review of predictions, performance objectives, management strategy, and/or field implementation procedures. Appropriate feedback mechanisms

should be in place to ensure timely management response to out-of-compliance, unexpected, or upset conditions. It is usually beneficial to maintain internal monitoring points in addition to the monitoring required at mandated external compliance points. Internal monitoring can allow early warning of potential problems before out-of-compliance conditions develop.

Closure

Waste disposal facility closure should create safe and stable landforms and allow land and water resources to be returned to productive postmining uses. Geochemical exposure hazards should be controlled, and long-term water management liabilities should be minimized. General reclamation and rehabilitation requirements are detailed in Chapter 16.7. Typical closure activities that are specific to mineral waste disposal facilities include the following:

- Removal of any surface debris or infrastructure.
- Large-scale recontouring to create natural-looking, safe, and stable landforms; to reestablish drainage lines; to reduce angle of repose slopes; and to comply with any other mandated closure criteria.
- Construction of long-term erosion and runoff control structures (Chapter 16.4).
- Placement of any cover material needed to prevent wind erosion, allow revegetation, preserve runoff water quality, limit infiltration, or control oxygen ingress. Cover material may be composed of benign mineral waste or imported borrow material with the appropriate physical and chemical characteristics. If erosion is a concern, a well-graded material should generally be used to support vegetation while also being resistant to erosion. If mineral waste is used as a growth medium, it should generally have the following characteristics:
  - Circumneutral pH (ideally between about 5.5 and 8.0) (Buckman and Brady 1969; Tucker et al. 1987),
  - Low salinity (typically an electrical conductivity of less than 2 dS/m [deciSiemens/meter] for moderately salt-sensitive species) (Maas 1990; ANZECC/ARMCANZ 2000),
  - Excess neutralization potential and low sulfide sulfur content (ideally a neutralization potential ratio of greater than 2:1 [Price et al. 1997] and total sulfur less than about 0.5%);
  - Metals concentrations that will not pose an exposure risk to plants or animals, and
  - Good moisture retention characteristics (adequate sand, silt, and clay in coarse wastes).
- Ripping or scarifying compacted surfaces to remove physical barriers to plant growth.
- Placement of topsoil and/or any soil amendments needed to promote plant growth. Topsoil that is free of weed seed will almost always enhance desired plant growth, and good topsoil management is an important part of most reclamation programs. Soil amendments may be needed when direct planting into mineral waste in order to modify the pH, increase water-holding capacity, improve soil structure, increase organic matter content, and add nutrients. Care should be taken not to overapply biosolids or other nutrients which may promote long-term weed dominance.
- Seed application and/or the planting of seedlings. The species selected for planting are likely to be based on the planned final land use, regulatory requirements, and stakeholder expectations.

Postclosure water management is commonly required for disposal facilities that contain chemically reactive mineral waste. Contaminated water that discharges from the waste material will typically need to be collected and treated before it can be discharged to the environment. Depending on the rates at which sulfide minerals oxidize and at which soluble constituents migrate out of the waste, water management may be required for decades or even centuries after closure. Spent heap leach pads containing hazardous process fluids may need to be flushed with many pore volumes of clean water to meet water quality discharge requirements. Long-term water management costs can be high, in many cases exceeding the cost of the initial rehabilitation. Postclosure monitoring programs are also usually required to ensure that surfaces are not eroding, the mandated vegetation is permanently established, and chemical exposure risks and impacts remain within acceptable ranges. If only inert waste is present, postclosure monitoring may be completed within a few years of closure, but if chemically reactive waste is present, monitoring may be required for many decades.

NONMINERAL WASTE

Common hazardous and industrial wastes generated at mining and mineral processing operations include used oil, oily debris, antifreeze, greases, batteries, solvents, coolants, spent reagents, used paint, and contaminated soils. These wastes are typically sent to off-site recycling, treatment, or disposal facilities. Other nonhazardous wastes, such as construction debris, packing materials, general office waste, and used tires, may be recycled, sent to an off-site municipal landfill, or placed in permitted on-site landfills. Remote operations that are not connected to municipal sewage systems must also construct and manage on-site sewage treatment systems.

Each waste stream needs to be characterized so that its hazards are understood, legal requirements are defined, and appropriate recycling, treatment, or disposal options are identified. Wastes need to be safely accumulated on-site until they are shipped off-site or placed into permanent on-site storage facilities. The volume of waste generated may be reduced by improving process efficiency, substituting hazardous materials with less hazardous but equally effective products, and by identifying on-site recycling and reuse opportunities.

The degree of effort required to characterize each waste stream will generally depend on its potential risks and management requirements. Some waste streams may only require detailed assessment during initial characterization and in response to significant changes in the generation process. Other wastes may require much more frequent analytical testing if the characteristics of the waste are highly variable or the final treatment or disposal method has strict physical or chemical requirements. For example, used oil burned for energy recovery typically has restrictions on metals and total halogens content and flash point. Municipal landfills and many industrial waste landfills are only permitted to receive nonhazardous wastes, so waste characteristics must be defined in accordance with local regulatory requirements to identify appropriate disposal facilities. Depending on the waste stream, key sources of information are likely to be

- Material safety data sheets;
- Other manufacturer and/or supplier information;

- Process and engineering knowledge and materials balances;
- Local regulations, which may list wastes generated by certain processes and/or industries and mandate how they must be handled;
- Analytical testing such as
  - Primary chemical constituents;
  - Trace chemical constituents and impurities such as metals, organic compounds, asbestos, and carcinogens;
  - Physiochemical characteristics such as flash point (typically considered hazardous if <60°C), corrosiveness (typically considered hazardous if pH <2 or >12.5), and reactivity (unstable when heated, compressed, or in contact with water or other wastes);
  - Toxicity leach tests such as the toxicity characteristic leaching procedure (Method 1311, EPA 2008) or the synthetic precipitation leaching procedure (Method 1312, EPA 2008); and
  - Radiological analysis.

Temporary on-site waste accumulation and storage areas should be clearly defined, utilizing fencing and appropriate signage as required by local regulations. Dispersed short-term accumulation areas typically will be located at or near the point of waste generation. Wherever possible, wastes should be segregated at source, which allows for improved recycling or recovery of materials, may increase the number of recycling or disposal options available for the waste, and may reduce the cost of waste disposal. In particular, disposal costs for mixed wastes may also be significantly higher if hazardous wastes are mixed with nonhazardous wastes.

Waste storage and containment practices must meet local, national, or international standards as applicable and must be commensurate with the risk posed by the waste. In many jurisdictions mines are required to have a central waste accumulation site where hazardous and industrial wastes are consolidated and stored before being shipped off-site. Central accumulation areas should typically be located in a secure location, on an impermeable surface to contain spills, and with a roof to minimize rainwater contact. New or used storage containers can be used, but they should be in good condition and must be compatible with the contained waste. Chemically incompatible wastes, which could react with each other, should not be stored together. Waste containers should be appropriately labeled so the contents and their primary hazards can be identified. In some jurisdictions, hazardous wastes have strict limits on the time they can be stored on-site before being shipped to a permitted disposal facility.

All waste must be permanently disposed in accordance with applicable laws, regulations, and permit conditions. Where local or national laws are weak or do not exist, internationally recognized good practices should generally be followed. The design and ongoing management of off-site waste disposal facilities must also be consistent with the regulatory classification and the hazards posed by the waste. Waste shipped off-site should be tracked and/or manifested in order to document its ultimate disposal location. It is often prudent to periodically audit off-site treatment, storage, and disposal facilities that are handling large volumes of hazardous waste to ensure that it is being appropriately managed. There are many examples of off-site contractors who have not correctly handled wastes, creating significant financial liabilities for the original waste generators.

Permanent on-site waste disposal should only occur within designed facilities with engineering and management controls commensurate with the health, safety, and environmental risks posed by the waste. In most cases the on-site disposal facilities will need to be permitted with the appropriate regulatory agencies. To ensure adequate levels of engineering design and management, active on-site landfills or waste storage facilities will generally require

- Clear restrictions on what types of waste materials can and can't be placed in the facility;
- Clear boundaries and limited access to the facility to ensure waste delivery is controlled and to minimize exposure risks to animals and people; and
- Operating procedures describing waste delivery and placement practices, inspection frequency, and covering requirements.

For active storage facilities and landfills that accept chemically reactive wastes capable of posing direct exposure risks or degrading surface and groundwater quality, additional controls are likely to be required, including

- Leachate and stormwater management systems consistent with the chemical hazards posed by the waste, for example:
  - Composite liners with leachate collection systems for chemically reactive wastes that may degrade groundwater quality,
  - Covered and enclosed structures for long-term storage of wastes that are unstable in contact with water, and
  - Stormwater collection systems for wastes that may degrade runoff water quality;
- Closure plans detailing how the facility will be closed—in particular, final cover designs needed to limit direct exposure risks to animals and people, to preserve runoff water quality, to limit infiltration, and to control wind dispersion of the waste; and
- Monitoring programs for groundwater, surface water, air quality, landfill gas, and windblown debris to ensure that potential impacts associated with the waste are being adequately controlled.

Remote sites may find it economic to operate dedicated recycling and/or incineration facilities for waste materials such as antifreeze, used oil, solvents, and medical waste. Again, these facilities must be designed and operated in accordance with all application waste management regulations and air quality standards.

HAZARDOUS MATERIALS AND CONTAMINATION CONTROL

Hazardous material is broadly defined as any substance (solid, liquid, or gas) that could pose a significant threat to human health or the environment if improperly handled or accidentally released. Typically, hazardous materials are toxic, corrosive, flammable, explosive, strongly oxidizing, or radioactive. Hazardous materials that are commonly managed at mining operations include cyanide, strong acids, caustic soda, lime, chlorine, pesticides, herbicides, explosives, solvents, gasoline, and hazardous waste. Other substances that can be considered hazardous under some circumstances include paints, diesel fuel, coolants, and lubricants. The actual risks posed by the handling of these materials depend on their innate hazards, the volumes that are present, potential receiving environments, and transport

pathways that could connect the point of release with potential receptors.

The mishandling or unintentional release of hazardous materials can create acute or chronic health problems for workers and nearby communities, damage ecosystems, degrade land productivity and water quality, and create costly cleanup liabilities. Hazardous materials should be managed to minimize the frequency and severity of any releases. Pipes and tanks should be designed to safely transport and store hazardous materials with minimal risk of failure. Pipelines and tanks should be designed for the pressures used and the material being transported, be well maintained, and be regularly inspected. In general, the use of underground bulk storage tanks should be avoided. If the risks posed by contaminant release are high, additional safeguards such as secondary containments, leak detection systems, and double-walled pipelines may need to be considered.

Secondary containment systems such as bunds, berms, and liners for bulk storage tanks need to be built and maintained in compliance with all local and national requirements and permit conditions, or, in their absence, internationally recognized standards. Secondary containment systems may be designed for individual tanks or for entire tank farms and drum storage areas. Containment and capture systems (such as concrete pads sloped to collection sumps) may also be constructed in areas prone to recurring spills such as haul truck refueling areas.

Secondary containment facilities should be sized to hold a volume greater than that of the largest tank in the containment, along with any piping that drains back into the tank or containment and additional capacity for the design storm event (typically 110% of the largest foreseeable leak into the containment is sufficient). Stand alone double-walled tanks can provide valid secondary containment if designed to contain all leakage from the internal tank. The impermeable material used to construct the secondary containment must have a design leakage rate that is consistent with the environmental hazards posed by the material. In most cases, the secondary containment should be constructed with highly impermeable materials such as concrete, asphalt, or synthetic liners like HDPE. However, if risks are relatively low, more permeable materials such as earth berms and compacted fine-grained soils may be acceptable.

Liner design for the storage of hazardous materials should also always meet or exceed local legal and regulatory requirements. Leach pads and process water ponds that contain hazardous fluids, such as cyanide-bearing solutions or extremely acidic, basic, and/or saline solutions, will generally need to be underlain by a composite liner. Tailings impoundments that contain hazardous pore fluids may also need to be underlain by a liner system unless sufficient hydrogeologic containment can be demonstrated along with adequate seepage collection and monitoring systems. Liner systems may also sometimes be required for chemically reactive waste rock dumps in wetter climates unless sufficient hydrogeologic containment can be demonstrated along with adequate seepage collection and monitoring systems. Many types of nonmineral waste landfills will also require liners to allow capture and collection of leachate and landfill gases.

Composite liners are typically constructed with an underlying low-permeability, compacted clay layer and an overlying synthetic liner. Again, the actual design leakage rate of the liner system must be based on a risk assessment that takes into account the hazards posed by the liquid and its potential environmental impacts. If a higher leakage or failure rate is determined to be acceptable, then a composite liner may not be needed. Conversely, if the hazards posed by the fluid and the environmental setting are high, then a double or triple liner system with intervening leak detection and pressure relief layers (to minimize head on the lower liners) is likely to be needed.

Leach pads and other process circuits that contain large volumes of hazardous fluids should be designed for gravity flow into engineered process ponds and containment structures during power outages and other upset conditions. The capacity of these structures should be large enough to hold the maximum credible volume of the fluid that would be released by drain down before the upset condition could be corrected. In many cases, backup emergency power systems for pumps may be required.

If there is an uncontained spill, rapid spill response can minimize the environmental damage by limiting the volume of material released, the surface area impacted, and the exposure duration. Emergency response procedures for spill containment and cleanup should be developed and appropriate spill response equipment stored on-site. Typical spill response kits may include sorbent materials, neutralizing agents, drums, shovels, and appropriate personal protective equipment. At port facilities where spills onto open water are possible, spill response boats and booms may be maintained. Most operations should also maintain a trained spill-response team.

CONTAMINATED WATER MANAGEMENT

Mining operations can impact surrounding water resources and water-dependent ecosystems by (1) water withdrawal and dewatering impacts, and (2) the discharge of contaminated water. Surface and groundwater withdrawals to dewater the ore body or to supply operations can lower surrounding groundwater water tables, causing seeps, springs, and wells to dry up; harming groundwater-dependent vegetation and ecosystems; and reducing in-stream flow. If necessary, dewatering impacts must be predicted, monitored, and mitigated. Mitigation strategies may include

- Improving water efficiency through process and management improvements so that less water needs to be withdrawn,
- Intentional surface water discharge at key locations to maintain in-stream flow,
- Providing alternative water resources for impacted communities,
- Intentional recharge of groundwater to minimize drawdown impacts, and
- Construction of slurry walls and other subsurface flow barriers to minimize hydrogeologic connections.

Water may be discharged to the environment through centralized, engineered, and permitted discharge points; more dispersed, uncontrolled stormwater discharge locations; and/or uncontrolled subsurface flow. If the released water is contaminated, it may degrade down-gradient water quality, harming ecosystems, human health, and water resources. Water that contacts chemically reactive mineral waste is commonly contaminated, but poor-quality water can also be generated by ore-body dewatering, mineral processing, sewage discharge, recurring hazardous material releases, and outflows from pit lakes and underground workings.

As discussed in the earlier section on chemically reactive mineral waste, mine-impacted water typically poses risks

because of ARD, salinity, metals soluble at neutral pH, radionuclides, nitrogen compounds, and added reagents such as cyanide. In many jurisdictions, discharge limits are established by law, regulation, or permit for potential contaminants of concern. In such cases, water may usually only be released from designated outfall points and must consistently meet the mandated discharge limits. These limits are typically based on maximum concentration, average concentration weighted by flow and/or time, and/or mass loading. In other cases, discharge limits must be selected and justified based on site-specific data and conditions. In these circumstances it is important to understand not only the potential discharge water quality but also migration pathways and the assimilative capacity and sensitivity of the receiving environment. It is important to differentiate between impacts to receiving environment water quality and environmental harm. Discharged mine water may result in measurable changes in solute concentrations in receiving water bodies without causing environmental harm. For example, metals concentration may measurably increase, while the ambient concentration remains well below threshold values for protection of aquatic ecosystems and quality of drinking, stock, and irrigation water. It is also important to consider cumulative impacts to the receiving environment. If multiple mines exist in a single drainage basin, the cumulative impact of all mine discharges must sometimes be considered.

Discharge water quality and volumes partly depend on the innate geology and climatic setting of the ore body being mined. However, mine and process design and management can also have a profound influence on the quality and volume of water that must be managed. The water and solute balance should be predicted and monitored during mine design, operation, and closure. These data can be used to select appropriate water management strategies to meet discharge limits and protect down-gradient water quality.

Water treatment before discharge can be costly, sometimes exceeding several dollars per 1,000 L. At large mines with significant ARD flows, cumulative treatment costs can be measured in the tens to hundreds of millions of dollars. Implementation of internal proactive management strategies that reduce the volume of water that must be treated and/or reduce the solute load in the water can be cost-effective, as well as ultimately more protective of the environment. The strategies discussed previously to minimize water contact with, and solute loading from, mineral wastes are a key component of overall site water quality management. Other broad internal water management strategies include the following.

- **Water diversion:** Capture and diversion of clean surface and groundwater flows up-gradient of the operation can limit the volume of water that may be contaminated by contact with the operational footprint.
- **Water segregation:** Within the footprint of the operation, careful segregation and separate handling of waters with different qualities can limit the volume of water that ultimately requires treatment. Clean stormwater can often be discharged without treatment if its quality is preserved. Unless needed as makeup water, precipitation and stormwater should generally be isolated from process water circuits, reactive mineral waste, hazardous materials, and contaminated areas.
- **Recycling and reuse:** Internal recycling and reuse of poor-quality water can reduce the volume of makeup water that must be withdrawn from the environment and allow beneficial use of poor-quality water, thereby reducing the volume of water that may need to be treated before discharge.
- **Improved water use efficiency:** Improvements in water use efficiency can also reduce the volume of water that must be imported into the operation and that ultimately must be discharged.
- **Reagent management:** Process water quality can be improved by the efficient use of reagents and/or replacement of hazardous reagents with less hazardous but equally effective substitutes.
- **Safe on-site storage and controlled release:** If sufficient safe water storage capacity exists on-site, mine water can sometimes be discharged without treatment at rates and times that can be assimilated by the receiving environment. For example, saline waters can be stored on-site during the dry season and discharged during peak storm-related runoff events, when natural salinity is low and in-stream flow is highest.
- **On-site evaporation:** Evaporative losses within the footprint of the operation will reduce the volume of water that must be discharged. Natural evaporation from storage ponds and tailings dams can be a significant source of water loss in some climates. Evaporation can be enhanced with simple sprinkler systems, and in some extreme situations energy intensive crystallizers may be used. Although evaporation can be effective for reducing the volume of water that must be managed, it does not remove soluble salts from the system and will ultimately produce saline solutions or soluble solids that must be managed.

In humid environments it is likely these proactive water management strategies will reduce but not eliminate the need to discharge water. However, mines in arid and semiarid climates may maintain a negative water balance because of evaporative losses, entrainment losses to shipped product, and long-term storage within tailings. The water balance implications of any significant operational changes such as new ore-body development, new processes, or footprint expansion must be carefully assessed. It is also important to distinguish between operational water balances when mining and processing activities may consume water, and postclosure conditions when these water sinks are no longer available.

In many cases, water treatment before discharge will be required. At a minimum, most mining operations will need to control sediment discharge via on-site erosion control and the use of settling ponds. Sewage treatment facilities will usually be required unless operations are connected to a municipal treatment system. Oil water separators are also likely to be needed to capture fuel, oil, and grease from refueling stations and maintenance shops. Mine waters that have been impacted by ARD, salinity, metals soluble at neutral pH, reagent addition, or other contaminants may require additional treatment before they can be discharged. Numerous mine-impacted water treatment technologies exist for different contaminants of concern. These technologies are too numerous to discuss in detail here, but many good summaries are available in the literature (Brown et al. 2002; Younger et al. 2002; INAP 2009). The various treatment technologies are most commonly designed to neutralize acidity and raise the pH, remove metals from solution via precipitation or adsorption, or remove salts from solution by membrane-based or ion exchange technologies.

Neutralization and metals precipitation is most commonly accomplished by the addition of alkaline materials such as lime,

limestone, and soda ash, but many other viable technologies are available. In some situations, multiple technologies must be used in sequence such as neutralization to raise the pH and remove metals from solution, followed by flocculation and filtering to remove fine total suspended solids and then reverse osmosis to remove dissolved salts. Treatment systems may be either active or passive. Active systems usually require extensive infrastructure, electrical power, and continuous staff involvement for operation and maintenance. They are usually required for large flows of poor-quality water that must be discharged from active mines. Passive systems generally do not require continuous reagent and energy inputs or operator involvement and so are appropriate at some closed operations and remote sites. However, passive systems are commonly only viable for smaller flows (typically less than 10 L/s), for water that is only weakly contaminated, or as a polishing step for water pretreated with an active system. Common passive treatment systems include wetlands, aeration and settling ponds, and anoxic limestone drains.

The water treatment systems that are selected and used should reliably meet the discharge water quality criteria in the most cost-effective manner. Keys variables that should be considered during the selection process include

- Initial water quality and its variability;
- Required discharge water quality;
- Volume and variability of flow that must be treated;
- Operational versus closure requirements;
- Capital, operations, and maintenance costs;
- Regulatory requirements;
- Reliability of the technology;
- Power, labor, and footprint constraints; and
- Solid waste (generally sludge) management requirements.

Contaminated water with high solute concentrations can generate large volumes of sludge. Although commonly overlooked during initial analysis, the costs and technical challenges to manage water treatment sludges can be significant.

CONTAMINATED SITES MANAGEMENT

Unplanned releases of hazardous materials will typically lead to the contamination of soils, sediment, groundwater, and/or surface water. Historic waste and hazardous materials management was generally less rigorous than current practices, so contaminated sites are most likely to exist at older mines and at new mines in historic mining districts. Common historic contaminated sites at mining operations include leaking underground storage tanks; locations of recurring spills such as refueling areas; historic landfills and waste storage areas; old mineral processing, smelting, and refining sites; and chemically reactive mineral waste repositories. Common contaminants of concern include hydrocarbons, chlorinated solvents, PCBs (polychlorinated biphenyls), asbestos, acids, and metals such as arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, and zinc.

Many jurisdictions have clear guidance on acceptable levels for these contaminants in soils, sediment, and water. When available, the appropriate local screening or investigation levels should be used. These criteria are generally derived from simple exposure models with conservative assumptions to protect human health, plants, and animals. Concentrations above these screening levels will generally trigger further remedial, management, or administrative actions to control the risks to human health and the environment. The appropriate criteria must be selected based on the media, the environmental setting, and the potential receptors requiring protection. Examples include standards for drinking water and the protection of aquatic life; and guidelines for stock and irrigation water, animal feed, and soil and sediment cleanup. Because the screening levels tend to be conservative, in some cases the cost and time required to derive site-specific criteria through a formal ecological or human health risk assessment process may be justified.

If current or potential future exposure risks are determined to be unacceptable, then remediation or management strategies (corrective actions) will need to be developed and implemented. Consideration should be given to stakeholder expectations, legal requirements, and the land's planned final use when defining remedial objectives. Corrective actions should then be selected to meet the environmental objectives in the most reliable and cost-effective manner. Only strategies that will consistently meet or exceed local regulatory or permit requirements should be considered. In some cases, more aggressive but more costly remediation strategies may be justified if they will raise the final value of the land or provide significant additional environmental or reputational benefit. Corrective action selection and refinement should be an iterative process with a range of potentially viable strategies assessed before the optimum strategy or combination of strategies is selected. Common general remediation and management strategies include those discussed in the following paragraphs (modified from Rio Tinto 2008c).

Removal Actions

Contaminated soils and sediments can be removed and transported to an engineered repository or treatment facility where the contaminants are neutralized or destroyed. Removal actions typically have a cleanup target in which all contaminated soils or sediments over a certain concentration are removed. The cleanup goals are typically based on the final assumed land use, such as industrial/commercial uses, which typically allow the highest residual concentrations to be left in place, and residential land uses, which usually require the lowest. Open space, wildlife habitat, or grazing and agricultural lands will typically (but not always) have intermediate values.

In-Situ Treatment

Some exposed or near-surface contaminated soils may be remediated in place without excavation and transport. Examples of such in-situ treatment techniques include

- Lime application to neutralize acidity and limit metals bioavailability and mobility,
- Application of nutrients or microbiota and mixing to accelerate the biological degradation of organic contaminants such as hydrocarbons,
- Air sparging and soil vapor extraction for removal of volatile compounds,
- Application of oxidizing agents to treat cyanide spills, and
- Bioremediation with plants that extract metals from the soil and can then be harvested.

Capping in Place

Contaminated soils can be capped with clean fill, soils, and impermeable layers (such as compacted soils, synthetic liners, asphalt, and concrete). Capping can serve several purposes, including

- Preserving runoff water quality;
- Controlling the dispersion of contaminated soils by wind, runoff, or tracking;

- Eliminating direct exposure risks to animals and people from contaminants exposed at the surface;
- Limiting plant contaminant uptake and subsequent exposure risks posed to browsing and grazing animals; and
- Limiting infiltration and subsequent contaminant migration to groundwater.

The cap must usually be designed to meet the environmental objectives for the long term because the contamination is left in place.

Groundwater Remediation

Contaminated groundwater may be remediated through a variety of pump and treatment systems, by in-situ treatment technologies, or by other subsurface control systems such as reactive barriers to control contaminant migration. Pump and treat systems typically involve either removal of the most contaminated portion of the plume (to remove the contaminant source) or capture of the leading edge of a migrating plume (to control its movement). Pump and treat systems for hydrocarbon contamination are usually focused on the removal of free phase product that is floating on the surface of the water table. Examples of in-situ treatment technologies for groundwater include injection of alkalinity to neutralize acidity; air sparging and vapor extraction to remove volatile organic compounds; and the addition of oxygen, microorganisms, and/or nutrients to promote biological degradation. Groundwater remediation will usually continue until water quality meets applicable criteria for drinking water, aquatic life, irrigation water, or stock water.

Groundwater Flow Control

The flux of contaminated groundwater may be reduced so that contaminant loading into and concentrations within down-gradient aquifers or surface water bodies remain within acceptable levels. Controls may include

- Impermeable covers that limit infiltration to groundwater through contamination in the vadose zone,
- Impermeable subsurface barriers that divert up-gradient flow around the contamination, or
- Impermeable subsurface barriers that divert down-gradient flows away from sensitive receptors.

Land-Use Restrictions

Exposure risks to people and animals may be controlled by establishing long-term land-use restrictions such as prohibitions against residential development and farming or fencing to keep even incidental visitors out. Areas where contaminated soils are capped in place will typically require restrictions against development or uses that could breach the cap and re-expose the underlying contamination. In some countries, long-term land-use restrictions may be difficult to enforce.

Natural Attenuation

Many organic contaminants such as solvents, hydrocarbons, and cyanide will degrade with time after they are released to soils, sediment, or water due to oxidation and biological activity. Acidic waters may be neutralized through mixing with more-alkaline waters or reaction with aquifer materials, and dissolved metals may be removed from solution by sorption and precipitation. Down-gradient mixing and dilution will also limit contaminant concentrations below the point of release. If these natural attenuation processes are identified and quantified, it may be possible to justify no further action other than long-term monitoring, if allowed in the local jurisdiction. However, generally, a rigorous evaluation will be needed to demonstrate that impacts to important receiving environments and receptors will remain within acceptable limits throughout the natural attenuation process.

In all cases, some form of post-remediation sampling or monitoring is generally required to ensure that environmental objectives are being met. For removal actions, this typically involves short-term sampling immediately after the excavation has been completed to confirm residual contaminant concentrations are below the target values. If natural attenuation is selected, then long-term monitoring will generally be required to ensure that contaminant concentrations in the affected media are declining at the rates predicted and that receiving environment criteria are being met.

CHAPTER 16.7

Closure Planning

Evelyn L. Jessup Bingham

INTRODUCTION

In recent years the minerals industry has recognized the importance of sustainable, integrated closure planning. Because of the finite nature of ore bodies, all mine and related facilities will eventually close, and the reputation of the industry is very much dependent on the legacy it leaves. Whether a facility has 10, 20, or 50 years of operational life remaining, integrating closure planning into the mining and metal processing business can result in value for both the company and the wider community.

Activities associated with mineral resource development have a significant impact on the social and environmental aspects of a site. Any site disturbance, even in the early stages of a project, creates a legal and financial closure obligation for the mining company. Communities, governments, and lending institutions are more and more aware of the benefit of good closure planning and demand it as part of the permitting process for new or expanded operations.

Closure of an asset, be it a mine or mineral processing facility, is generally not straightforward and requires dealing with the uncertainty of future conditions and events concerning commodity prices, stakeholder demands, regulatory requirements, environmental conditions, and ore grade. Ideally, closure is carefully planned and occurs with the exhaustion of the mineral resource, but it is not uncommon for closure announcements to come suddenly with the fall of commodity prices or some other unplanned event. Risk-based closure planning is inclusive of such uncertainty.

Closure of an asset is a process that works toward an end point that can be referred to as completion. Planning for a successful closure is a complex, multi-disciplinary task that is essential to minimizing long-term risk for the mining company, the environment, and affected stakeholders.

CHAPTER ORGANIZATION AND APPLICABILITY

This chapter is intended to provide basic practical guidance on closure planning. The information presented should be considered just a first glimpse of the wide-ranging discipline of closure planning.

In recent years a number of comprehensive and specialty documents have been created by governments, industry associations, and nongovernmental organizations (NGOs) on the subject of asset closure planning and financial assurance, such as those available through the International Council on Mining and Metals at www.icmm.com.

The core information provided in this chapter includes a number of practical tables and lists of information that have been found to be useful for closure planning practitioners who are creating or reviewing best-practice integrated closure plans.

After a brief overview of closure planning issues and a description of what integrated closure planning means, a set of principles for creating a framework for closure planning is presented. Following this, the steps involved in closure planning are outlined, and detailed components of an effective closure plan are described according to the closure planning steps. Also presented are a number of common risks to be considered in closure planning. Lists of this type are often useful in preparing for closure risk assessment workshops with a multi-disciplinary team to assist in the completeness of the review. Finally, a checklist is offered, showing how the detail and contents of a closure plan can change through the life cycle of a mineral resource development project.

The chapter content is applicable to a wide range of facilities and activities including mines, processing facilities, and greenfields and brownfields projects. The concepts and tools are appropriate for creating a closure plan for the first time or reviewing an existing closure plan.

COMPLETING THE ASSET LIFE CYCLE—CLOSURE PLAN OBJECTIVES

A successfully completed closure process is one in which the land affected by the asset has been rehabilitated to a sustainable condition. Ideally, in this completed state, the mining lease ownership has been relinquished by the mining company to another land user with minimized continued liability. This sustainable completed state can only be achieved through careful and informed planning over the long term. Closure planning is the responsibility of the mining company, but it cannot be done in a vacuum. Mining companies must involve governments, the communities of which they are part, and

Evelyn L. Jessup Bingham, Group Manager, Closure & Waste, BHP Billiton, Melbourne, Victoria, Australia

other stakeholders in closure planning to achieve a successful closure outcome.

Increasingly, financial institutions lending capital to mineral resource development projects set a high standard for asset closure planning as they seek to maximize value from the project and minimize risk. These institutions have learned hard lessons from the past where poor operational closure practices have resulted in ongoing legacies of water pollution, safety and health hazards, and the resulting public outrage and continuing liabilities. Many countries have specific regulations concerning closure planning and completion. Currently, however, there is no overarching world governance body covering mine and mineral processing facility closure, and there are still areas in the world where closure regulation is minimal or nonexistent.

External mining stakeholders such as local communities, conservation groups, and biodiversity advocates are becoming more and more sophisticated about the outcomes of good and bad closure planning practices. Given the opportunity, external stakeholders can become partners in closure planning, ultimately to the benefit of all.

Good closure planning toward the outcome of sustainable mine completion requires communication and engagement with stakeholders to develop agreed-on closure plan objectives, which should include the following:

- Comply with regulatory requirements or industry-leading practice where local regulatory requirements are insufficient to manage risk.
- Protect public health, safety, and welfare over the long term.
- Maximize environmental sustainability.
- Mitigate socioeconomic impacts during and after closure.
- Provide a reasonable basis for estimating and managing closure costs.
- Minimize costs for the mining company, the government, and the public.
- Achieve sustainable land-use conditions as agreed with stakeholders.
- Enhance the reputation of the mining company as a responsible corporate citizen, and ensure that shareholder value is preserved.

Timing and how these objectives are achieved through the life of the asset life cycle is very site specific. Certain types of mines (such as porphyry copper deposits and other hard-rock mines) and mineral processing centers may not allow for any concurrent or progressive rehabilitation or reclamation (for the purposes of this chapter, *reclamation* and *rehabilitation* are used interchangeably) during the operating phase because the disturbed areas (such as the open pit, tailings impoundment, waste dumps, and concentrator buildings) are in constant use during the operations. Assets of this type may spend many decades planning for closure activities that will occur at the end of the asset life.

Coal mines, on the other hand, generally have the opportunity to execute and obtain sign-off on rehabilitation through the life of the asset. However, even projects conducive to progressive closure will face challenges associated with life-of-asset (LOA) plans changing as commodity prices go up and down. It is not unheard of for coal mines to have to dig up or cover over well-established rehabilitation because coal seams once thought uneconomic are now scheduled to be mined.

Economic conditions going in the other direction more commonly present a serious obstacle to sustainable closure planning and ultimate completion of the closure process. A downturn in commodity prices usually results in a lack of resources for progressive rehabilitation (if the mine continues to operate) and for closure execution if sudden closure of the asset is announced.

To minimize the ups and downs of economic cycles and resource availability, effort on the part of the mining company must be made to understand and forecast changing conditions that might affect closure planning and execution as well as possible changes in stakeholder needs. Closure plans must be adjusted through time and adequate resources allocated for difficult economic conditions. Postmining land use and other objectives may need to change according to changes in the LOA plan and external factors.

INTEGRATING CLOSURE PLANNING FOR EFFECTIVENESS

A mining company's commitment to good closure planning practices will pay off in reduction of liabilities for the company and improved reputation with stakeholders. In the past, closure planning has often been a stand-alone activity in the business, usually done as a one-time effort to meet a regulatory obligation.

It is not uncommon for the asset closure plan to be the responsibility of the environmental function at a site while the LOA plan is the responsibility of the mine planners and the updates to the closure financial provision are handled by the accounting department, whose focus is on meeting accounting guidelines. A lack of communication between these various departments can cause the closure plan scope and details to fall well behind the inevitable updates to the LOA plan and the closure provision carried on the books to be out of date with both.

To address closure planning issues and meet business objectives to manage risk, it is necessary to ensure that closure planning is fully integrated in the core business of the asset. As business conditions change, LOA plans change, and so must the closure plan change. Additionally, the detail and accuracy of closure plans must change through the life cycle of the asset—starting out as conceptual and progressively becoming more detailed over time. Finally, as regulations and stakeholder expectations change, the closure plan needs to change. Effective closure plans must be integrated in a number of levels including the following:

- Integration with the LOA and long-term business plan. The closure plan necessarily links past disturbance, current operations, progressive rehabilitation, and future disturbance planned until the end of asset life.
- Integration with external stakeholder affairs. A focus of closure planning should be engagement with the external stakeholders affected by closure. This will include working with the government, local community, and NGOs to understand their needs and concerns. Interaction with external stakeholders during closure planning not only results in compliance with regulations but also affords the development of robust closure criteria to support an acceptable end land-use and communities that are better prepared to support the company when it comes time for completion and lease relinquishment.

- Integration with all the relevant functional disciplines on-site. Closure planning and ultimately the execution of the closure project toward completion will involve senior management, human resources, project engineering, business improvement specialists, environmental managers, operations, planning engineers, community and external affairs, legal advisors, risk management, and finance; all are necessary for effectiveness. Commonly, the following key roles and responsibilities will be essential to the multidisciplinary team:
  - Technical services provide the engineering design, LOA plan, and rehabilitation plan.
  - Project engineers and cost specialists are responsible for cost estimates, design of necessary pilot tests, and execution by project management.
  - Environmental specialists are responsible for developing closure criteria and performance requirements working with government representatives to meet regulations.
  - Community specialists are responsible for stakeholder engagement and closure scenario building.
  - Finance and accounting personnel are responsible for provisioning and maintaining closure risk registers.
  - Management is responsible for setting key performance indicators and milestones for closure.

Integrated closure plans are developed, reviewed, and updated starting in the LOA concept phase and moving through prefeasibility, feasibility, execution, operation, and closure phases of a mineral development project. Throughout this lengthy period, integration in the key areas will increase the probability of a closure plan meeting the business objectives upon execution.

CREATING A MANAGEMENT FRAMEWORK FOR INTEGRATED CLOSURE PLANNING

In order to fully integrate closure planning in the business, a long-term commitment to a set of basic principles is necessary from senior management. Closure planning is not a one-time endeavor but one that takes place over many years or decades. The people involved in closure planning will come and go; however, if the company has adopted a framework of principles, closure planning can proceed and improve through the life cycle of the mineral development project.

The following basic list of principles should be considered and adjusted as required for adoption as a company "closure policy" to form a solid framework from which the closure planning team can work over time.

- **Framework Principle 1: Regular Review and Updates**
  - Closure plans shall be maintained throughout the life cycle of all mineral development assets.
  - Closure plans shall be reviewed annually in conjunction with the LOA planning process. Closure plans and associated cost estimates shall be revised when there is a significant change to the LOA plan, and when there are regulations or factors significantly affecting the closure plan and associated cost estimates.
  - Closure planning processes and closure plans and cost estimates shall be subject to reporting, audit, and governance procedures, particularly where there is a risk of material misstatement on financial reports or a significant effect on business decisions.

Table 16.7-1 Closure plan upgrades across life-cycle phases

Life-Cycle Phase	Closure Plan Class
Projects in study phase	Conceptual-level closure plan and cost estimate ±50% to 30%
Assets with >10 years life remaining	Conceptual-level closure plan and cost estimates, e.g., ±30%. Expectation of progressive improvement in uncertainty and cost estimates annual review.
Assets 10–3 years life remaining	Prefeasibility-level closure plan and cost estimates, e.g., ±20%. Expectation of progressive improvement in uncertainty and cost estimates annual review.
Assets with 3–1 years life remaining	Feasibility-level closure plan and cost estimates, e.g., ±15%.
Assets in closure execution or postclosure	Execution-level closure plan and cost estimate, e.g., ±10%

- **Framework Principle 2: Management of Business Risk**
  - Closure planning shall include an assessment of all risks associated with closure including, but not limited to, risks associated with
    - Postclosure liabilities;
    - External stakeholder needs, aspirations, concerns;
    - Deferral or delay in progressive rehabilitation during operations;
    - Uncertainty in environmental, regulatory, or community aspects;
    - Uncertainty in cost estimations;
    - Uncertainty in technical aspects of closure; and
    - Delay in closure execution.
  - The management of closure risk shall be developed in accordance with formal risk management standards and associated guidance approved by company management.
- **Framework Principle 3: Accurate Estimates of Cost**
  - Closure plans shall be prepared in accordance with project management principles and contain sufficient detail to determine the cost of closure to the extent necessary to manage closure risk.
  - Closure plans will be progressively upgraded according to the life-cycle stage of the mineral development project as shown in Table 16.7-1.
  - Environmental and engineering studies will be performed to increase the certainty of closure cost estimates as an investment comes closer to the need to execute the required closure activity.
  - All closure plans shall include an estimate of the provision for closure, in accordance with international accounting guidelines.

THE CLOSURE PLANNING PROCESS

Whether creating a closure plan from scratch for a greenfield project, exploration project, or simply reviewing an existing closure plan for a large, mature mining property, the steps in the closure planning process are essentially the same. The level of detail and effort required to develop the closure plan through this process will vary as a function of site-specific issues and the life-cycle phase of the project.

Sudden or unplanned closure due to a downturn in commodity price or other adverse business decision may call for an acceleration of this process and require such things as interim care and maintenance plans to be implemented while the closure execution plan is being finalized.

Workshop Approach

The process of developing and updating an integrated closure plan should take as much thought and effort as that dedicated to design and development of any significant project. The result of the closure planning, even in the early phases, has the potential to significantly affect the business and stakeholders. Closure planning sets the course for years of activities, and it involves the expenditure of material funds for studies and, ultimately, closure execution.

Because of the multi-disciplinary nature of closure planning, facilitated workshop sessions are useful at intervals in the closure planning process. An internal closure risk assessment workshop is useful in the beginning to set the context, agree on strategy, and explore risks.

Workshop sessions with external stakeholders can be effective in building relationships and obtaining input about expectations. If available, an expert in workshop facilitation can add significant value, keeping the participants on point, while enabling constructive brainstorming, debate, discussion, and challenge.

A single point of accountability, a team organizational chart, and a work breakdown structure and schedule should be developed for the closure planning team to refer to. This should be updated annually during the regular closure plan review.

Basic Steps in Closure Planning

Recommended steps for closure planning are as follows:

1. Set the context by reviewing background data regulations, LOA plans, environmental baselines, and previous closure plans. Review stakeholders and engage as needed to understand their issues. Review the current status of the progressive rehabilitation plan and implementation schedule to determine whether the LOA plan, progressive rehabilitation plan, and closure plan align.
2. Establish closure plan strategy and criteria including scope, objectives, assumptions, design criteria, and completion criteria. This sets the basis for all subsequent steps. It is essential that the closure team reaches agreement on the standards and strategy to efficiently complete the planning.
3. Assess risks and evaluate closure options. The closure risk assessment process forms the backbone of integrated closure planning, and therefore a standardized risk assessment process, such as that developed by Australia and New Zealand (AS.NZS 4360:2004), should be used. Involving the proper set of people with the detailed knowledge of the site is essential to identifying all the risk issues. Standard options analysis techniques that would be used on any large project involving significant costs should be applied to ensure sufficient rigor in providing the basis of the preferred closure plan.
4. Select a preferred closure plan from the option analyses to control closure risks at an acceptable level. This step is usually an iterative process with Steps 3 and 5, as cost estimate and the risk profile necessarily enter into the decision-making process. The preferred closure plan will be adjusted with changes to the LOA plan and other changes to the context and risk profile of the site as the annual reviews proceed over time.
5. Generate robust cost estimates for the preferred closure plan in accordance with sound engineering and project management principles. The engineering cost estimate serves as the basis for a number of subset estimates, including internal business investment valuation, accounting provision for financial statements and government financial assurance or bonding. Both deterministic and probabilistic estimates may be generated depending on the level of uncertainty. Probabilistic techniques such as Monte Carlo simulations may require specialist effort but can very effectively incorporate the uncertainty of such items as undefined contamination and cost fluctuation. As the site nears closure, specialist demolition, salvage value, and remedial experts will be required to establish the cost of an executable closure plan.
6. Establish an action plan for improvement. Effective integrated closure planning requires improvement in the knowledge base in preparation for the next review cycle and beyond. This will include further stakeholder consultation, engineering and environmental studies, site characterization studies, definition of existing contamination, and rehabilitation pilot testing. These actions may require allocation of significant resources, and therefore a formal action plan for improvement establishing schedule and budget is necessary.
7. Update the closure document and record management system. The closure plan process represents a significant investment in human and financial resources over many years. A readily retrievable archive of the process, the information used, and the decisions made is essential for annual reviews and audits.

COMPONENTS OF THE INTEGRATED CLOSURE PLAN

Table 16.7-2 provides a guide to the components of a typical closure plan organized by the high-level steps taken by the closure planning team. Because of the site-specific nature of closure planning, components will vary according to many factors. The list in Table 16.7-2 can be used in a number of ways: as a closure planning checklist, a table of contents for a closure plan, an update list during the annual closure plan review, or a closure plan audit checklist.

CLOSURE RISK

Assessing closure risk requires a systematic, structured evaluation. As mentioned, the risk assessment forms the basis of the closure plan and cost estimates. The focus of the closure risk assessment will be to establish an acceptable risk profile for the company and all other stakeholders upon completion of the closure project.

Materiality of risks will be an important consideration for the closure team to prevent the closure planning process from becoming bogged down in unnecessary detail. It is useful for the team to establish a materiality threshold at the beginning of the closure planning process as an assumption. This will depend a great deal on where the asset is in the life cycle, the class of closure plan (concept, prefeasibility, feasibility, etc.), and the overall magnitude of the closure plan.

For example, a closure team may decide that risk issues identified which have a worst-case cost of addressing less than $200,000 are not material to the process of updating a concept-level closure plan that will total more than $100,000,000. The closure planning team may record these lesser risks or review them in subsequent updates but not spend valuable time putting them through the full risk assessment and option evaluation process.

Table 16.7-2 Key components of an integrated closure plan

	Plan Component	Description and Comment
▶	**Closure Planning Step 1**	**Set the context.**
1a.	**Life-of-asset (LOA) plan summary and map**	The LOA plan is the basis of the closure plan. Additionally, the closure plan can affect the LOA plan when the cost and risk profile of the closure plan is considered. The LOA plan establishes the impacted area and scope of works to be decommissioned, rehabilitated, closed, and released. Summaries of the final configuration of pits, dumps, and plant areas are included in the closure plan. LOA plans necessarily change with changing economic conditions and changing technology. Closure plans should be fully integrated and updated with the LOA plan.
1b.	**Progressive rehabilitation plan summary and map**	Plans to rehabilitate areas of disturbance back to final configuration during the operating phase (prior to closure execution) are integrated in the closure plan. Progressive rehabilitation plans are integrated with the LOA plan and closure plan, and are reviewed annually. Expenditures for progressive rehabilitation are part of the operations budget and commonly are excluded from the closure plan and cost estimate. A significant closure planning risk is that progressive rehabilitation during operations falls behind schedule and unexpectedly needs to be completed as part of closure execution. Similarly, sudden closure (e.g., due to commodity price downturn) can result in a breakdown in the progressive rehabilitation schedule and an underfunded closure plan.
1c.	**Studies register—environmental, cultural, heritage, and biodiversity conditions**	A reference list of studies documenting conditions for the LOA plan footprint, pollutant management area, and regional area impacted must be established. Baseline studies and recent reviews of conditions are important in establishing closure criteria. In particular, incorporating the ongoing results of groundwater monitoring, surface water monitoring, and vegetation studies into closure planning is critical. Basis for remedial projects (current and forecasted) and their expected outcome should be reviewed regularly and factored into closure planning.
1d.	**Legal and corporate requirement register**	A register of regulatory/legislative mandatory government requirements that cover the environmental, social, financial, and legal aspects of the closure plan must be kept up-to-date and reviewed annually. These requirements vary significantly from country to country and site to site, and must be well understood as they become the basis for the absolute minimum criteria for the closure plan to meet. Site-specific permit requirements are specified. Legal commitments to joint-venture partners, financial institutions, or other entities affecting closure planning must be met. A register of company requirements, such as internal, environmental, or community standards and industry-leading closure criteria and practices, must be kept. Distinctions must be made as to which are considered mandatory (as in the case where a constructive obligation has been created by publicly indicating a standard higher than legislative requirements) and which are discretionary.
1e.	**Land and property ownership register**	A register summarizing the site land information impacted by the site disturbance should be created. Property boundaries, geographic information system data, lease arrangements, deeds, and related obligations must be clearly recorded and reviewed for their impact on the closure plan.
1f.	**Stakeholder analysis register**	External and internal closure stakeholders must be identified; known stakeholders' needs, concerns, and expectations must be assessed and considered. Requirements and community expectations in developing overall closure objectives and criteria for postclosure land use and cultural and heritage values must be evaluated. This register is updated as closure planning proceeds through the years to reflect current demographics and changing views as the stakeholder consultation and external affairs management plan (discussed further in step 6b) is implemented.
▶	**Closure Planning Step 2**	**Establish closure plan strategy and criteria.**
2a.	**Closure boundary and scope summary**	This may be a simple list and diagram of the key elements of the site, established by the multifunctional closure team after review of existing information. Establishing the boundaries of the closure plan may not be completely straightforward. The closure plan may or may not include such elements as a joint venture or contractor-run coal processing plant. A rail spur on-site may be included in the closure plan at one site, while another site's third-party-owned railway passing through the site is not included. Intangibles such as the human resources severance plans or a company-sponsored community support trust are to be key elements recorded and clearly included, or not included, in the closure plan to avoid confusion and errors in closure provisions as time goes on.
2b.	**Closure strategy, objectives, and assumption documentation**	Site-specific high-level vision, strategy, and objectives, followed by a more detailed listing of supporting assumptions (e.g., target closure date, costing basis in-house or contractor), should be established. These are updated as needed during the annual review to reflect any changes in stakeholder and company requirements. The materiality of risks should be established for consideration in the risk assessment for the rest of the closure process.
2c.	**Closure criteria register—design criteria and performance indicators**	Determining closure design criteria and performance indicators is an interactive process that takes form as the closure team proceeds through the risk assessment and closure options analysis. Examples of specific criteria include depth of topsoil, minimum requirement for slopes to control erosion, and storm criteria for sizing water management structures. The specifics of these items will vary depending on where in the life cycle the asset is, starting out as conceptual when closure is many years away and becoming very specific during the closure execution and postclosure monitoring phase. The closure criteria register should provide a high-level summary of rationale and references for how the criteria were determined (e.g., reference to international engineering standards, site-specific risk control basis, local regulatory mandate).

(continues)

Table 16.7-2 Key components of an integrated closure plan (continued)

	Plan Component	Description and Comment
▶	**Closure Planning Step 3**	**Assess risks and evaluate closure options.**
3a.	**Closure risk register**	The closure plan can effectively be thought of as a set of risk control measures. Documenting the output of the formal detailed assessment of all business, environmental, and social sustainability aspects and risks of closure is critical to the closure planning process. It is essential that risk assessments are reviewed and updated annually or whenever there are major changes in the LOA plan or regulatory requirements. The risk register should document the full range of closure risk, risk rating, and enough background information to enable efficient review and communication for audit. The risk register also serves as the basis of the annual closure plan review. Table 16.7-3 provides a list of examples of common closure risks and the associated closure plan controls.
3b.	**Closure opportunities register**	While risks associated with closure are usually the primary focus of the closure planning team, it is important to identify and develop any closure opportunities. Postclosure land uses for the large expanses of land typically involved in a mining property should be explored. Industrial parks, emerging carbon sequestration techniques, alternative energy (such as solar and wind power generation stations) may present economic development opportunities. Timber, agriculture, and grazing may be appropriate. Biodiversity preserves and wildlife conservation areas are postclosure land uses that may present long-term opportunities. The community or regional government may have an interest in using infrastructure such as roads, bridges, power plants, and warehouses after operations have ceased. The capacity of a third party to manage these facilities needs to be carefully gauged prior to the release of the infrastructure. It is not uncommon for the mining company to find the liability coming back unexpectedly if the recipient of the infrastructure finds itself unable to bear the maintenance or operating costs. Other common opportunities to evaluate include third-party reprocessing of low-grade ore stockpiles prior to rehabilitation, recovery of metals from postclosure water treatment, and revenue created by salvage value during demolition. Closure opportunities assessment should be evaluated and documented in the same manner as downside risk.
3c.	**Closure option analysis summary**	As the closure team works through the evaluation of risks and opportunities, various closure plan options will be generated. Formal and informal options analysis will be required to choose the preferred set of activities that become the updated closure plan. As options are considered, objectives and criteria may need to be adjusted, data gaps may be identified, and the interactive nature of closure planning becomes apparent. Concisely documenting options considered will make subsequent reviews and updates more efficient.
▶	**Closure Planning Step 4**	**Select preferred closure plan.**
4a.	**Postclosure land use and final landform plan**	Postclosure land use will be developed and agreed upon with relevant stakeholders (both internal and external) and as the result of risk assessment and options analysis. The postclosure land use will have a significant effect on the final landform plan, and both are tied to developing an acceptable postclosure risk profile. Examples of this interaction include reducing erosion risk, where final landform slope angles are minimized; establishing self-sustaining vegetation, where landforms are designed to promote or discourage access for timber or grazing activities; or achieving flora and fauna biodiversity goals. More than one postclosure use may be compatible at the same site, such as a solar panel installation on a rehabilitated waste dump, which may work well with managed grazing. Conversely, postclosure land uses may be at odds with each other or pose unacceptable risk, such as managed grazing vs. biodiversity uses or access to water for grazing animals vs. public safety issues. Landform plans should reflect the postclosure public access situation. Re-contouring of land to deter public access where necessary may be possible in lieu of fencing that requires maintenance. Public safety and long-term environmental sustainability should always be an overriding consideration and must be worked through with applicable stakeholders. The final landform plan should include maps and other documentation that clearly show the final landforms and how they support the postclosure land use.
4b.	**Closure execution plan**	An adequate description and schedule of closure actions and activities are required. The level of detail included in the closure execution plan will depend on the class of closure plan (conceptual, feasibility, etc.), regulatory requirements, and the company's internal project management requirements. This plan is sometimes referred to as the annual closure plan update or preferred closure plan and commonly addresses all activities required for closure including • Infrastructure decommissioning; • Remediation of contaminated soils; • Water remediation; • Earthmoving, topsoiling, revegetation; • Social management—community and work force (training, economic development); and • Project management and administration. Attention to completeness is required, as this will provide the basis for the cost estimates. Supporting documentation may include organizational charts, work breakdown structures, and contingency plans. It is not uncommon for an asset to develop and mange multiple versions of a closure execution plan that contains varying levels of detail depending on the whether the audience is community stakeholders who want a high-level summary or the engineering functions needing the detailed plan.

(continues)

Table 16.7-2 Key components of an integrated closure plan (continued)

	Plan Component	Description and Comment
4c.	**Postclosure plan**	It is critical that a schedule of postclosure actions and activities be developed and updated. Following the initial phases of decommissioning and rehabilitation, the postclosure period continues until the mining lease is relinquished or the company is otherwise released of liabilities. This postclosure phase needs to be considered in the risk assessment process. Indeed, it can be a surprisingly lengthy and expensive phase, perhaps continuing into perpetuity at some older more problematic operation sites. Postclosure activities include long-term water monitoring, data analysis, and reporting to company and government. They also include maintenance of remaining facilities, such as fences, water treatment plants, and water conveyance structures; actions required to repair erosion; and other rehabilitation repairs. The project management and administrative activities required for the postclosure period must be included in the plan.
4d.	**Completion plan/mining lease relinquishment plan**	In most cases, one of the prime objectives of a closure plan is to meet the performance indicators set by government and other stakeholders and to obtain formal relinquishment of the mining lease and sign off that all company obligations are complete. Unfortunately, there are very few examples where this has been successfully accomplished. Developing a mining lease relinquishment plan in the early phases of mine life is intended to give clarity to the process and mechanisms required for completion of closure. Ideally, the plan is developed in conjunction with the formal approval body such as the state or federal government. Attention should be given to the fact that most governments around the world (in both developed and undeveloped countries) do not have adequate procedures to sign off on the relinquishment plan or officially release the company, even when it is clearly demonstrated that the closure criteria have been met.
▶	**Closure Planning Step 5**	**Generate cost estimates with sound principles.**
5a.	**Deterministic cost estimate and range analysis**	Cost estimates are made for the activities that constitute the selected closure execution plan. Typically, a deterministic range analysis estimating the range of costs of each activity is captured as line items in a spreadsheet. Cost estimates should follow the standard project management and engineering estimate procedures that would be undertaken for any large-scale, multimillion-dollar projects. It is useful to forecast expenditures for a 30-year period following the targeted closure date to see the larger, long-term picture and to ensure that all costs are captured to avoid underestimating the cost of closure. The closure team will need to review applicable government, accounting, and corporate requirements to decide if a deterministic cost estimate is a sufficient end point or if probabilistic modeling is required.
5b.	**Probabilistic modeling for expected cost of closure**	Probabilistic cost modeling, using various techniques including the Monte Carlo simulation method, can be very effective in managing the inherent uncertainty of closure cost estimates. Probabilities can be assigned to the cost range analysis, event risk occurrence, and timing of key aspects affecting present value calculations and the like. The results of a probabilistic cost model for closure may satisfy a number of government, accounting, and corporate requirements to report the "expected value" of closure that demonstrates an incorporation of risk management into to the cost estimate. The closure team will want to include the expert advice of probabilistic financial modelers as would be done for any large-project costing effort.
5c.	**Closure cost summary report**	The results of the base cost estimate (whether deterministic or probabilistic) will be manipulated for various purposes according to specific guidelines. The three most common types of closure cost estimates required are the following: • Business valuation. This all-inclusive cost estimate is used primarily for internal business decisions and follows company-specific investment standards. The closure valuation looks at the LOA disturbance (rather than existing disturbance), integrates progressive rehabilitation, and is usually adjusted to account for salvage value and tax benefits. • Accounting provision. International accounting standards are very specific for determining an acceptable provision to be declared in the mining company's financial statements. Review of current accounting standards by an accounting professional is necessary to ensure compliance with corporate government requirements such as the Sarbanes–Oxley Act of 2002 in the United States. Generally, provision calculations do not include salvage value, do not allow tax benefits to be recognized, and only address current reporting year current disturbance (rather than LOA disturbance). • Government financial assurance. Guidelines vary greatly country to country and state to state. It is critical that the closure team adequately reviews the site-specific regulatory requirements for calculating financial assurance. Progressive rehabilitation is most often treated as an operating cost and is not included in any of these closure cost estimates. Progressive rehabilitation is budgeted and tracked as any other operational expenditure according to local accounting guidelines. Discount rates are generally applied to all of the above cost-of-closure calculations. Assumptions made to determine present value may vary and should be carefully documented to avoid errors and confusion. Documenting assumptions made and guidelines followed to determine the reported costs of closure is important to avoid confusion in subsequent reviews and to provide a basis for internal and external auditing.
5d.	**Closure plan review and audit plan**	Regular, formal review of the closure plan and associated cost estimates are critical to keeping the closure plan accurate and effective for managing risk and liabilities and for making sound business decisions. An annual review by the closure planning team, integrated with the LOA plan update, should be scheduled and results documented. Review by an entity outside the closure team can be very helpful due to the complex nature of closure planning and the potential for errors in the risk-assessment process. This review can take many forms, including expert peer review, internal audit, audit by joint-venture partners, or consultant review. The scope and details of the internal and external peer reviews will vary with the level of site-specific business risk and where the mining venture is in the life cycle. As the site nears closure execution, detail reviews and audit of the closure plan and cost estimates become critical to managing business risk.

(continues)

Table 16.7-2 Key components of an integrated closure plan (continued)

	Plan Component	Description and Comment
▶	**Closure Planning Step 6**	**Establish an action plan for improving the closure plan.**
6a.	**Closure study plan**	A schedule of environmental and engineering studies and projects is required to systematically reduce the uncertainty in the closure plan. Examples include piloting wast dump covers, vegetation trials, groundwater studies, waste characterization, and community surveys. The closure study plan should contain sufficient detail on goals and objectives to be effective. The study plan should include estimates of human and cost resources required and should identify where the resources are budgeted.
6b.	**Stakeholder consultation and external affairs management plan**	A plan for engaging and informing stakeholders around closure issues should be prepared. Economic development for the community postclosure must take place over many years to be effective and should be explicitly addressed in the external affairs management plan. Additionally, planning is necessary to receive sufficient input on postclosure land use and sustainable development. Frequency and range of activity will change over time depending on the life cycle of the asset. Human resources and budgets required should be identified and scheduled.
▶	**Closure Planning Step 7**	**Update closure document and record management system.**
7a.	**Closure document and record retention management system**	Closure planning updates will take place over many years or decades and will be subject to audit and regular review. A formal system with accountability will need to be established for the short and long term. Information gathered during the closure planning process should be documented in a manner that allows easy access and change management. Particular attention to effective document retention is required in the postclosure period and following completion and lease relinquishment.

Table 16.7-3 Common closure planning risks

Type	Closure Risk Issue	Possible Causes	Potential Impacts	Example Controls
Safety and health	Worker injury during closure execution	Asbestos, exposure to hazardous materials, inexperienced demolition crew	Injury, loss of life, company reputation, financial loss, regulatory penalties	Effective health and safety, safety and change management program, use of qualified people
	Public injury postclosure	Subsidence of underground workings, open pits, high-wall failure, unsecured open voids, standing water	Injury, loss of life, company reputation, financial loss, regulatory penalties	Engineering design eliminating hazard, controlled access, public education, monitoring program, maintenance plan
Environment	Water contamination	Acid rock drainage, metal and salt seepage from waste rock/ tailings/pit/underground workings, hydrocarbon soil/water contamination from poor operations practices, water catchment overflow, erosion, pit lake water quality deterioration	Third-party legal action, extensive remediation postclosure financial loss, relinquishment delay, loss of company reputation	Long-term water monitoring programs, baseline data collection, preventive actions during operations, adequate closure design criteria
	Water balance, water management	Inadequate quantitative water balance, poor storm design criteria, climate change	Uncontrolled discharge, legal action, penalties, contamination flow off site, overflow or failure of dams, catchments, injury or loss of life, financial loss, loss of reputation	Baseline climate and water data studies, quantitative water balance inclusive of water quality issues, understanding of surface/groundwater interaction, proper storm design criteria, climate change risk analysis
	Air	Improper air pollution control during operation (dust/stack emissions), decommissioning activities, inadequate cover/vegetation, improper void management	Soil contamination off property, financial loss, third-party lawsuits, loss of company reputation, community complaints	Effective air control programs during operations and closure execution, monitoring cover design criteria

(continues)

Table 16.7-3 Common closure planning risks (continued)

Type	Closure Risk Issue	Possible Causes	Potential Impacts	Example Controls
Environment (continued)	Tailings and landform failure	Slope failure, visual impairment, soil loss, storm erosion, vegetation failure, fauna habitat impaired, unsustainable ecosystem, seismic stability	Water contamination, financial loss, nongovernmental organization and community complaints, loss of company reputation, delay in relinquishment	Adequate baseline studies, rigorous engineering criteria development inclusive of ecosystem considerations and stakeholder desires
	Tailings and waste disposal	Geochemistry of rock dumps, tailings. On-site disposal of hazardous waste, long-term stability compromised by seismic or erosion events, radiation isolation, unknown hazards in landfill	Long-term water treatment, financial loss	Adequate environmental impact studies, qualified expert consultation, engineering criteria development
	Failure of remedial plan or closure activity	Poor execution by third-party contractor, soil or water contamination more serious than anticipated, vegetation failure	Financial loss, regulatory penalty, delay in relinquishment	Due diligence of third-party contractors, appropriate indemnities and insurance, independent review of high-risk plans, adequate environmental studies, and pilot testing
Community	Employee	Union strife, management retention during decommissioning, rehabilitation, and postclosure	Company reputation, access to qualified employees for closure project and future projects	Redundancy/severance planning, training programs, incentives for retention/hiring qualified personnel
	Local community outrage	Loss of income, real estate devaluation, population decline, loss of tax base, unrealistic expectations of mining company viewed as "deep pockets," failure of third party to maintain infrastructure handed over postclosure, safety hazard postclosure	Socioeconomic disruption, poverty; relocation of population; loss of emergency, medical, and educational services; company reputation; access to new projects; financial loss; long-term liability returns to company	Proactive community planning over entire life cycle, economic development partnerships, education and regular information updates to external stakeholders on LOA plan
Financial and legal	Government requirements change	Current regulations not clear, changes over time, sudden changes with change in government party. Common considerations: pit backfilling, sulfate limits for water discharge, return to original contour, unacceptable postclosure land use	Closure plan inadequate, financial loss, inability to achieve completion	Engagement of government and nongovernmental organizations, monitoring of regulations, obtaining government sign-off incrementally, participating in industry forum, adjusting LOA plan as required (including consideration of early closure)
	Loss of reputation/ third-party actions	Contamination of surface water, groundwater, air; relinquishment of closed property to third party unable to provide proper care and maintenance; exposure to workers and public during operations and closure	Financial loss through payment of compensation, return of property and liabilities after relinquishment, loss of reputation, environmental penalties, and other statutory penalties	Thorough risk-based remediation, external review of third parties and appropriate sign-off, monitoring programs during operations in closure phase
	Inadequate provisioning	Failure to consider all possible risks/contingencies including tax consequences. Common shortfalls: long-term water treatment costs, soil remediation costs, lack of topsoil and cover availability, inadequate estimate of postclosure monitoring time period, inadequate project management, overestimation of salvage value	Financial loss, misstatement of financial report, poor business decisions	Use of standardized risk assessment processes throughout the asset life cycle, audit and other assurance activities, review by legal and tax experts, closure project planned and executed by project management professionals
	Sterilization of resource	Untimely execution of closure	Resource not available when commodity price rises	Use of standardized risk assessment to evaluate closure decision

Table 16.7-4 Life-cycle closure plan comparison checklist

Life-Cycle Phase	Concept Phase and Prefeasibility Study	Feasibility Planning and Execution/Project Construction	Operating Phase	Closure Execution Phase—Decommissioning and Postclosure
General considerations	Closure options are considered in these early study phases of an asset. If a study phase involves pilot testing, drilling, or other actual land disturbance, a closure plan is prepared to address any liabilities created.	A preferred conceptual closure plan for the asset is generally selected during the feasibility phase. As soon as construction of the mining asset begins, land disturbance is created and a closure plan and closure cost estimate should be in place and regularly updated to accurately reflect the closure liability as it is created.	Operation is usually the longest phase in the asset life cycle. A life-of-asset (LOA) plan is updated annually and addresses all closure liabilities by integrating the asset business plan, progressive rehabilitation plans, and closure activities to be executed at cessation of operations.	Following the announcement by management that operations have ceased, the closure plan becomes a project to be managed according to standard project management principles. The closure project does not end until relinquishment of the property has occurred.
Closure plan class	Preparation of a conceptual class of closure plan and cost estimate ±50% to 30% to support project evaluation. Expectation of progressive improvement in uncertainty and annual review of cost estimates. When asset has less than 10 years of life remaining, upgrade closure plan and cost estimate class to prefeasibility/feasibility level.		Transition to prefeasibility/feasibility-level closure plan and cost estimates, e.g., ±20% to 15%	Execution level closure plan and cost estimate, e.g., ±10%
1. Basic closure planning actions	The following applies to closure planning in all phases of the life cycle: ☐ Identify fatal flaws in operation plan that would prevent compliance as a result of closure. ☐ Identify information gaps, update plan, and schedule to rectify. ☐ Establish current government and other stakeholder requirements.			
2. Completion criteria and exit strategy	☐ Identify likely completion criteria. ☐ Outline completion strategy.		☐ Establish completion criteria and preliminary relinquishment sign-off process through studies and stakeholder engagement.	☐ Refine and implement relinquishment sign-off process.
3. Stakeholder engagement	☐ Establish stakeholder identification register. ☐ Identify stakeholder issues. ☐ Outline concept of how stakeholders are to be engaged.		☐ Prepare, maintain, and implement community relations plan that includes community consultation with respect to closure issues.	☐ Implement community relations plan focused on decommissioning, postclosure, and completion issues. ☐ Confirm community acceptance of closure actions for completion.
4. Closure risk management	☐ List closure risks identified in order of priority. Formally assess top closure risks to avoid fatal flaw issues.		☐ Conduct formal qualitative closure risk assessments. ☐ Establish and update a documented closure risk register.	
5. Closure plan cost estimate	☐ Document basis of closure cost estimates. ☐ Document use of deterministic and probabilistic methods used. ☐ Confirm that closure cost estimates are risk based and clearly tied to closure plan, i.e., expected value at the appropriate accuracy level for risk management.			
6. Government	☐ Prepare an overview of requirements.	☐ Generate a register listing requirements and high-level plan for compliance.	☐ Generate a register listing completion criteria requirements with plan, schedule, and cost for compliance.	☐ Obtain formal acceptance for and implement the relinquishment sign-off process.
7. Environmental baseline for issues affecting closure	☐ Identify baseline issues including preexisting contamination, sensitive ecosystems, and biodiversity.	☐ Implement baseline study plans fit for purpose. Compile information and use to plan for additional work as needed.		
8. Postclosure land use	☐ Describe current land use. ☐ Conceptualize postclosure land use for project and alternatives. ☐ Identify land tenure risks and issues for closure. ☐ Plan for additional information needed. ☐ Plan for stakeholder engagement on postclosure land use.	☐ Determine detailed land capability/postmining/postclosure land-use alternatives. ☐ Discuss postclosure land-use alternatives with stakeholder engagement. ☐ Prepare a preliminary LOA plan that includes postclosure land-use issues.	☐ Include postclosure land-use goals when LOA and closure plan are integrated into business. ☐ Progressively evaluate rehabilitation against final land-use status (species regrowth, fauna assemblages, etc.). ☐ Validate land-use status against closure completion criteria.	☐ Document how postclosure land-use goals are met.

(continues)

Table 16.7-4. Life-cycle closure plan comparison checklist (continued)

Life-Cycle Phase	Concept Phase and Prefeasibility Study	Feasibility Planning and Execution/Project Construction	Operating Phase	Closure Execution Phase—Decommissioning and Postclosure
9. Water management	☐ Describe current surface and groundwater status. ☐ List broad closure water management goals. ☐ Identify on-site and off-site water-related risks. ☐ Establish storm design criteria.	☐ Prepare a conceptual water management plan to address on- and off-site risks including • Surface and groundwater, • Impact on quantity, and • Impact on quality. ☐ Finalize landform drainage plan. ☐ Generate a preliminary monitoring plan. ☐ Assess on- and off-site risks. ☐ Determine postclosure goals including final use and completion criteria for dams and voids.	☐ Clearly define and document water completion criteria. ☐ Progressively update current water status report including • Surface runoff patterns, • Storm sizing criteria, • Aquifer delineation, • Surface and groundwater quality and quantity. ☐ Evaluate and validate status against closure completion criteria. ☐ Schedule and cost pollution prevention and remediation plans. ☐ Schedule and cost monitoring plans. ☐ Quantify final landform and drainage patterns (including creek diversions, dams, future flooding impacts).	☐ Implement closure water management, remediation plans. ☐ Decommission and/or rehabilitate any water facilities (wells, boreholes, dams, canals, diversions, etc.) that are not part of postclosure land use. ☐ Monitor and evaluate progress toward final hydrology and water quality completion criteria.
10. Plant/ infrastructure	☐ Identify major infrastructure and define footprint. ☐ Prepare a conceptual decommissioning plan including what infrastructure will remain in place postclosure.	☐ Summarize demolition and decommissioning quantities. ☐ Identify off- and on-site disposal needs. ☐ Establish rehabilitation plan for footprint and adjacent areas.	☐ Progressively update decommissioning plans and cost estimates. ☐ Monitor salvage value and adjust closure cost estimate as required.	☐ Perform decommissioning. ☐ Perform remediation if necessary. ☐ Monitor and evaluate progress toward completion.
11. Overburden/ rock piles, tailings dams, open-pit features	☐ Describe quantity and quality of material. ☐ Conceptualize alternative locations and forms identified. ☐ Conceptualize disposal and closure methods described. ☐ Quantify volumes. ☐ Quantify types including acid generation potential. ☐ Prepare topsoil stripping and management plan. ☐ Prepare preliminary LOA plan for dumps, tailings, pit features.	☐ Generate LOA plan to include • Final slope angles; • Structural safety defined for tailings and rock/ overburden piles; • Water and sediment control features; • Structural stability including settlement, subsidence program; • Facility closure and rehabilitation methodology (impoundment capping, revegetation, final void); • Topsoil and other cover material plan; • Rehabilitation schedule; and • Configuration.	☐ Revise and update LOA plan in conjunction with development of closure plan annually. ☐ Progressively monitor final voids (including borrow pits and quarries), and report against closure goals. ☐ Regularly address gaps found in integrated LOA plan, progressive rehabilitation plan, and closure plan.	☐ Perform rehabilitation. ☐ Perform remediation if necessary. ☐ Monitor and evaluate progress toward completion.
12. Waste and chemical management	☐ Identify types of chemicals used. ☐ Identify types of waste to be generated. ☐ Describe general management and disposal plan. ☐ Quantify chemicals. ☐ Quantify waste generated.	☐ Generate chemical spill prevention and management plan. ☐ Develop waste management plan. ☐ Develop spill prevention and response plan. ☐ Develop rehabilitation plan for on-site waste disposal facilities.	☐ Track waste generation and annual disposal capacity against plan. ☐ Quantify accumulation of waste on-site. ☐ Develop soil decontamination plans. ☐ Document disposal plans for cumulative waste over operating life and at closure.	☐ Implement soil decontamination plans. ☐ Implement closure waste disposal plan for project. ☐ Monitor and evaluate progress toward completion.

(continues)

Table 16.7-4 Life-cycle closure plan comparison checklist (continued)

Life-Cycle Phase	Concept Phase and Prefeasibility Study	Feasibility Planning and Execution/Project Construction	Operating Phase	Closure Execution Phase—Decommissioning and Postclosure
12. Waste and chemical management (continued)	☐ Identify gaps between generation and disposal capacity. ☐ Identify off-site disposal facilities.		☐ Within 3 and 5 years of projected management decision to close, finalize detailed closure waste disposal plan.	
13. Haul roads and access roads	☐ Identify road system. ☐ Identify roads to remain at closure and likely completion criteria. ☐ Conceptualize rehabilitation plan for roads.		☐ Formalize completion criteria for roads to remain at completion of closure. ☐ Develop progressively more detailed rehabilitation plan for roads. ☐ Perform progressive decommissioning of roads where feasible.	☐ Perform decommissioning and rehabilitation of roads that will not be retained. ☐ Configure roads to be left upon completion of closure for long-term use. ☐ Perform remediation if necessary. ☐ Monitor and evaluate progress toward completion.
14. Air quality management	☐ Identify baseline air quality status. ☐ Describe project risks including air contaminant impact off- and on-site at closure.	☐ Conduct baseline air monitoring to establish air quality key performance indicators. ☐ Prepare air-quality management plan for minimizing on- and off-site impact.	☐ Develop a mitigation plan for surface treatments and revegetation to reduce dust and odor in accordance with key performance indicators at completion.	☐ Complete surface treatments and revegetation to meet air quality key performance indicators at completion.
15. Underground workings	☐ Describe subsidence-control issues. ☐ Describe water management issues.	☐ Identify underground workings areas. ☐ Prepare LOA subsidence management and mitigation plans. ☐ Prepare LOA underground water management plans.	☐ Develop underground decommissioning plan. ☐ Develop long-term subsidence management plan.	☐ Implement project plan for decommissioning underground workings.

Closure risks are very site specific and must be assessed by a cross-functional team familiar with the site and issues. However, there are a number of risks issues that are commonly encountered. Table 16.7-3 may serve as a helpful guide to brainstorming site-specific closure risks.

LIFE-CYCLE CLOSURE PLAN COMPARISON

Table 16.7-4 provides a comparison of how the closure plan should change as the mineral development project moves through the life cycle from a study project and feasibility plan into the lengthy operating phase and ultimately to the closure phase. The table is not meant to be exhaustive but can be used to prompt discussion and develop a high-level checklist to ensure that closure plans contain the correct level of detail as the mineral development project progresses.

ACKNOWLEDGMENT

This chapter was drafted with the assistance of Gary Bentel, geotechnical manager, BHP Billiton.

PART 17

Community and Social Issues

CHAPTER 17.1

Community Issues

Robin Evans and Deanna Kemp

INTRODUCTION

> The excavation, refining and shipping of this ore to the smelters of Japan could bring great profit over the next 20 years to the shareholders of Rio Tinto–Zinc—at the cost of damage to the physical, social and spiritual well-being of Bougainville, which, until the mine came, was a peaceful and prosperous island. Moreover there is a danger that arguments over the ownership of the mine could cause political strife, even civil war, in this part of the South Pacific (West 1972).

In 1989, following a series of increasingly violent protests that included sabotage of power supplies and attacks on mine workers, Bougainville Copper Ltd. evacuated its work force from the Panguna mine located on Bougainville Island in Papua New Guinea. The operation was shut down at relatively short notice, with most equipment left in place, and has not operated since. In the year prior to the shutdown, Bougainville Copper was capitalized at US$1.5 billion (Humphreys 2000), and the operation represented one of the world's largest open-pit mines. In the ensuing years, the civil unrest developed to a full-scale conflict between the Bougainville Revolutionary Army and the Papua New Guinea Defence Force that devastated the island, with several thousand deaths and approximately 50,000 people (a third of the island's population) displaced from their homes (Regan 2001). A peace process that commenced in 1998 between the government and local communities has returned some calm to the island, but the events that surround the abandoned Panguna mine remain the most vivid and tragic example of community conflict surrounding a major mining operation.

The underlying causes of the conflict that erupted on the island were many and complex: they included ethnic differences and the emergence of a secessionist movement prior to the transition of Papua New Guinea from Australian administration to full independence in 1975. The mine became a catalyst, with community concerns about the distribution of economic benefits and the environmental impacts of mine waste on the local river system featuring prominently. According to Denoon (2000), for many of the landowners "Panguna was a social, economic and environmental disaster, and a spur to militant protest."

Mines and the communities they are associated with have always been inextricably linked via a complex network of relationships and issues such as these. Local community members usually form part of the work force at a mining operation, while others in the area supply goods and services. At the same time, individuals, families, and sometimes whole communities can be displaced by the development of a mining lease, while some may be affected by environmental impacts associated with an operation. Community livelihoods can be impacted both directly by land-use changes, and also by changes within local social structures. While safety standards in the industry have improved significantly in most areas, there is a history of workplace accidents and health issues that remains an important factor in the relationship between mining companies, work force, and communities. In some locations, operations can be in competition with parts of the community for scarce resources such as productive land and/or water. In others, mining companies are welcomed as an agent of development that can bring infrastructure, essential services, and economic opportunities to a region. In most cases there is a continuum of views held about proposed or existing mining operations.

The balancing of the benefits and costs of mining operations for local and regional communities has attracted debate for centuries: "Thus it is said, it is clear to all that there is greater detriment from mining than the value of the metals which the mining produces" (Agricola 1556). While Agricola himself went on to staunchly argue the case for the 16th-century mining industry, others have taken more critical positions when considering modern operations. Notwithstanding the resilience and intrinsic strengths of some mine-affected communities for dealing with changes and transformations brought about by mining, there are often power disparities between mines and many remote, rural, and/or indigenous communities (e.g., Banerjee 2001). Compared to companies,

Robin Evans, Senior Research Fellow, University of Queensland, Sustainable Minerals Institute, Centre for Social Responsibility in Mining, Brisbane, Australia
Deanna Kemp, Senior Research Fellow, University of Queensland, Sustainable Minerals Institute, Centre for Social Responsibility in Mining, Brisbane, Australia

communities usually have more limited access to information, knowledge, technology, and capital that can be leveraged to shape the nature and pace of mining development. Such disparities have been the primary driver for the increasing involvement of rights-based nongovernmental organizations (NGOs) that have seen international campaigns launched against companies or particular projects when grievances escalate. The boom/bust nature of the industry adds another dimension to the debate about whether mining brings positive or negative change, with mining's contribution to development challenged by "resource curse" theories.

In short, the issues associated with interactions between mining companies and communities have become more prominent, and have increasingly required more attention from those associated with managing resource companies and mineral operations. Those working in the industry are increasingly required to respond to "community issues" in ways that their predecessors were never expected to. It is also likely that many technical staff who get involved in social aspects of mining have little training or prior experience in these issues. The purpose of this chapter is to provide an introduction to the types of social and community issues involved with mining, and the contexts in which they could emerge. It explores what is meant by the term *community*, and also reviews how community issues have increasingly been investigated in the last 20 years, particularly through projects such as the Global Mining Initiative (GMI). Subsequent sections explore more systematically the contextual factors that influence community relationships, and also the types of impacts that attract most attention. More detailed chapters follow this overview and address specific themes in more detail, including indigenous peoples and mining projects, and specific processes to assess and manage social impacts.

WHAT IS "COMMUNITY"?

The concept of "community" is usually used in the minerals industry to describe those who live in the geographic region of an operation, either in defined settlements or dispersed settings. However, there are other equally valid ways to consider the term, especially as modern industry practice has moved to include a greater incidence of fly-in/fly-out arrangements whereby workers and their families live in a distant location. Another relevant example is where traditional owners of the land associated with the mining development have maintained their links to the land but reside elsewhere. In such cases, community impacts can occur many hundreds of miles from an operation. Mining projects often include transport infrastructure and supply chains that span large distances, connecting networks of mines, processing centers, and ports, significantly increasing the range and types of other potential community impacts. There are also many different definitions of community that are not geographically based, such as communities of practice and spiritual communities. However, the mining industry tends to emphasize physicality and proximity to an operation, either spatially or by issue. Leading industry practice acknowledges that communities are complex, evolving, political, and heterogeneous entities (DITR 2006). In 2005, the Australian Ministerial Council on Mineral and Petroleum Resources (MCMPR) defined community as

> a group of people living in a particular area or region. In mining industry terms, community is generally applied to the inhabitants of immediate and surrounding areas who are affected by a company's activities.
>
> The term *local* or *host* community is usually applied to those living in the immediate vicinity of an operation, being indigenous or nonindigenous people, who may have cultural affinity, claim, or direct ownership of an area in which a company has an interest.
>
> *Affected community* refers to the members of the community affected by a company's activities. The effects are most commonly social (resettlement, changed services such as education and health), economic (compensation, job prospects, creation of local wealth), environmental, and political.

A community is usually a diverse group of people with some common bonds. Diversity can come in the form of gender, ethnicity, religion, race, age, economic or social status, wealth, education, language, class, or caste. As a result, members of any community are likely to hold diverse opinions about a mining operation and its activities, as well as most other subjects. As mentioned earlier, individuals within a community will have different and sometimes overlapping associations with the mine as neighbors, employees, suppliers, and so on. It is not uncommon for disagreement and sometimes conflict to develop between different sections of a community in relation to mining operations. To different degrees, conflict will also exist within a community prior to the start of mining, from low-level tension to violent conflict. Some companies choose to operate in conflict or postconflict zones, which will involve yet another layer of complexity to the process of understanding the local community.

More recently, the term *stakeholder* has become a common term that is related to but distinct from *community*. The idea that business has responsibilities broader than its traditional role of generating a return for shareholders is reflected in stakeholder theory, popularized by Freeman (1984) in his seminal work, *Strategic Management: A Stakeholder Approach*. This theory holds that successful companies recognize that they have responsibilities to *stakeholders*, a term referring to any individual or groups who can affect or are affected by a corporation's activities (and where corporate responsibility extends beyond maximizing a financial return to shareholders). Stakeholder theory has not only been a powerful force in academic circles in terms of developing its own research tradition, but also in encouraging the corporate sector to see community concerns and aspirations as key considerations.

A common definition of stakeholders is "those who have an interest in a particular decision, either as individuals or representatives of a group. This includes people who influence a decision, or can influence it, as well as those affected by it" (MCMPR 2005).

Stakeholders might therefore include local community members, NGOs, governments, shareholders, and employees. The use of the term *stakeholder* has been contested on the basis that some communities are in fact *rights holders*—a stronger term than stakeholder—due to rights defined by relevant national or state law. For example, indigenous peoples in Australia with a recognized claim to an area have the right to negotiate under the Native Title Act (Commonwealth of Australia 1993). While local communities are usually viewed as key stakeholders, the potential range of all stakeholders is considerably broader. Both terms are relevant to the discussion that will occur in the next few chapters, although the

main focus will be on the narrower group of "community" as outlined in its definition.

MINING AND SUSTAINABLE DEVELOPMENT

The increased focus on the mineral industry's impact on the environment and society, including the local community, can be attributed to both global trends associated with attitudes to private enterprise and large multinational corporations, and also to the mineral industry's poor track record with high-profile cases such as the Bougainville crisis and various other environmental incidents (e.g., Ok Tedi in Papua New Guinea, Marcopper in the Philippines, and Baia Mare in Romania). During the 1990s the minerals industry came under increasing challenge from various quarters, with the result that it found itself losing its "social license to operate." This term has now become a popular way of describing the influence that society in general has over the ability of an organization to carry out its activities, above and beyond the legal license issued by governments, which govern the extraction of mineral resources. Social license is variously described but commonly considered an ongoing process of approval from the community that is given at a point in time, and not necessarily for the future (AccountAbility 2004).

In response to this increased societal pressure, there were several early initiatives in different countries as local industry bodies sought to engage with both governments and their critics. One example is the Whitehorse Mining Initiative in Canada (Cooney 2008), a multistakeholder initiative developed in 1994 involving industry, government, and NGOs, which aimed to develop general principles for responsible mining. In Australia the Minerals Council of Australia developed the Australian Minerals Industry Code for Environmental Management, modified in the late 1990s to include additional requirements focusing on social and community issues. These types of initiatives were often linked to the concept of sustainable development, a term that has emerged over the last 20 years as a key organizing framework for the global community to consider the links between the development and environmental protection agendas. Dresner (2008) outlines both the history and the politics of this process, including key milestones such as the Brundtland report (WCED 1987) and the United Nations Rio Earth Summit in 1992. Sustainable development remains a contested concept, with many competing definitions and sets of principles, but its popularity has meant that many organizations have chosen to use it to frame their own activities in social and environmental areas.

In 1998, a dialogue between a small group of senior mining industry CEOs including Hugh Morgan of Western Mining Corporation and Sir Robert Wilson from Rio Tinto led to the formation of the GMI, an industry-led process that expanded to involve many of the world's largest mining companies. The initiative had three elements: a 3-year research project to investigate the activities of the industry through the lens of sustainable development; a major conference held in Toronto in 2002 to review the outcomes of the project; and the creation of a new global industry body, the International Council on Mining and Metals (ICMM), charged with implementation of the industry response to the outcomes of the project. The Mining, Minerals and Sustainable Development (MMSD) research project was managed by an independent research group, the International Institute for Environment and Development, and resulted in the *Breaking New Ground* report produced in 2002 in time for the Toronto conference (IIED 2002). It is beyond the scope of this chapter to explore the full range of issues covered by the MMSD report (many are touched on in other chapters in this handbook), but it is noteworthy that one of the nine key challenges identified for the industry to address was the area of mines and communities. A number of supporting research reports addressed specific issues under this theme such as indigenous peoples' rights, social impact analysis, and socioeconomic development. Danielson (2006) provides a comprehensive account of the origins and progress of the MMSD project, including a range of different stakeholder perspectives on various elements of the process. There is little doubt that the GMI and its associated research has been the most influential process to date of all those designed to examine the social and environmental aspects of mining industry activities.

In reviewing the progress and outcomes of both the Whitehorse Mining Initiative and the GMI, Cooney (2008) suggested that the companies who launched the two initiatives were primarily concerned about the public image of mining. Public criticism was being driven by misinformation about the actual impacts of mining, and improved communication would help address this. However, he suggested that through the course of both initiatives and subsequent processes such as the World Bank's *Extractive Industries Review*,

> the mining industry learned matters both of process and of substance: from the engagement process, mining companies have learned different models of comprehensive dialogue and consensus building with critics; by listening to their critics, the companies have learned different approaches to analyzing and managing critical issues. Self-education was not the mining industry's initial purpose in either the Whitehorse Mining Initiative or the Global Mining Initiative, but it was to be the outcome.

In addition to these industry-driven initiatives, many other stakeholder groups have initiated reviews and developed frameworks for reviewing environmental and social aspects of projects, some specific to the resources sector but others more generally focused. Such nonregulatory drivers are pushing minerals companies to focus on local-level social and community issues. Particularly for publicly listed companies, the screening process for socially responsible investment or ethical investment funds, other indexes such as the Dow Jones Sustainability Index, and public ratings are also influencing behavior. Most of these indexes and rating agencies require that organizations establish a systematic approach to managing the social dimensions of their projects, as they would environmental and economic aspects. Many funding agencies, such as the International Finance Corporation (IFC) also require this as a condition of finance. In the absence of mandatory legislation, pressure from third parties has helped to sustain attention on community relations in the mining industry. This growth of "soft" regulation has been significant in the past 10 years—examples that are relevant and referenced by the minerals industry include the following:

- **ICMM Sustainable Development Framework**—Ten principles and various elements that provide guidance on applying sustainable development principles to mineral

operations. Reporting against this framework is obligatory for members of the ICMM.

- **Kimberley Process Certification Scheme**—A multistakeholder initiative that aims to provide product certification for diamonds and reduce the trade in "blood diamonds."
- **Extractive Industries Transparency Initiative**—A voluntary initiative focused on ensuring transparency of payments associated with resource projects.
- **Equator Principles**—A set of environmental and social benchmarks developed by a group of major international banks for addressing environmental and social issues in development project finance.
- **IFC Environmental and Social Standards**—A standards framework developed by the IFC to apply to projects in which they invest World Bank funds.

As well as pressure from this type of "soft" regulation to improve social and environmental performance, many governments are becoming increasingly involved in regulating the community aspects of the development, operation, and closure of mines (Brereton 2002). The focus of governments was initially on environmental issues, but social dimensions are increasingly being regulated in developed and developing countries alike. In Australia, for example, most states have made basic community consultation mandatory for major new development projects, including mining, often as part of environmental and social impact assessments. The Australian Native Title Act (AustLII 1993) has also become a central part of the Australian regulatory regime, providing indigenous groups with the right to negotiate and a potential vehicle to deliver both social and economic benefits for indigenous communities. South Africa has a regulatory framework in place to progress black economic empowerment in the mining and petroleum industries. The Philippine Mining Act of 1995 requires that proposed projects undergo a comprehensive environmental assessment, which must consider socioeconomic as well as environmental impacts and provide evidence of broad social acceptability. In Canada, the requirement to incorporate sustainability considerations in environmental assessment processes has seen community issues come to the fore in several high profile and controversial mining cases such as the Voisey's Bay project, as described by Gibson (2006), and the more recent Kemess North review.

CONTEXT IS CRUCIAL

Before considering some examples of the types of community issues that emerge, it is important to emphasize the influence and importance of context. Many factors can have a significant impact on the interactions and relationships between mining operations and communities, including various social and political aspects, as well as the stage of the mining life cycle involved. Mining is a truly global activity, involving many different types of organizations and communities in settings that range from arid mountains in parts of the Andes, to remote areas within the Arctic Circle, to established agricultural regions in developed countries, and to tropical rainforest settings in developing economies in Asia. In addition to the obvious geographical differences, other contextual factors can be very important.

The history of mining in a country and region can influence community attitudes to mining projects. In some cases mining may be a relatively well-accepted activity, as, for example, in certain well-developed coal-mining areas of the United States and Australia. A number of well-known mining towns around the world have been created close to major mining deposits whose economies continue to be based around the exploitation of these resources. Examples include Kalgoorlie in Australia, Sudbury in Canada, and Cerro de Pasco in Peru. However, in some of these areas, the cumulative and historical social and environmental impacts associated with the mining operations can still be the subject of community debate. As the industry increases its activities in less-developed countries with little or no experience of large-scale mining, community attitudes can vary widely. A good example is Mongolia, which has only recently opened its industry to direct foreign investment. Large-scale mining by global companies is a new phenomenon, and the management of mineral revenues was the principal issue in the 2009 election held in that country.

Existing community land uses can include broad-scale farming, intensive agriculture, open grazing of livestock, and hunting and fishing (among many others). Although the physical footprint of mining operations is usually relatively low, its interaction with other land uses in terms of impacts on other resources such as water, labor, and infrastructure can be significant. In some locations, small-scale or artisanal mining (particularly of gemstones and precious metals) may already be a significant community activity—some estimates put the number of people involved in this type of mining worldwide as high as 20 million, including large numbers of women and children. In this sense, the displacement of artisanal activities by large-scale mining projects can have significant negative ramifications for certain groups of people. By the same token, mining companies have worked with artisanal mining communities to address health and environmental issues and to find opportunities for artisanal miners to find alternative sources of income.

In many parts of the world, elements of the physical landscape play an important role in the culture of local communities. A desert clay pan may represent a physical feature to be managed by a mining company, but it is a significant site to a local indigenous community. In some parts of Australia, red ochre is used by male members of indigenous groups in cultural ceremonies, and therefore its presence in mine overburden becomes a major logistical issue that requires an appropriate response. There are cases where the development of mining projects has resulted in the destruction of sites of major cultural significance, such as at the Argyle mine in Western Australia, for example. There are also cases where the presence of such sites have been the main reason for mining projects not going ahead, and some sites where mining projects have been designed to accommodate cultural heritage considerations.

Political and legal frameworks within a country will have a significant impact on the scale and nature of the mining industry and can also often be the subject of intense community focus. Government capacity to regulate the minerals industry and manage the benefits of mining for the local communities has been identified as a crucial aspect by recent studies (e.g., ICMM 2006) and has been the subject of recent World Bank projects in several developing countries, such as through the provision of technical assistance to the government in Laos and other countries in Asia to strengthen their ability to manage the burgeoning mining sector. Also of interest are legal and customary rights concerning land management, especially in cases where mining occurs on lands

claimed by indigenous peoples. In Papua New Guinea, there is a well-developed system of customary land ownership that is linked to family descent, whereas in some parts of Africa communal tribal ownership and shared land-use arrangements make negotiations for land access for mining purposes considerably more complex. All around the world, many rural or traditional communities have operated on a system of land use and ownership that has not required formal land ownership. If a company compensates only those people with formal land ownership, there is a high potential that it will negatively affect livelihoods, culture, and social traditions that have been in place for generations. Where land titles are in place, it is also men who often hold title and receive compensation for land, highlighting the potential for women to be negatively impacted unless strategies are in place to ensure equitable distribution of benefits.

Other important contextual factors include the nature and scale of the mining operation itself. Large-scale open-pit and strip mines can result in more visible manifestations of mining activity in the form of spoil piles and waste dumps and can be more disruptive to other land uses such as agriculture. Underground mines generally employ more selective mining methods and produce less waste, but subsidence effects in longwall mines can result in impacts on surface environments and water resources. In some countries, the safety record of underground mining is significantly worse than surface mines, as, for example, in the underground coal industry in China (which includes many smaller, informal operations), where the reported fatalities in 2007 from a series of methane and dust explosions and cave-ins numbered nearly 3,800. It is believed that many fatalities and injuries go unreported in China and other countries.

The nature, size, and reputation of the company involved can also be influential. The larger global multinational companies tend to be engaged in the sustainable development debate and signatories to many of the frameworks and conventions that deal with community issues, whereas many of the smaller mining and exploration companies are less active in these areas. Size does not, however, always correspond to enhanced social performance. Not all operations within a large company perform to the same standard. Small or junior companies with a single asset may find creative ways to work with the local community to address social concerns, although they usually have significantly less capacity to adequately resource a community relations function and therefore do not always give social aspects the attention that is warranted. Smaller companies can also have a short-term outlook, as their focus is on discovering and developing the asset to the extent they can sell it, rather than operating the mine themselves. This tends to lead to an avoidance of social investment. Whether a company is from the country of origin can also determine the extent of community opposition. In several parts of the world, there has been community opposition to the involvement of foreign companies in mining and exporting valuable minerals when much of the profit is perceived to go offshore.

Finally, the stage of the mining life cycle can also have a significant bearing on the development of community issues. Some issues are specific to certain phases. For example, the impacts associated with accessing hitherto virgin jungle for the purposes of exploration or with a community hosting a large, temporary construction work force are very different from those that occur during actual mining operations. Closure is often associated with community concerns over the withdrawal of the mining work force and related economic activity. Some closures are planned, where the mine comes to a natural end because the resource has been exhausted, but other mines close suddenly because of changes in commodity prices, which means the mine becomes unprofitable. Mines can also be disrupted or closed because of community protest or conflict, as in the case of Bougainville discussed earlier. Community issues are not fixed; they evolve throughout the life of the operation.

Consider the example of Newmont Waihi Gold's mine located in Waihi, New Zealand, shown in Figure 17.1-1. At this historic mining town, the conversion of old underground workings into an open-pit development during the 1980s has brought the upper benches of the mine to within feet of residences and the town's main street. Although mining has been an activity in the area for more than 100 years, the impacts associated with the mine have affected many residents living close to the edge of the pit, and also the community more broadly. The community relations landscape has been dominated by these issues of amenity, including the impacts of noise, dust, and blast vibrations. However, there are many other contextual issues that also influence how the community perceives and interacts with the operation. The mine and its work force make up about 25% of the town's economy, with many local people employed at the operation. The development of the open pit removed a small hill that was of cultural significance to some Maori tribes of the area, who continue to oppose the presence of the mine on the basis of their traditional beliefs and values but remain in discussion with the company on the management of cultural issues. The mine operates in a developed country with strong environmental protection legislation, and is located in a farming area close to a major tourist region. Recently, the company worked with the community to develop a vision for the town after mine closure, which has been imminent for the past few years, and it is the potential closure of the operation and its impacts that are the current focus for many in the community. A good understanding of the overall context—economic, cultural, political, social, and environmental—as well as an understanding of the issues particular to each community and each group within the community, is therefore crucial in identifying and addressing the many issues that emerge from the closure process.

What Are Community Issues?

The introduction of the term *triple bottom line* (Elkington 1997) and its application in the context of sustainability reporting has seen social or community issues identified as a separate category to environmental or economic issues within the sustainable development framework. In reality, however, most communities are extremely focused on all aspects of mining development and do not necessarily separate out these issues into neat categories. Consider a remote traditional community that relies on the local waterway for catching fish as well as for spiritual worship and ceremony. They may explain the water as important to their survival, their traditions, their family, and their future, seeing these aspects as interconnected rather than separating them. Although there are different ways of understanding these dynamics, it is often environmental or economic aspects that are the main focus of attention. Figure 17.1-2, while not intended to be comprehensive, illustrates both the breadth of issues under consideration and their interrelated nature.

Courtesy of Newmont Waihi Gold.
Figure 17.1-1 Newmont Waihi Gold's operation in Waihi, New Zealand

Some themes have become particularly prominent in the last decade, partly as a result of such initiatives as the MMSD project but also due to a range of other drivers. Some of these have been mentioned previously, such as nascent "social regulation" in the form of legislation, voluntary initiatives, and pressure from NGOs and civil society. In recent years some investment funds have been deliberately disinvested from major companies in the minerals industry because of concerns about social risk. Several of these issues, which have become the focus of various groups and organizations, are explored briefly in the following sections.

Economic Development

The positive influence of mining projects on local, regional, and national economies has always been an argument used by proponents to support new developments. In contrast, the resource curse hypothesis suggests that in fact countries with high levels of natural resources suffer lower rates of economic growth than those with more diversified economies, in effect suffering a paradox of plenty. Much research supports arguments both for and against this proposition, one example being the Resource Endowment Initiative involving the ICMM, the United Nations Conference on Trade and Development, and the World Bank (ICMM 2006). This study concluded that mining investment does provide opportunities for economic growth, poverty reduction, and engagement in the global economy, pointing to specific examples such as Chile and Botswana where increased mining investment has coincided with an upturn in national economic growth. However, it also emphasized the need for effective and transparent governance regimes for the management of mineral wealth. Transfer of some of the benefits from taxes and royalty streams back to the regions where mines are located has been an issue of some contention in several countries such as Peru, for example, where several problems have developed as a result of changes to legislation (Arellano-Yanguas 2008).

In recent years more research has been focused on economic impacts at the local and regional levels. Companies are now starting to report on how much of the added value associated with wages and purchase of goods and services for mining operations stays at the local and regional levels. For example, see the economic indicators in the *Sustainability Reporting Guidelines and Mining and Metals Sector Supplement* (Global Reporting Initiative 2009). In addition, a company's contribution to community development activities are directed at growing local economic activity, often with a focus on nonmining-related businesses, in order to provide for a postclosure future. However, the additional cash flows injected into local economies can have negative impacts as well, as in the form of disproportionate inflation, for example. This can apply equally in less-developed contexts where market economies may be significantly changed by the introduction of mining industry wages, as well as developed economies where industry expansions can result in distortions in real estate and labor markets, with consequential impacts for other sections of the community.

Water and Mining

Access to fresh water represents an essential human need. Water is also fundamental to other ecosystem services required to sustain human life and is high on the political agendas of all levels of government, including the United Nations. It was recognized as a key theme in the MMSD project, with mines operating in the driest and the wettest regions on the planet. While not extracting as large a quantity of water as the agricultural sector in most countries, individual mines are often large consumers in their local context, and their impacts can be significant. Mining companies compete for water use within a range of market and nonmarket jurisdictions, and can often afford to pay considerably more than others, thereby running the risk of reducing the viability of other industries. Companies can also affect access to water if mining development does not consider the usage patterns of the local community. For example, by building roads or operations, some mining developments can inadvertently make access to water sources in developing countries more difficult. At the same time, mining companies are often responsible for developing water infrastructure used by other industries and communities (e.g., Brereton and Parmenter 2006).

Water use in many processing activities results in bodies of contaminated water in tailings storages and flooded pits that, if incorrectly managed, pose risks for downstream users. Many environmental legacies of mining have involved pollution of water systems, including the frequent incidence of acid mine drainage at closed or abandoned mines on many continents. Potential impacts of mining operations on both the quantity and quality of surface and groundwater resources are increasingly being raised as concerns by local communities, and in several cases have been the principal reason why some projects have not gone ahead.

Community Health

There are many ways in which mining operations can impact the area of community health. Population changes including in-migration in developing countries such as Papua New Guinea can be responsible for the spread of diseases such as human immunodeficiency virus (HIV) and tuberculosis. The ICMM recently released a report titled *Good Practice Guidance on HIV/AIDS, TB and Malaria* (ICMM 2008) for its members, reflecting the incidence of HIV in mining work forces and communities in different parts of the world. Other direct health impacts can come from emissions from processing operations, such as high blood lead levels found in communities located near older lead smelters on several continents. Local controversies have developed over the potential health impacts of riverine and marine tailings disposal processes

Figure 17.1-2 Examples of community issues in mining

such as those at Marinduque in the Philippines and Minahasa in Indonesia, for example. Both of these cases attracted significant international attention.

On the other hand, mining developments are often responsible for the establishment of health infrastructure and services in remote areas. Despite the environmental impacts associated with riverine waste and tailings disposal at the Ok Tedi mine in Papua New Guinea, the antimalarial and health clinic campaign introduced by the company to isolated communities near the mine resulted in extremely significant improvements in infant mortality and life expectancy statistics in those areas. A mining company–initiated campaign to eliminate filariasis from the island of Misima in the same country realized similarly impressive results, and there are many examples in Africa of similar involvement in regional antimalarial campaigns. While such initiatives at one level represent a risk reduction measure for the company's own work force, they often extend well beyond the level required for pure mitigation.

Resettlement and In-Migration

Mining often requires or results in movements of people, either out of or into a mining area. When minerals are located where people are living, resettlement is often required in order for the resource to be exploited. Resettlement may involve one family or a whole community. The IFC's resettlement standard has, by default, set the industry standard for resettlement. Aside from physical resettlement, mining can result in social, economic, and cultural dislocation, often stemming from physical resettlement, but not necessarily. For example, a haul road may inadvertently divide an otherwise connected group of people, or may impact access to resources such as productive land or water. But while it may serve to dislocate in some instances, a new road can also increase people's mobility and access to new markets for expanded economic opportunity, although these opportunities may not be experienced across the board.

There is a vigorous debate around whether mining companies should ever undertake resettlement involuntarily. There are some sites where communities have been involuntarily settled in the past, and as a result harbor resentment, particularly when relocation was facilitated by force or violence. In some cases, new owners have been faced with legacy issues from prior resettlement that cannot be ignored. While some communities are moved to enable resource extraction, there are other circumstances that result in migration into an area as a result of people seeking economic benefit through direct or indirect employment or other business opportunities, sometimes known as the honey pot effect. In-migration can be just as challenging for a company as resettlement, particularly if it is uncontrolled. Often companies expect governments to take responsibility for community planning around mine settlements or squatter camps, which, if not done adequately, can often cause great resentment.

Security and Human Rights

Human rights discourse has recently grown in strength, as have calls for business, and in particular multinational companies, to ensure that their activities do not harm the rights of others. The key international reference for human rights is the Bill of Rights, which includes the United Nations' Universal Declaration of Human Rights, proclaimed in 1948 by the UN General Assembly, and the two covenants—the International

Covenant on Civil and Political Rights, and the International Covenant on Economic, Social and Cultural Rights. As elements of the bill are ratified by governments, not companies, it has not been clear how human rights responsibilities confer to companies, particularly those operating on a transnational basis, including whether and how companies should be held accountable for their actions should they abuse human rights. The nature of global businesses has meant that it is often difficult to apply home country laws to companies operating abroad, although there have been attempts in both Canada and Australia to introduce legislation that specifically focuses on mining companies in this area. Further, the laws of some host countries may not have enshrined human rights into law, or may have weak or ineffective legislative frameworks that fail to hold companies to account for human rights violations. While the debate about the human rights responsibilities of companies continues, a recent report from the UN special representative of the secretary-general clarified the different yet complementary roles of governments and companies with respect to human rights (Ruggie 2008). The three-part framework outlines three key principles: the state duty to protect, the corporate responsibility to respect, and access to remedies. Under the recently extended mandate, "operationalizing" the framework will gain particular attention.

In the mining industry, human rights are most often raised in the context of the use of security forces to protect mining operations, which has been particularly controversial in militarized regions. Safety and working conditions have also been the subject of intense scrutiny. Attention is also being called to the human rights issues associated with environmental impacts, particularly if mines impact on the ability of local communities to establish sustainable livelihoods, as well as a number of other rights-related impacts, such as on culture (e.g., if sacred sites are impacted by mining activities), discrimination in the workplace, and the right to an adequate standard of living. While attention is often called to the negative impacts that mines have on local communities, it also needs to be recognized that companies help uphold a variety of human rights in their day-to-day business. Their contribution to economic growth, for example, can provide the support necessary for fulfillments of various economic, social, and cultural rights. Responsible mitigation of environmental impacts, close consultation with local communities, and employment procedures also help uphold different sorts of rights (ICMM 2009).

Mining, like many other economic activities, has often been conducted with little regard to the rights and interests of indigenous peoples on whose lands resources were located. Over the last few decades, indigenous peoples have been recognized as a distinct category of human societies under international law and, to varying degrees, in national law as well. The adoption in 2007 of the United Nations Declaration on the Rights of Indigenous Peoples has brought a sharper focus to this area. Harms that indigenous peoples suffer as a consequence of poor practices have included dispossession and forced relocation, destruction of culturally significant sites, loss of livelihoods, exposure to disease and "social vices" such as alcohol and prostitution, and in extreme cases, total cultural and social breakdown. It is vitally important that the rights of indigenous peoples are taken into account in any mining project. However, as human rights assessments are not yet common in the industry, particularly those that are publicly disclosed, the degree to which companies respect or otherwise impact human rights—indigenous or otherwise—is not always clear.

COMMUNITY ENGAGEMENT AND DEVELOPMENT

The common terminology for the processes undertaken by mining companies to understand and address community issues include both *community engagement* and *community development*. Community engagement is usually undertaken so that the company can better understand community perspectives. Community engagement is increasingly required by legislation, most commonly as part of project approval processes. It can also be undertaken voluntarily, as part of developing good relationships with local or host communities. Community engagement is not new in the sense that mining companies have always interacted with a range of groups around mining operations. However, in recent times, the focal point and rationale for community engagement has increasingly fallen under the banner of sustainable development and been linked to a broader range of issues than previously considered.

Community development is focused on the needs and aspirations of the community. Community development is concerned with issues of social justice, human rights, and empowerment of all groups in a community, including the most vulnerable. Community development can contribute to the management of the social impacts of a mining project, but this is not the core focus. Effective engagement is essential for community development, but community development does not automatically flow from engagement. The mining industry tends to present community development as a "mature" form of stakeholder engagement practice. A common reference in this area is the spectrum of public participation developed by the International Association for Public Participation (IAP2 2009), which shows a progression from informing and consulting to collaboration and empowerment of local communities. Under this model, community development is "high end" participation compared with public relations, which focuses more on corporate reputation through formal communication and information dissemination.

There are several stages of mine life, from exploration and project development to construction, extraction operations, and closure. In different ways, depending on the context, community engagement and development is important and relevant. Exploration is important in terms of establishing early relationships. This stage sets the scene for the future. By the time project development commences, there should have been sustained dialogue between the company and the community, various studies and assessments undertaken to determine potential impacts and benefits that might occur, and strategies for either impact mitigation or maximization discussed and agreed. The construction phase can result in significant changes and impacts to local communities. Regular dialogue remains important in these phases. It is often only after operations commence that profits are reaped and significant money starts to flow. Community development often becomes a central focus at this point, but the foundations for good development are ideally laid from the very beginning of the project life cycle. Closure and postclosure considerations should be discussed from the very outset. If community development has succeeded, a community will be well placed to deal with the changes that closure may bring.

The mining industry tends to use community development to describe activities undertaken directly or indirectly with communities in the geographic proximity of operations

that aim to achieve positive economic, environmental, and/or social outcomes for those communities. Some companies also use terms such as *community programs*, *community support*, and *social investment*. The sphere of activity varies from site to site, depending on the context, size of operation, commodity, impact of the operation, and various social and political expectations. Activities typically included in sustainability reports under community development tend to include local employment (direct or indirect through the supply of goods and services), training and skills development, provision of infrastructure (such as roads, water, and sanitation facilities), service delivery (such as health and education), employee volunteerism, donations, and nonmining-related opportunities (such as capacity building and empowerment programs). However, it is often not the activities themselves that denote community development, but the processes used. An employment program can serve company goals, but if community-directed and empowering, it can also meet the needs and aspirations of the local community. Process is key to successful community development.

Of particular interest to this chapter is the increasing alignment of various mining companies with the international development and poverty agenda as expressed, for example, by the CEO of Anglo American Corporation at a mining industry conference in South Africa: "Mining companies are not development agencies, but we are important development actors…. I believe that the mining sector will—and must—play an increasingly important role in development and poverty alleviation in the continent" (Carroll 2008). Several multinational mining companies have publicly aligned themselves to the Millenium Development Goals, a set of ambitious targets released by the United Nations to address pressing global development needs. This move toward community development is unsurprising, given that mining companies increasingly operate in some of the poorest and most marginalized communities of the world. Many of the world's leading companies, particularly those operating within a sustainable development framework, are becoming involved in the provision of infrastructure and services, such as for health and education, and economic opportunities through compensation, royalties, direct or indirect employment, and small business enterprise, as well as initiating capacity building and other community development programs. However, while the core business of mining can have adverse impacts, so too can development projects initiated to secure social license to operate, and companies should always analyze the potential for perverse consequences of development projects, including the issue of community dependency.

ADDRESSING COMMUNITY ISSUES

As a testament to the increasing voice that society has over company affairs, and the continued emphasis on the social aspects of mining, in 2009 Newmont Mining Corporation released a major community relationships review. This was undertaken in response to a shareholder resolution at its 2007 annual general meeting put forward by Christian Brothers Investment Services Inc., endorsed by the board, and supported by almost 92% of shareholders. The aims of the review were defined as follows:

- To better understand Newmont's current community relationships and their contexts;
- To assess future risks and opportunities to Newmont with regard to these relationships;
- To analyze the relevance and effectiveness of Newmont's policies, systems, and controls as they relate to community relationships; and
- To identify the impact of resources, capacity and governance on the implementation of these policies and controls (Newmont Mining Corporation 2009).

The project was undertaken by an independent working group and reviewed by an external advisory panel whose members included some who had been publicly critical of the industry's approach to dealing with communities. It was designed around case studies of five Newmont operating sites located in different continents and with vastly different contexts. In reviewing the final report, the Environment and Social Responsibility Board Committee commented on the project outcomes:

> The Company has learned much about the need to foster and maintain good relationships with governments, communities and other stakeholders, not just the ones who support the Company in its mining ventures, but also those who object to mining in general or the Company in particular. We firmly believe that the future viability and sustainability of the Company's business requires that the Company manage our community relationships more effectively and with consistency. The Company must ensure that community engagement, community relations and conflict management become a more integral component of the Company's business (Newmont Mining Corporation 2009).

In responding to the emerging agenda around mines and communities, the industry has made some significant changes at a number of levels, including both policy and planning activities to address community issues. Typically, corporate policies of leading companies in the minerals industry now explicitly address a range of broader social justice objectives, which include such aspects as local and indigenous employment, security and human rights, sustainable livelihoods, culture and heritage, ethical procurement, and stakeholder and/or community consultation. Increasingly, these policies are focused not only on mitigating the negative impacts of mining on the environment and people, but also on delivering sustainable benefits for local and regional communities. However, "good deeds" undertaken in one area in order to maximize benefits does not compensate for social harms. At a minimum, companies must focus on avoiding or mitigating social harm that occurs as a result of their activities.

At the level of process, there is a growing emphasis on the need to adopt a more participatory and inclusive approach to interacting with stakeholders, including local communities. In order to achieve this, there are a series of essential processes that should be undertaken from the outset and repeated throughout the mine life, including inclusive engagement and relationship building, social mapping and baseline studies, social impact assessment, and social risk assessment and community planning. These processes are explored in more detail in a subsequent chapter. In an effort to improve their performance in community relations, some minerals companies

are now investing considerable resources in developing and implementing management systems for this area. This entails adaptation and extension of the approach being taken in other dimensions of sustainable development, such as occupational health and safety and environmental management. The elements of these systems typically include an annual planning process, detailed documentation of procedures, regular reviews and audits against defined corporate standards, and a strong focus on information management. Examples that illustrate the "systematization" of community issues include cultural awareness protocols and training, and procedures for managing community complaints or grievances.

Structural arrangements for community relations vary according to contextual and organizational factors. Some operations include community relations departments within the communications, public relations, or external affairs functions, whereas others position community relations as part of the environmental or sustainable development departments. Many large mine sites, particularly those in developing countries or where there is a large indigenous population, have dedicated community development units or departments. Some companies detach or semidetach community development through a dedicated foundation or trust. At the corporate level, there is often a senior executive or separate department that has responsibility for social policy, as well as a board subcommittee in the area of sustainable development or social and environmental policy.

There are no known studies, either regionally or globally, that provide a comprehensive profile of organizational arrangements for community work within the global minerals industry. A notable contribution, however, was a study undertaken by Reichardt and Moshoeshoe (2003) that considered the structural arrangements and capacity for sustainable and community development undertaken in the context of the African mining industry. In the Australian context, a practitioner survey undertaken by Kemp (2004) found that people involved in community relations work were generally well educated and had considerable industry experience, but the majority did not hold qualifications in the social sciences. In addition, the group had a low level of prior experience in community relations–type work, either within or outside the industry. Subsequent anecdotal evidence suggests that the industry has recently targeted people with social science backgrounds from sectors such as international development, aid, social services, and community development while also building the social science and relational capacities of those from technical or operational backgrounds (Kemp 2009). The policy, structural, recruitment, and professional development arrangements outlined above speak to an ever-increasing focus on the institutionalization and professionalization of community relations in mining.

SUMMARY

Although many of the issues explored in this chapter are not new to the industry, and indeed have been the subject of public debate for decades, there is no doubt that the focus on community issues in mining has increased substantially in recent years. There are many reasons for this, some of which have been identified earlier, but in general the change does reflect an underlying shift in societal attitudes toward business and society, and the extractives industry in particular. For those working in the industry, it means that significant attention needs to be paid to this area, and not just by those working in dedicated community roles. In particular, engineers should recognize the diversity and complexity of communities, rather than viewing them as a collective entity; understand the direct and indirect ways in which mining operations impact communities; and appreciate the significance of contextual and cultural factors that might affect community responses to mining activities. They should also understand that the nature of community issues will change over the life cycle of a project, and they should appreciate the need for early and continuous engagement with the communities associated with their operations.

The mining industry has, to a great extent, accepted aspects of the moral arguments being made in this area. The industry also appears to be persuaded that investing in community relations activities to address these types of issues makes good business sense. A former chief economist for Rio Tinto identified two main sets of business case arguments, which he termed "show-stopping pressures" and "competitive pressures" (Humphreys 2000). The former includes disruptions and delays to projects that threaten their existence, while the latter focuses on the desire to be the "developer of choice" and the ability to move faster in the project establishment process. However, in the same paper the author adopted a less-instrumental argument: "How companies behave reflects underlying currents in the value systems of the world in which they operate. They and their employees are not something apart from civil society. They are an integral part of it and, as such, need to be sensitive to changes in its priorities and perceptions." The maintenance of the industry's "social license to operate" has become an imperative in an increasingly connected and challenging global environment.

The Panguna mine on Bougainville referred to at the beginning of this chapter has not operated since 1989. There have been suggestions in recent years that some in the local communities would like to investigate the possibility of reopening the mine. Other landowners remain bitterly opposed because of the environmental and social legacies left by the operation and subsequent conflict. As in many other locations, the possibility of using the economic benefits of resource development to provide opportunities for local communities remains attractive. Amidst the complexity, one thing is clear—in negotiating the future of any renewed mining activity on the island, the approach taken by mining companies, governments, and local stakeholders in addressing "community issues" will need to be very different from the past. To be successful, mining companies must reflect a better understanding of the needs, aspirations, strengths, and perspectives of local communities and focus on these social aspects as much as on the engineering design of any new mining proposal.

CHAPTER 17.2

Social License to Operate

Ian Thomson and Robert G. Boutilier

ORIGIN OF THE TERM

Mining is accepted by the public at large because of the role it plays in society as a provider of minerals and metals for the public's needs and general well-being. There can be no doubt as to the historic role that mineral exploitation has played in the advance of societies, and in more recent times in the economic growth and industrialization of specific countries such as Australia, Canada, Chile, South Africa, and the United States. At the level of individual mining projects, however, this acceptance is neither automatic nor unconditional, and since 1990 has become increasingly tenuous.

During the 1990s, the mining industry found itself under close public scrutiny following a series of well-publicized chemical spills, tailings dam failures, and increasing conflict with local communities around exploration and development projects (Thomson and Joyce 2006 provide a review of this time period). In 1996, a Roper opinion poll showed mining to rate last among 24 U.S. industries in terms of public popularity, behind the tobacco industry (Prager 1997). Internationally, mining became a pejorative term in many circles and widely regarded as a problem industry that was the cause of unwanted pollution and undesirable social impacts. This pervasively negative reputation constituted a liability to the industry.

At a meeting with World Bank personnel in Washington in early 1997, Jim Cooney, then director of international and public affairs with Placer Dome, proposed that the industry had to act positively to recover its reputation and gain a "social license to operate" in a process that, beginning at the level of individual mines and projects, would, over time, create a new culture and public profile for the mining industry. The concept and terminology surfaced in May 1997 in discussions within a conference on mining and the community in Quito, Ecuador, sponsored by the World Bank, and soon entered the vocabulary of the industry, civil society, and the communities that host mines and mining projects.

CHARACTER AND DEFINITION

At the level of an individual mine or mining project (including exploration projects), the social license is rooted in the beliefs, perceptions, and opinions held by the local population and other stakeholders about the mine or project. It is therefore "granted" by the community. It is also intangible, unless effort is made to measure these beliefs, opinions, and perceptions. Finally, it is dynamic and nonpermanent because beliefs, opinions, and perceptions are subject to change as new information is acquired. Hence the social license has to be earned and then maintained.

The social license has been defined as existing when a mine or project has the ongoing approval within the local community and other stakeholders (Business for Social Responsibility 2003b; AccountAbility and Business for Social Responsibility 2004), ongoing approval or broad social acceptance (Joyce and Thomson 2000), and most frequently as ongoing acceptance.

The differentiation of approval (having favorable regard, agreeing to, or being pleased with) and acceptance (disposition to tolerate, agree, or consent to) can be shown to be real and indicative of two levels of the social license—a lower level of acceptance and a higher level of approval. Although the lower level is sufficient to allow a project to proceed and a mine to enjoy a quiet relationship with its neighbors, the higher level is more beneficial for all concerned, including the industry as a whole.

On occasion, the social license can transcend approval when a substantial portion of the community and other stakeholders incorporate the mine or project into their collective identity. At this level of relationship, it is not uncommon for the community to become advocates or defenders of the mine or project since they consider themselves to be co-owners and emotionally vested in the future of the mine or project.

EXAMPLES FROM REAL COMMUNITIES

In the spring of 2008, a tourist traveling across southern British Columbia, Canada, checked into a motel in the community of Trail and chatted with the receptionist. As part of the exchange, the receptionist mentioned how excited she was about "our" new project. Thinking this to be some improvement to the motel, the visitor asked for more information and was interested to learn that the new project had captured the imagination of the whole community. It was, in fact, a process

Ian Thomson, Principal, On Common Ground Consultants, Inc., Vancouver, British Columbia, Canada
Robert G. Boutilier, President, Boutilier & Associates, Vancouver, British Columbia, Canada, and Cuernavaca, Mexico

to recover recyclable scrap metals at the nearby Teck Cominco smelter. Clearly, the receptionist and her neighbors had very positive feelings toward the project, the company, and the smelter; they not only approved of it, they identified with it, and in their collective minds the project was fully "licensed" to go ahead.

The same type of community identification with a company's operations can be found in small cities and towns throughout the world. In the information economy, San José, California, United States, and the surrounding vicinity identifies itself with the high-tech industry, dubbing itself "Silicon Valley." With this level of support, community and private sector organizations see their interests as highly aligned, both politically and economically.

PROBLEMS OF INTERPRETATION

The concept of an informal social license is comfortably compatible with legal norms in countries that operate under the principles of common law. However, the concept runs into difficulties in countries such as those in Latin America that operate under the principles of civil law, whereby only an official authority can grant a license. As a consequence, while communities and civil society are eager to see the social license in terms of a dynamic, ongoing relationship between the company and its stakeholders, regulators (and in turn many companies) see the license in terms of a formal permission linked to specific tasks and events in which the regulator plays the central role in granting the license.

In parallel with the above, there have been attempts in Canada and the United States to link the social license to specific tasks, and also to reformulate the concept as something that is established by the company and, once gained, becomes permanent. For example, Shepard (2008), suggests that the social license be defined as "a comprehensive and thoroughly documented process to have local stakeholders and other vested interests identify their values and beliefs as they participate in scoping the environmental impact assessment and in identifying alternative plans of operation for the project." (Notably this does not stipulate that the community, stakeholders, and other groups accept, approve, or support the project).

Neither of these capture the vision of the social license as being dynamic, granted by the community (or at the higher level, society in general), descriptive of the quality of the relationship between company and stakeholders, or involving the reputation of the company and hence industry. Moreover, the words *to operate* are sometimes confused with the strictly operational phase of a mine's life cycle when ore is extracted for processing. A better sense of the term *to operate* is to continue the project, no matter where in the mine life cycle, from the initiation of exploration through to closure.

COMPARISON WITH OTHER FORMS OF CONSULTATION AND CONSENT

FPIC is the acronym used to describe free, prior, and informed consultation and free, prior, and informed consent. Both involve close interactions with communities around resource development projects and have become critical issues for the mining industry. Superficially, there appears to be much in common between a social license and FPIC. From an operational perspective, however, while there is convergence, there are also significant differences between them, with FPIC limited in scope and time to gaining permission to enter land and/or initiate a mining project. More specific definitions can clarify the distinctions.

The free, prior, and informed consultation version of FPIC is perhaps best expressed in the Performance Standards on Social and Environmental Sustainability of the International Finance Corporation (IFC), although it is widely incorporated into national regulations for environmental impact assessment and the permitting of mining projects. In the IFC performance standards, free, prior, and informed consultation is defined as "an obligation of private sector project proponents to engage with project affected populations in a process of consultation that is 'Free' (free of intimidation or coercion), 'Prior' (timely disclosure of information—in effect before any decision is made), and 'Informed' (relevant, understandable, and accessible information)" (IFC 2006). Guidelines accompanying the IFC standards indicate that the process of FPIC should lead to "broad community support," an aspect that is substantially similar to gaining a social license. However, the FPIC process is a specific action or series of actions limited to the period before a one-time decision is taken about a project and focuses on application to the provision of information about a project and its potential consequences.

The free, prior, and informed consent version of FPIC is rooted in two international instruments: the International Labour Organization (ILO) Convention 169, also known as ILO 169, and the United Nations Declaration on the Rights of Indigenous Peoples, or UNDRIP (ILO 1989; UNGA 2007). It is important to note that these instruments are directed to governments, not the private sector, and are limited to interactions with indigenous and tribal peoples. Nevertheless, they are of concern to the private sector because companies are typically the advocates for development projects and frequently introduce the idea of a mining project before any such discussion has taken place between government and the indigenous people. Therefore, as the initiators, companies should take care that discussions with indigenous communities do not proceed ahead of consultation between government and the indigenous people, neither in the timing nor direction of the content.

ILO 169, which has been adopted by 20 nations (the majority in Latin America), requires governments to "consult the peoples concerned…whenever consideration is being given to legislative or administrative measures which may affect them directly;…establish means by which these peoples can freely participate…at all levels of decision-making"; and stipulates that "the consultations…shall be undertaken, in good faith…with the objective of achieving agreement or consent to the proposed measures" (Article 6). With respect to mineral resources and mining projects, ILO 169 is quite specific in requiring governments to consult indigenous and tribal people "with a view to ascertaining whether and to what degree their interests would be prejudiced, before undertaking or permitting any programs for the exploration or exploitation of such resources pertaining to their lands" (Article 15).

UNDRIP includes a much stronger statement on free, prior, and informed consent in requiring governments to "consult and cooperate in good faith with the indigenous peoples concerned through their own representative institutions in order to obtain their free and informed consent prior to the approval of any project affecting their lands or territories and other resources, particularly in connection with the development, utilization or exploitation of mineral, water or other resources" (Article 32.2).

In summary, FPIC is limited in scope and timing to a period before exploration or development can take place, is linked to a one-time decision-making process, and, in the case of ILO 169 and UNDRIP, is an obligation of governments. In contrast, the social license to operate is an expression of the quality of the relationship between a private sector project/company and its neighbors. In terms of mining, this begins with first contact at the initiation of exploration and continues through the entire life of a project, which, if successful, includes mine construction, mine operation, closure, and increasingly into postclosure.

WHO GETS SOCIAL LICENSE AND WHO GRANTS IT

A social license is usually granted on a site-specific basis. Hence a company may have a social license for one mine or operation, but not for another. Usually the company has to have an operation that affects other groups, organizations, or aggregates of individuals. The bigger the effects, the more difficult it becomes to get the social license. For example, an independent Web-site designer working from a computer in his bedroom will normally get an automatic social license in most communities. A mining company wanting to relocate an entire village faces a much bigger challenge.

The license is granted by the *community*, a term used generically throughout this chapter to describe the network of stakeholders that share a common interest in a mining or exploration project and make up the granting entity. Identifying that the entity is a *network* makes salient the participation of individuals, groups, or organizations that might not necessarily be part of a geographic community, and recognizes the reality that communities are inherently heterogeneous. Calling them *stakeholders* means the network includes individuals, groups, and organizations that are either affected by the operation or that can affect the operation. For example, ranchers who would have to accept a land swap involving part of their pastureland would be affected by a proposed mining operation, without having much effect on it, provided they accepted the deal. By contrast, a paramilitary group of insurgents or an international environmental group that might attack the mine site, each in their own way, would *affect* the operation, without being affected much by it. They would be stakeholders too.

Use of the terms *community* and *stakeholder network* implies that the license is not granted by a single group or organization. It is a collective approval granted by a network of groups and individuals. Therefore, the existence of a handful of supporters amid a larger network of opponents would mean that the license has not been granted.

The requirement that the license be a sentiment shared across a network of groups and individuals introduces considerable complexity into the process. It invites the question about whether a coherent community or stakeholder network even exists. If one exists, how capable is it of reaching a consensus? What are the prerequisites a community must have before it becomes politically capable of granting a social license? These complexities make it more difficult to know when a social license has truly been earned. The complexities of the granting process are discussed later in this chapter.

COMPONENTS OF THE SOCIAL LICENSE

Accumulated experience supports the proposition made by Thomson and Joyce (2008) that the normative components of the social license comprise the community/stakeholder perceptions of the legitimacy and credibility of the mine or project and the presence or absence of true trust. These elements are acquired sequentially and are cumulative in building toward the social license. The mine or project must be seen as legitimate before credibility is of value in the relationship, and both must be in place before meaningful trust can develop.

THE BUSINESS CASE FOR INVESTING IN IT

Earning a social license to operate plays havoc with financial and engineering schedules. It involves a fuzzy relationship-building process that does not fit comfortably into technical planning frameworks that are built around concepts like material objectives, deadlines, and deliverables. So, why is this necessary?

The same question could be asked about safety. Doing safety training does not seem to directly contribute to the bottom line, so why bother? Several decades ago, health and safety was viewed in the same way that many people view social responsibility today. It was the responsibility of a specialist in the company. Accidents were accepted as the aspect of the job that justified higher pay. Today, safety is everyone's responsibility. The leading companies have systems in place to identify dangerous situations so that accidents can be prevented before they happen. The same will eventually be true for the social license. The leading companies will establish positive stakeholder relations before complaints and controversies erupt. Seeing the earning of a social license as an essential part of the project requires a higher-level perspective that is usually only the concern of executives and members of the board. However, project planners need to understand this bigger picture too, in order to allocate sufficient time and resources to earning a social license. The next two sections deal with this bigger picture.

Dependence on Resources Controlled by Stakeholders

It is an axiom of the mining industry that mines are made where mineral deposits are found. This truism reflects the fact that economically viable mineral deposits occur in relatively rare situations. As a result, the mining company has to adapt to the location of the deposit and engage with the people who live there and who consider the location part of their "backyard." By way of contrast, manufacturing industries can select the location for a new plant or facility based on a variety of factors, including the willingness of the local community to accept them. Indeed, during the first part of the decade, there was open competition between communities in North America to host new manufacturing and assembly plants and wholesale distribution depots.

Mineral deposits always have neighbors. Sometimes they have a village right on top of them. Roads always go through someone's land or affect someone's traffic or hunting ground or watershed. Even the most remote mines have to rely on the closest towns as supply centers and transportation links. The many ways that mines affect their neighbors make those neighbors stakeholders. However, the effects go in the opposite direction too. The mine can be affected by road closures, road use regulations, water rights negotiations, protests, blockades, and many other tactics that restrict access to essential resources. Even with the legal right to mine from a government, a company can still be stopped by a community determined to withhold the social license to operate. For example, in Peru alone, at the time of this writing, there were more than 80 sites where communities had prevented mining companies from exploring or exploiting mineral deposits.

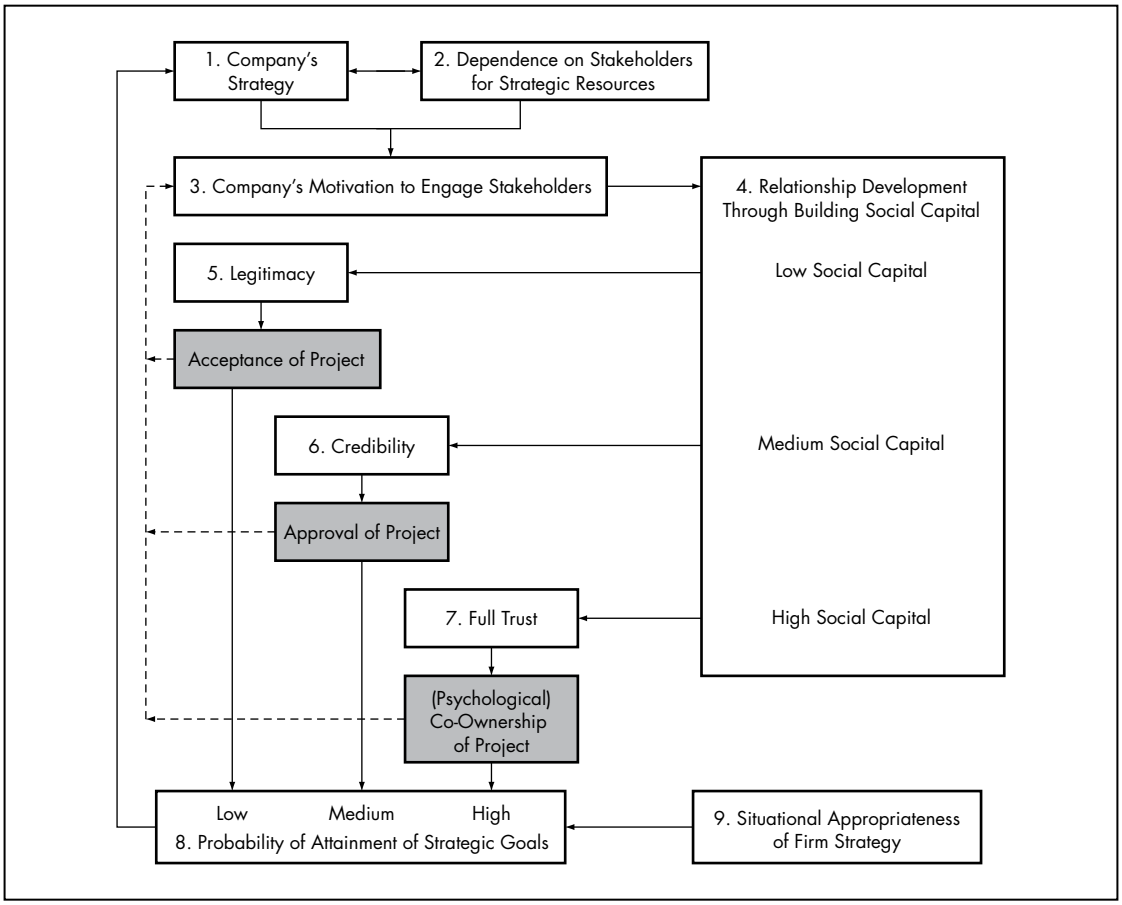

Figure 17.2-1 Adaptation of resource-based view to include process of gaining a social license to operate

The management theory that covers this type of challenge is called the *resource dependence* view of competitive advantage and the firm (Barney et al. 2001 provide a review). It explains why some companies thrived while others struggled. The theory emphasizes that companies need good relationships with those who control essential resources that are scarce, non-substitutable, or imperfectly imitable. That can include things like labor skills, some materials, risk financing, access to some markets, special legal permits, and, for mining, access to land and mineral deposits.

The Role of Strategy

Figure 17.2-1, shows the resource-dependence view augmented with acknowledgment of the role of strategy in setting priorities among resources. The chosen strategy (box 1) determines which resource-controlling stakeholder (box 2) must be dealt with. At the same time, because strategy is often based on existing strengths, the stakeholders the company can deal with best or worst influence what strategy will be chosen. Together, these factors identify the stakeholders with whom the company must engage (box 3).

Different Strategies at Different Stages of the Mine Life Cycle

Companies have different strategies for financial success at different stages in the life cycle of a mine. In the earlier stages of exploration and feasibility, the strategy is to buy the rights inexpensively, prove the richness of the deposit, and sell the property to a mine operating company. The financial gain depends on demonstrating the quality of the ore deposit (grade, tons, mineralogy, feasibility, etc.) and finding a motivated buyer who has the capital and knowledge needed to develop the property into an operating mine.

In the later stages, operating companies pursue a strategy of getting the property into production as quickly as possible in order to reap the financial rewards of selling the minerals from the site. Financial gain depends much more directly on the prices that mineral processors and industrial manufacturers are willing to pay for metals.

Mine builders want to buy properties that are fully permitted. They avoid properties at which stakeholders threaten to block construction or access to the deposits or other vital resources (e.g., water, power). Unfortunately, too many exploration companies think they can ignore or hide these kinds of stakeholder problems.

For example, from late 2003 to late 2004, the stock price for Monterrico Metals, a mineral exploration company, rose from around 150 to 600 pence per share on the London Stock Exchange. Drilling results had shown that the company had a world-class copper deposit at its Rio Blanco property in northern Peru, and the company was actively seeking a buyer to develop a mine. During 2005 and 2006, however, local peasants demonstrated against the development. A group of academics and British parliamentarians known as the Peru Support Group went to Rio Blanco to investigate. Their findings noted a permitting dispute between two Peruvian government bodies and, more particularly, widespread community

opposition (Bebbington et al. 2007). The news of the apparent absence of a social license was followed by fall in share prices with their value ultimately dropping almost 70%. In early 2007, a Chinese mining company bought control of the company amid complaints from some Monterrico investors about the low price being paid. At the time of this writing, the project continues to be mired in conflict and there is no indication that a mine can be developed in the near future. In retrospect, the Monterrico investors should be satisfied with the price paid by the Chinese, but they have also learned the hard way that a social license to operate has a financial value when a buyer is sought to develop the property.

Identifying Stakeholders Based on Strategy

Boxes 1 and 2 in Figure 17.2-1 cover the criteria for identifying stakeholders. Those who will be *affected by the company* are implicated by the company's strategy (box 1). Those who have the potential to *affect the company* are covered by the company's dependence on others for resources (box 2). The combined set represents the stakeholders with whom the company should establish relationships.

When an exploration team determines that there is an interesting deposit, the activities in the first three boxes transpire. The team must identify by name local stakeholders who make up the community and then determine who speaks for each stakeholder group as an opinion leader in relation to the project. When the exploration team first introduces itself to those stakeholders, the social capital in the firm-stakeholder relationship is very low (box 4). The social capital dimension of stakeholder engagement and relationship is explored later in this chapter. For now it is sufficient to think of social capital as the collaborative capacity in the relationship.

The pivotal role of relationship building (box 4) implies that a policy aimed at keeping a low profile raises the sociopolitical risks associated with the project. This is especially true during the earlier stages of the project. If the company does not engage with all elements of the community, there is no way the community can collectively grant a social license. If relationship development is delayed, the social license will also be delayed, usually at a high financial cost to the company. Thus, anyone who argues that there is no time for a lengthy relationship-building process with the community is unwittingly advocating for lengthy delays to be imposed by the community.

Building Social Capital and Earning Higher Levels of Social License

Engagement entails the building of a relationship with the stakeholders, who are often already organized into a geographically based network (the community). If the relationship proceeds well, the community may view the company as legitimate (box 5 in Figure 17.2-1) and may grant a provisional/conditional social license (gray box, "acceptance of project").

Acceptance of the project can heighten the company's motivation to engage with the stakeholders, provided the company realizes that this is an investment in raising the probability that corporate strategic goals will be attained. Because not all companies realize this, the line feeding back to a company's motivation (box 3) may be dashed. Assuming the company does choose to build more social capital in the relationship, the community will come to see the company as credible (box 6). Consequently, it will grant full approval of the project (gray box, "approval of project"). Ideally, the relationships should evolve to this point before the company embarks on the feasibility and permitting stages of a project.

Probabilities of Success

If the company continues to put effort into the relationship (dashed line to the left in Figure 17.2-1), it can raise the probability of realizing its strategy and lower the inverse probability of sociopolitical risk. Taking the relationship to the level of full trust (box 7) yields exponentially more benefits for the project and the parent company. At that point, the social license reaches the level of "psychological co-ownership." This will result in the success of the project, provided that the company chose a winning strategy in the first place. Outside factors, however, like the price of metals, can always stop a project (box 9).

Figure 17.2-2 shows how the process of earning a social license to operate impacts a company's bottom line. *No access* means "red ink." Good access makes "black ink" possible, provided all other aspects of the project are positive. Although the relationship-building process might sound at first like a nonessential nicety, it is in fact a make-or-break factor for the successful development of a project. Every continent has its "off limits" mineral deposits that represent projects which failed at the relationship-building stage.

Dynamics of Stakeholder Influence in Networks

Some stakeholders have legal powers to affect the company. Governments, for example, can often act unilaterally to impose conditions or restrictions on mining activities. Most stakeholders, however, have their effects through political maneuvering. Some have direct control over the resources the company needs. They can exert influence by restricting access to those resources through tactics like prohibitive pricing, blockades, and boycotts.

Still other stakeholders have no legal power and no direct control over essential resources. They can, nonetheless, form alliances that pressure those with such direct power to act in solidarity with them. Environmental and human rights groups, for example, usually fall into this category. They often use tactics such as putting pressure on senior governments to change mining regulations or on municipal governments to withhold resource access (e.g., water) or on consumers to boycott the product (e.g., the blood diamonds campaign).

Because political alliances among stakeholders often determine their level of influence, it is important to know about those networks in order to identify the stakeholders who deserve more attention. Methods for acquiring this kind of information are discussed later in this chapter. For the moment, it is simply important to recognize that the sociopolitical dynamics in the stakeholder network do affect the project's support among stakeholders. Thus, acquiring a social license to operate is partially a sociopolitical task.

Resource Access Restriction at the Corporate Level

Stakeholders can also have influence over a project in less direct ways. For example, they can exert pressure through control of access to local resources; they can also affect access to the resources that the parent company needs. The local project may or may not be constituted as a subsidiary company of a larger company. In any case, the "parent(s)" sponsoring the project also needs resources. These include equity or debt

financing, new highly trained employees, access to minerals at other sites in the future, and willing customers.

Stakeholders sometimes restrict the parent company's access to those resources by launching national or international campaigns that damage the company's reputation. The effect on share value, for instance, can restrict access to equity financing, which is particularly damaging to junior exploration companies, but can also affect operating companies. A company with a negative reputation will also have more trouble attracting talented employees. If the international campaign includes a consumer boycott (e.g., the dirty gold campaign), the pool of willing customers will shrink and income could be depressed. A bad reputation in community relations can also limit the number of sites a company can have access to in the future, no matter whether they are greenfield sites or acquisitions.

At the international level, the absence of a world government to regulate mining has led to the creation of a world governance regime instead. This network of international agreements, standards, and principles is supported by organizations that frequently finance mining projects, including the IFC and the banks that have adopted the Equator Principles (EPFIs 2006) as criteria for project financing. They stand ready to legitimize the complaints of local stakeholders and impose a variety of sanctions against the offending company. Again, these affect the parent company's reputation and access to money, talent, willing customers, and even further national legal permits.

In summary, earning a social license to operate is necessary for protecting the financial viability of the project and the company. It is as deserving of time, money, and career prestige as drilling to estimate ore reserves or preparing quarterly financial statements.

PHASES OF EARNING A SOCIAL LICENSE

A social license has distinguishable levels. At the same time, the process of moving from one level to another can be thought of as a smooth gradient of continuous relationship improvement through increasing social capital.

Figure 17.2-2 shows the four levels of social license and the three boundary criteria that separate them. The levels represent how the community treats the company. The boundary criteria represent how the community views the company, mostly based on the company's behavior. These transition criteria were derived from language repeatedly heard from communities themselves. Although the terms *legitimacy*, *credibility*, and *trust* emerged out of years of conversations while consulting with mining communities, social science and management literature has been shown to support these common-sense views.

The levels and boundary criteria are arranged in a hierarchy. It is possible to go both up and down the hierarchy. For example, if a company loses credibility, approval will be withdrawn and the project will hobble along on acceptance only. If a company loses legitimacy, the project will be shut down. If full trust is gained, the community will support and protect the project as its own.

Withholding/Withdrawal Level

Starting from the base, the rejection level of a social license is the worst-case scenario. This is when the community stops progress on the project. Many mineral deposits cannot be exploited because the community does not grant any level of social license to proceed.

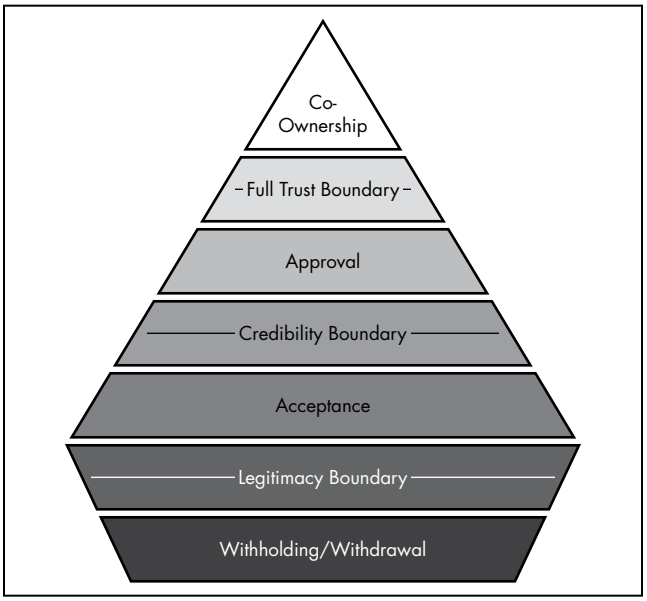

Figure 17.2-2 Levels of social license with boundary criteria between them

The withholding/withdrawal level is shown as narrower than the acceptance level above it in order to symbolize the possibility that, globally, more projects are accepted than rejected. However, at present, this is a supposition. The empirical studies to determine the correct width of each level in Figure 17.2-2 have yet to be done.

Legitimacy Boundary Criterion

The academic meaning of the term *legitimacy* is evolving as interest grows in how organizations gain or lose it, and what they can do with it once they have it (Deephouse and Suchman 2008 provide a review). Knoke (1985) defines legitimacy in the context of stakeholders and politics as "the acceptance by the general public and by relevant elite organizations of an association's right to exist and to pursue its affairs in its chosen manner." This adequately summarizes the bare minimum of legitimacy even when the company has no social license. Suchman (1995) offered a typology in his definition, which has become a touchstone for scholarship on legitimacy. He proposed a three-category typology of "legitimacies." They were (1) pragmatic, based on audience self-interest; (2) moral, based on normative approval; and (3) cognitive, based on comprehensibility and taken-for-grantedness. Each of these has aspects that continue to be important through higher levels of social license. For each type, the community asks itself questions such as the following:

- What do they want, and what is in it for us? How will the consequences of their actions affect us? How will the project affect the environmental resources we absolutely depend on for survival? If we cannot know that for sure, then can we at least discern whether they will be responsive to our concerns, or even share decision making with us? (Pragmatic legitimacy)
- Does anyone in authority recognize/respect us? Are they conforming to our social, cultural, or political norms? Have they followed the specific norms for approaching us with their proposal? Will the consequences of their

activity promote the general welfare of the community, according to our (i.e., the community's) own values? (Moral legitimacy)
- Does what they say make sense, or is it confusing or strange? Has this been done anywhere else? Are their proposals routine practice, or is this uncharted territory? Does that company have the capacity to do what they say they could do? In the case of an expansion of an existing operation, it is precisely the absence of questioning that indicates cognitive legitimacy. This occurs when the presence of the company and its activities are already taken for granted. They are seen as an inevitable part of the community economy. (Cognitive legitimacy)

In addition, particularly for mining exploration projects, the community may also ask questions about legal legitimacy. Do they have the legal permits and permission to do what they want to do?

The behaviors that lead to a company's gaining legitimacy are associated with spreading awareness about the company and what it does, listening to community concerns, and following the official and unofficial local norms, customs, and practices. The company should also have legal status nationally, inform the general public about how the proposed approach has worked for the benefit of other communities elsewhere, and solicit participation in planning and decision making in order to allay fears about the company implementing an arbitrary, uninformed, or high-handed development process.

Failure to engage all segments of the community (e.g., young, old, men, women), to inform them and to solicit their opinions, is often seen as evidence of illegitimacy by those excluded. It is normally important to communicate directly with the bases and not rely solely on leaders. At the same time, following local norms and protocols requires an understanding of, respect for, and use of local social structures and decision-making processes.

Acceptance Level

When legitimacy is established, the community response is that they will listen to the company and consider its proposals. If, by their own standards, they have no reason to doubt the company's credibility, they may allow the project to tentatively proceed. This constitutes the acceptance level of social license. It is a minimal objective for any company.

As can be seen in Figure 17.2-2, the acceptance level is bounded by the legitimacy criterion and the credibility criterion. This represents how acceptance requires that the company's legitimacy must be firmly established and its credibility should at least not be damaged.

Credibility Boundary Criterion

Credibility is the foundation of trust. When a company is regarded as credible, it is seen as following through on promises and dealing honestly with everyone. There is little danger of the company saying one thing one year and a different thing the next. Moreover, the company's policies are the same for everyone that it deals with.

The promise-keeping aspect of credibility is related to the company's responsiveness to community concerns and requests. Legitimacy can be earned by just listening; credibility requires doing something about what has been heard. Community members need to see action following their discussions.

An essential component of credibility comes from openness and transparency in the provision of information and decision making that demonstrates the company to be consistent in the way it treats different groups. Alternatively, transparency reveals the principles that determine why one group might be treated differently than another, reducing the risk of feelings of discrimination or marginalization.

The community asks itself questions such as these:

- Will they deliver on their promises? Are they living up to their responsibilities? Are they acting yet on what we have already said concerns us? Do their promises sound unrealistic?
- Do we understand why they treat some groups differently and how that is consistent behavior?
- Are they keeping any secrets? Do they avoid contact or avoid answering certain questions? Do they acknowledge difficulties or do they often sound glib?

Establishing credibility involves the cycle of listening to the community, responding with information and proposals, and implementing approved proposals. Demonstrations of responsiveness and principled action on a number of quick, short-cycle initiatives help to build a reputation for credibility in the early stages. There is pressure to show immediate benefits, as opposed to long-term promises. The planning horizons in rural communities seldom reach beyond one agricultural cycle. By contrast, exploration teams may make promises to be fulfilled by the future buyers of their properties.

In communities, credibility rests in a person's willingness to keep one's word. This is a significant challenge for the credibility of an exploration company that does not expect to be around when its promises are to be fulfilled. Many communities are suspicious of anyone who intends to transfer responsibility for stated promises to some unspecified, hypothetical person who may or may not even appear in the intangible marketplace for mineral deposits.

To earn credibility, the company should make and keep short-term promises. This is best done by using participatory processes to identify community priorities that the company can help make real. It helps to bring in third parties to verify the truth of company statements and to empower the community to be the watchdog on the company's activities (e.g., community-based environmental committees). Formal agreements and contracts give structure; manage expectations; avoid misunderstandings; and define rules, roles, and responsibilities. Providing false or incomplete information or failing to deliver on promises will quickly destroy credibility and lead to questions as to whether the company is even legitimate. Acceptance can be rapidly withdrawn.

Because companies usually carry so much economic clout, they are often expected to provide the kinds of services that are provided by the government in the developed world (e.g., education and health care). In contexts where governments have not provided these, a company's reluctance to talk about them may be taken as a sign that the company cannot be trusted to make an effort around basic community needs. The best way to address these expectations is with programs to help governments develop the capacity to shoulder such responsibilities. This shows a concern for the problems and a respect for local institutions. It avoids the trap that occurs

when governments decide they do not need to do anything because the company is taking care of the community.

Even when relations with the community are good, there may still be attacks on the credibility of exploration companies from civil society sources that warn about the broken promises or social or environmental problems experienced by other communities that accepted mines. Even if some of these stories are false or exaggerated, the sources are credible because they do not appear on the surface to have anything to gain from misrepresenting the facts. When it is their word against a company's word, the company appears to have the greater motive to distort the truth.

Approval Level

When a company has established both legitimacy and credibility, a community is likely to grant approval of the project. This means the company has secure access to the resources it needs. The community regards the project favorably and is pleased with it. The community is now resistant to the "us-versus-them" rhetoric of antimining groups.

This level of social license represents the absence of sociopolitical risk. However, it is really only at the threshold of opportunity. Moving toward the top of this level, as represented in Figure 17.2-2, a company can begin to reap some positive benefit from their relationship building, such as strong community support for expansion of operations.

Full-Trust Boundary Criterion

In management research, trust has been shown to be important in relationships between and within organizations. It is just as important in relationships between organizations and stakeholders. Trust is especially important when bridging the boundary between businesses and civic sector organizations, which include many community groups.

Many typologies of trust have been proposed, some of which range from weak or superficial trust to deeper, more comprehensive trust. As used here, the term *full trust* means a broader and deeper trust.

Credibility is a basic level of trust related to honesty and reliability. A full trust relationship is one where there is a willingness to be vulnerable to the actions of others. Communities that have a full level of trust in a company believe that the company will always act in the community's best interests. Before moving to that level of trust, a community asks itself questions such as these:

- Have they fulfilled their promises repeatedly and consistently?
- Did they handle the unexpected problems in a way that showed they had our best interests at heart?
- Did they share power in a partnership approach?

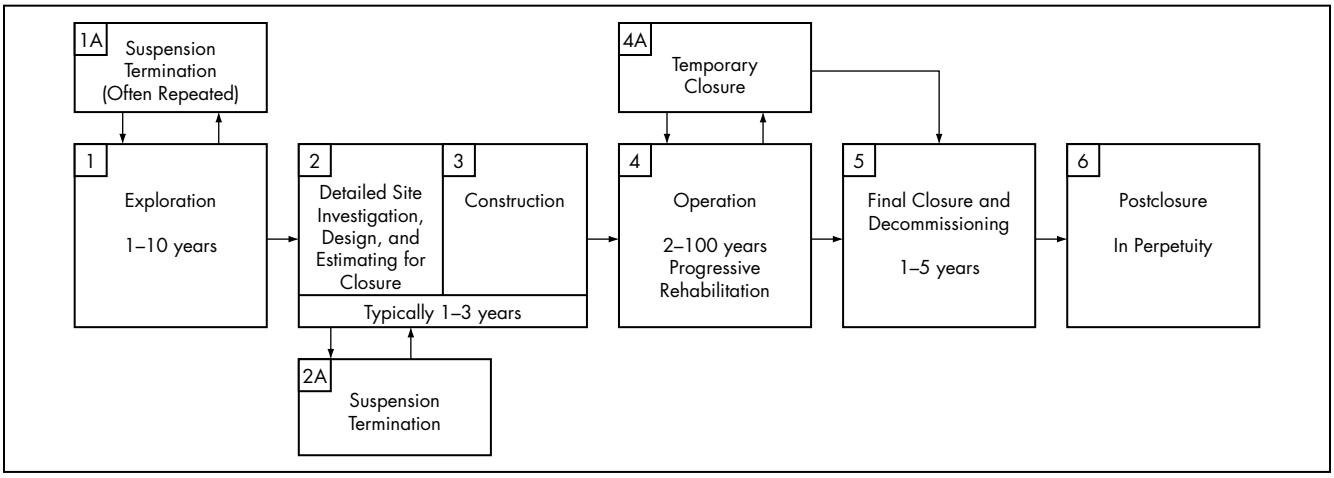
In order to gain full trust, a company has to go beyond fulfilling its promises to jointly envisioning new development goals with the community. The company will have initiated activities to strengthen the community's ability to plan and achieve its goals for the future. For example, this can involve training in project management for local nongovernmental organizations (NGOs) or technical training for government employees. The company has managed to explain its decision-making principles to the degree that people accept rejection of proposals calmly because they trust the decision makers.

When fulfillment of a promise will be delayed, the company explains why and asks the community for ideas about how to overcome the obstacles to fulfillment. Whenever possible, the company involves community groups in decision making to ensure that no opportunity for capacity building and economic development is missed. The company hands over responsibility for specific aspects of the project to the community so that it takes ownership of both the opportunities and the risks.

Trust is the much desired quality in a relationship that is only earned over time and typically emerges as the product of shared experiences that have positive outcomes for all parties. Trust is hard to earn, easy to lose, and very difficult to recover once lost.

Co-Ownership Level

When the community sees the company as having full trust in it, the community takes responsibility for the project's success. Psychologically, both parties come to view it as a co-ownership arrangement. The limits of the responsibilities of each party are clear, as are ultimate decision criteria.



At this co-ownership level of social license, the company becomes an insider in the community social network. In social sciences, social identity theory describes this level of relationship as the dissolution of the us–them boundary (Williams 2001). Working closely together, the company and community often develop creative solutions to all types of challenges. If outside stakeholders, like the national government or an international NGO, move against the interests of the company, the community will mount a campaign in defense of the company. There have been cases where community members have traveled to foreign countries to challenge false information being promoted by NGO critics. In another case, community members marched on the national capital to make a point to politicians who were proposing a new tax that would affect the mine.

Few companies have taken their community relations to the co-ownership level. Many have difficulty seeing beyond the immediate transactions to the much greater benefits of establishing strong collaborative relationships. Nonetheless, as awareness of the potential benefits grows, more companies are attempting to win a higher level of social license.

MINE LIFE CYCLE AND FIRST IMPRESSIONS

The level of social license that a company enjoys can fluctuate throughout the life cycle of a project. Figure 17.2-3 shows the six stages of the mine life cycle: (1) exploration, (2) feasibility, (3) construction, (4) operation, (5) closure, and (6) postclosure. Obviously, the earning of an initial social license to operate has to be complete before construction begins (stage 3). However, in the past many companies have treated it as an afterthought sometime during the feasibility stage (2). Experience shows that ignoring the social license matter during exploration only creates problems in later stages.

In the first two stages, the key issue affecting the social license is access to land for exploration and feasibility studies. The exploration stage is especially important because that is when first impressions are made. It is a challenging period that can affect community relations during the whole mine life cycle. A positive relationship can lead to the early acquisition of a social license. If that is maintained, it can create the tolerance and mutual understanding needed to deal with conflicts and different interests during the whole life of the mine. Conversely, bad relationships during exploration can lead to social tensions, conflict, and premature shutdown of the project.

Figure 17.2-3 Stages of the mine life cycle

A DIFFERENT STARTING POINT IN EVERY COMMUNITY

First impressions are important, but the preexisting disposition to trust also matters. Some societies are less trusting than others. Figure 17.2-4 shows percentages of generalized trust by population in selected countries from a survey by Delhey and Newton (2005). Obviously, earning a social license in Brazil would be much more difficult than in Norway. The reasons for these differences are not entirely clear, but there are suggestions that lower trust of people in general might be associated with fractionalization in terms of income inequality and political diversity and with higher levels of commitment to family, as opposed to the collective society.

In addition to these cultural factors, each community has its own history. Some have had negative experiences with previous operators of a mine or exploration project. Some have had bad experiences of a more general nature, such as exploitation by foreign companies or governments during colonial times. In many developing countries, there is still suspicion of corporations from developed countries as a result of the Third World debt crisis that followed World Bank policies aimed at encouraging developing countries to imitate rich countries.

All of these factors affect how long it will take to earn a social license in any particular community. Just because it took 18 months to earn enough of a social license to buy land in one community, it cannot be assumed that the next community will require the same amount of time.

DIFFERENT CULTURES, DIFFERENT EXPECTATIONS

There are profound cultural differences between corporations and communities, especially communities that are rural and operate at subsistence level. Companies tend to expect communities to be coherent, cohesive, rational economic actors with a keen sense of judicial impartiality regarding the issuing or revoking of a social license. However, cultural differences can radically redefine the meaning of these qualities. The community's perceptions are filtered through their world view. For example, the Dongria Kondh tribe, in the state of Orissa, India, consider their mountain sacred and view the bauxite mining proposal by Vedanta Resources as an assault on all that is good and holy (Survival International 2008). In these cases, the company must decide if it should withdraw, and avoid the risk of conflict, or invest in working with the community and other stakeholders over a longer period with the hope that a creative compromise can be found.

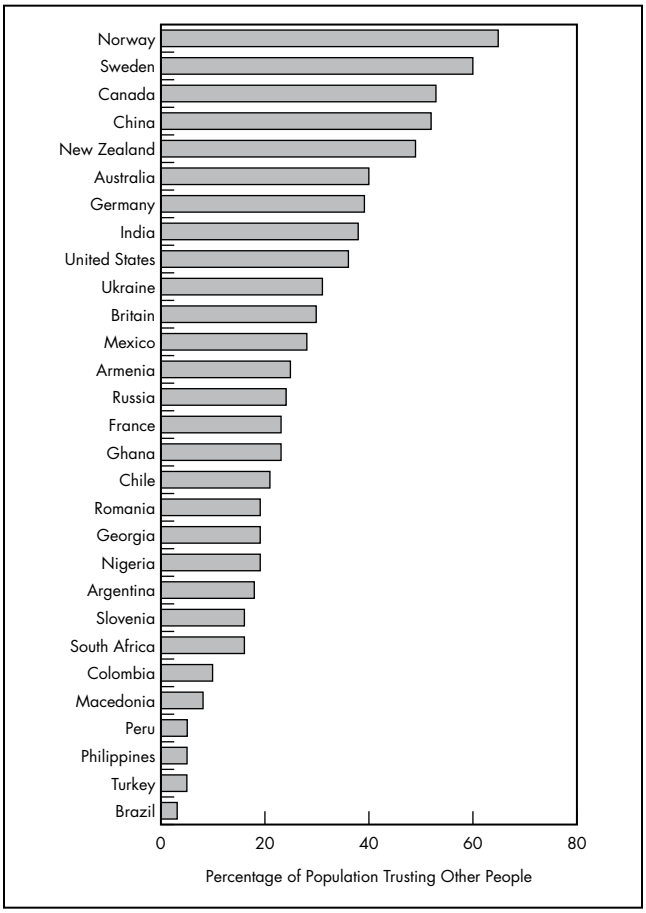
Many rural communities work on the tribal principles of personal authority and obligations to relatives. Such communities may see profit making as proper for the benefit of a family or community but improper for the benefit of any other body, from individual to company to state. In these societies, all companies, except family and community-owned businesses, start out as morally illegitimate because of the way they treat money and resources.

In many rural communities, nepotism is seen as commendable, not condemnable. Being seen as legitimate entails a willingness to treat community members like family. The company is expected to hire on the basis of local residence, rather than qualifications. Becoming qualified is seen as something that comes after being hired, rather than before.

Time is a common point of difference. Companies want things to happen according to a firm schedule, usually related to a budget. Communities, on the other hand, react organically, take time to reach decisions, and typically have no concern for the schedule set by the company.

THE LOW-PROFILE FALLACY

Earning a social license is complicated work. Occasionally companies are tempted to opt for a strategy that seems easier. They decide to keep a low profile or "stick to their knitting," especially in the exploration stage. This, of course, makes establishing legitimacy, credibility, and full trust quite impossible. The following anecdote describes the consequences.



> In July 2002, Meridian Gold, Inc., completed its acquisition of Brancote Holdings and took possession of the Esquel gold deposit, an exploration project located in the Cordón de Esquel in northwestern Chubut, Argentina. At the time, the concept of developing a mine at the Esquel gold deposit enjoyed general acceptance in the nearby town of Esquel as a result of successful efforts by Brancote to develop a positive relationship with the community. However,

popular sentiment changed very quickly as Meridian failed to respond to requests for information and assistance, and as local permitting authorities expressed a lack of confidence in the company and its actions. Over the following months, the situation became more polarized with the formation of community-based groups organized to seek information and clarification from the company on various issues. In the absence of replies that satisfied these community groups, an organized opposition to the idea of a mine formed in the town. Various protests, marches, and meetings took place with a common theme of "No to the Mine." Attempts to reach a solution through dialogue led by the Church failed to gain any momentum and, under increasing pressure from the local population and growing national and international opposition to the project, the mayor of Esquel authorized a plebiscite on the future of the proposed mine development. On March 23, 2003, the population of Esquel voted 81% (of a 75% turnout) against the mine. In a subsequent independent investigation by Business for Social Responsibility (2003a), it was noted that the Esquel gold mine project was characterized by a lack of engagement by Meridian with the community. This lack of engagement and the inability to have a meaningful dialogue about potential risks (and benefits) was the dominant factor influencing the community not to support the mine. In practice, the company did not provide timely and useful information, and on occasion made it difficult to obtain information, for example when the company refused to provide copies of the environmental impact study, a public document, available in CD format. What community members wanted was to feel informed and listened to, to participate in a real dialogue, and for the company to be responsive to their concerns. In short, the community wanted a partnership, something that the company never attempted to deliver (Business for Social Responsibility 2003a). The collapse of the Esquel project was financially disastrous for Meridian, with the company obliged to take a write-down of US$542.8 million. As of June 2009, the project remained frozen with a majority in the community firmly opposed to any form of mineral exploration or mine development.

Such scenarios are becoming more frequent. They are not always caused by a failure to talk to the community stakeholders. In most of these types of cases, the exploration teams have held community meetings. They have explained their plans. The community representatives showed approval for the projects. So what went wrong? Why do things so often fall apart?

Practical experience points to a number of problems created by the exploration team themselves. The most common problems are as follows:

- A failure to invest fully in relationship building, an approach generally justified by the knowledge that most exploration projects fail. Explorers often choose to delay full engagement with stakeholders until the "right moment" or when there is certainty that the project will go ahead.
- Selective engagement. Talking only to those who are already friendly toward the project creates a group marginalized from information and participation that may well respond by rejecting the project.
- Undermining the company's credibility by failing to deliver on promises already made or by providing false or incomplete information.
- Failing to understand the internal structure of the community and existing relationships between stakeholders and thereby unwittingly creating or amplifying rivalries or divisions that lead to conflict.
- Failing to respect and listen to the community and relying on legal positions and permits to operate.
- Failing to maintain close contact with the community when there is a change in project management or ownership, thereby weakening the continuity needed to sustain the social license.
- Misunderstanding, usually overestimating, the quality of the relationship with the community by confusing acceptance with approval, and cooperation with trust.

Source: Data from Delhey and Newton 2005.

Figure 17.2-4 Percentages of generalized trust for selected countries

The last pitfall is particularly pernicious. Individuals and groups will cooperate with the company for many reasons, including courtesy, a desire for gain, a perception of having no alternative, or, as is often the case with authorities, a sense of obligation. Cooperation for these motives does not necessarily require a trusting relationship.

MAINTAINING A SOCIAL LICENSE

The four-level-phase view of earning a social license is simplistic. It helps mark progress and breaks the process into a practical, phase-like approach. It also highlights important pitfalls. However, every community and stakeholder network is unique in some ways. There is no one-size-fits-all process for earning a social license. There is always a need to adapt and adjust to the specifics of each case. For that reason, it is also important to understand the theoretical process underlying the phases. Any necessary adjustments and adaptations can then be derived from first principles.

Continuous Building of Social Capital

The movement from legitimacy through credibility to full trust is a process of building and balancing the social capital in the relationships between the company and the members of the network.

Definition of Social Capital

Adler and Kwon's (2002) definition of *social capital* says, "Social capital is the goodwill available to individuals or groups. Its source lies in the structure and content of the actor's social relations. Its effects flow from the information, influence, and solidarity it makes available to the actor." In other words, the effects of social capital flow from what it is, namely, information, influence, and solidarity.

Examined more closely, social capital can be seen as a set of benefits that network members can enjoy because of their unique patterns of connections in a network. (In social network analysis, the technical terms for connections in a network is *ties.*) The benefits fall into three general categories. First, social capital is access to the *information* that flows through the network. People who act as bridges between otherwise unconnected clusters of network members are especially likely to enjoy this type of benefit. They have "bridging" social capital. Second, social capital is *solidarity* in support of group norms and shared identity. For example, members of immigrant communities often stick together and police one another's behavior for mutual protection and benefit. This is an aspect of "bonding" social capital. Third, social capital is *influence* in the network. Those who have a good balance of bridging and bonding often enjoy a greater capacity to solicit assistance and resources from others, whether it is for a sociopolitical purpose or a more personal goal.

Sources of Social Capital

Adler and Kwon (2002) say the source of social capital is in the structure and content of the social relations of network members. The structure refers to the network pattern—a bridging or bonding pattern, for example. The content refers to qualities of the relationships between pairs of network actors. Adler and Kwon drew upon a set of distinctions proposed earlier by Nahapiet and Ghoshal (1998), who also identified a *structural* source of social capital, but divided the content into two distinct sources, the *relational* and the *cognitive*. The relational source encompasses qualities like reciprocity, mutual trust, and shared identity. The cognitive source covers shared language, shared problem-solving paradigms, common strategies, and even shared goals and values.

By cultivating these three sources of social capital simultaneously, a company can raise social capital in the community. Then it can "cash in" the social capital for a social license to proceed.

Tapping Sources of Social Capital Across the Phases

Developing the Structural Source of Social Capital

The structural source of social capital deals mostly with the patterns of connections in a network. For example, many networks have a core-periphery structure. The members at the core are well connected and influential. The peripheral members are more isolated with less access to resources. The structural dimension also deals with the strength of each tie. In a community network, for example, the groups or individuals with many weak ties will have access to a greater variety of information than others who have only a few strong ties. However, those with strong ties will be more capable of collaborating with one another to get things done.

When company representatives first arrive in a remote community, they begin forming ties with the network of community stakeholders. In the process of everyday transactions, they form very weak network ties with the hotel desk clerk, the restaurant owner, and the taxi driver. Since these people are all well embedded in the community, these ties represent bridges between the community network and the company's internal network. The leftmost panel of Figure 17.2-5 shows one thin line going from the company (i.e., the solid circle) to one rather central member of the community network. This is meant to represent a bridging relationship between the company and community. With nothing more than a weak bridging relationship in the community, the company is a peripheral member of the community network.

As the project proceeds, the company's presence grows in terms of numbers of representatives and in numbers of contacts with community members. Some of these relationships deepen. The company goes from having bridge relationships, to actually being a semiperipheral member of the community network. At this point, the company may also have created enough trust (relational source of social capital) and understanding (cognitive source of social capital) to be able to use its social capital to get an acceptance level of social license. The network structure would look something like the middle panel of Figure 17.2-5, where the original line representing the relationship formed in the leftmost panel becomes thicker in order to represent a stronger relationship.

The rightmost panel of Figure 17.2-5 shows the company as a member of the core of the community network. In this position it has considerable influence in the community and much more ready access to community-controlled resources. This would be a typical pattern for a company with an approval level of social license.

Developing the Relational Source of Social Capital

The relational source of social capital includes related qualities of social interactions like reciprocity, shared identity, and trust.

Reciprocity. Reciprocity begins with the simplest of courtesies in polite interaction. In many cultures this quickly involves mutual gift giving. As relationships develop, it is most prominent as various kinds of mutuality, including mutual respect and mutual self-disclosure. Reciprocity shades into generalized trust when the parties forgo immediate advantages to themselves in favor of actions that support the long-term interests of the group or of the bilateral relationship. This shows reciprocity because it requires a faith that such sacrifices will be reciprocated by others. In this way, reciprocity contributes to the solidarity benefit of social capital.

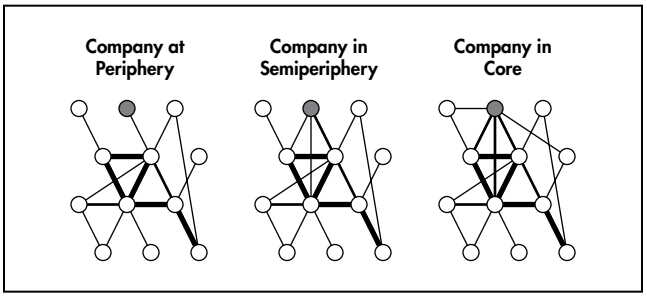


Figure 17.2-5 Structural dimension of social capital at each stage of the social license

Shared identity. Shared identity is important in preventing us–them dynamics from taking root. Members of stakeholder groups all share an identity by virtue of their membership in that group. Likewise, company representatives share an identity, especially in their roles as representatives. Two strategies can be used for avoiding intergroup conflict in such situations.

First, ties that cut across groups insulate members of each group from viewing members of the other group as "them." Crosscutting links either bilateral relationships or group memberships (that include people from both the stakeholder group and the company). For example, some company employees and stakeholder group members might both attend the same church and participate cooperatively in events there.

The second strategy is to heighten the salience of group memberships that completely encompass both groups. For example, both stakeholder group members and company employees might be citizens of the same country. Appeals to nationalistic sentiments can dissolve intergroup rancor and focus people on their shared interests.

At the highest level of social license, psychological coownership, the community, and the company share an identity centered around the industry itself. This happens, for example, when a community starts describing itself as a "mining town."

Trust. Trust is a very important aspect of the relational source of social capital. As Figure 17.2-5 shows, a company will start at different levels of trust even before any relationship begins. Early in relationships, trust is based more on calculations of risks and benefits and is limited to specific short-term transactions. Later on, trust comes to be based more on knowledge of the other party gained from experience over a period of time. Trust grows as the other party consistently keeps promises and demonstrably acts in the interests of the perceiver. This knowledge-based trust is important for gaining the acceptance level of social license. Companies can foster this kind of trust early by taking every opportunity to listen to the community and respond quickly (Svendsen et al. 2003).

Developing the Cognitive Source of Social Capital

The cognitive source of social capital comes from mutual understanding and agreement between the parties in a relationship. At the most basic level, speaking the same language creates a modicum of social capital. The level of language, however, is just as important. Companies must always use nontechnical language in their communications with stakeholders, even when it means using more words or losing some nonessential precision in meaning.

At a more abstract level, parties might use the same cognitive tools for approaching problems. For example, if both community stakeholders and the company habitually use strategic planning frameworks like cost–benefit analysis, strength-weakness-opportunity-threat analysis, critical-path analysis, and decentralized decision making, then they will enjoy more social capital together. More often, the stakeholders do not share these cognitive frameworks with companies. In those cases, both sides need to learn each other's ways of approaching collective action tasks. As the community learns the company's analytic techniques, it gains capabilities that it can use to achieve whatever goals it sets for itself, whether those goals are poverty reduction, ecological footprint reduction, or general community development.

Quite often the issues on which firms and stakeholders must develop a mutual understanding concern the general direction of future development in the community. Community stakeholders want to know what life will be like after the mine opens or after the mine closes. They need to know about downsides such as population influx and the possibility of more crime. For its part, the company wants to know what the community's priorities are for future development. Balancing short- and long-term interests here means not promising too much just to get an acceptance level of social license. In these cases, a future visioning process is in order. The process helps set planning priorities and taps the cognitive source of social capital.

How the Sources Work Together

Although the sources of social capital can be described as distinct, in practice they are intertwined in every action and activity. Likewise, the stakeholders' perceptions of legitimacy, credibility, and full trustworthiness develop organically along with the structural, relational, and cognitive aspects of the relationships.

Structural with Cognitive

Speaking the same language allows more communication to occur in the same amount of time. Inversely, communicating more frequently tends to create a shared set of understandings and frameworks. Shared understanding contributes to credibility because the stakeholders understand more thoroughly how mining works. Understanding, of course, also contributes to the cognitive aspect of legitimacy.

Structural with Relational

The gradual integration of the company into the stakeholder network (e.g., Figure 17.2-5) begins to create a shared identity. The community gradually sees the company as a fixture in the network. As crosscutting ties increase in number, a shared identity can emerge, thus tapping into the relational source of social capital. Likewise, any preexisting shared identity can facilitate the company's integration into the local network. For example, a local or domestic company might be able to create and strengthen ties more easily within the network.

Integration into the network builds legitimacy. Early in the process it creates the awareness and helps spread understanding needed for cognitive legitimacy. Later it contributes to the taken-for-grantedness of the company's presence, a more advanced form of cognitive legitimacy. Similarly, building trust, reciprocity, and shared identity contributes to moral legitimacy. Cognitive understanding contributes to pragmatic legitimacy, and vice versa.

Relational with Cognitive

A future visioning process affords an opportunity for the company to demonstrate honesty, transparency, concern for the community's priorities, respect for the community's leaders, responsiveness, and a willingness to share decision making on matters of mutual concern. All of these, in various proportions, contribute to stakeholder perceptions of legitimacy, credibility, and trustworthiness.

Often the process of coming to hold shared goals and visions for the future entails putting oneself in the other party's shoes. This can be difficult, but social capital from the relational source can make it much easier and often overlaps with the mutual perspective-taking feat (e.g., shared identity).

Dynamism in the Process

The levels of social capital in the firm–stakeholder relationships can fluctuate through the life cycle of the mine. Some of the determining factors may be beyond the control of either or both parties. More often, the actions of one or both parties raise or lower the level of social capital, with predictable effects on the level of social license. An example from an actual mine illustrates the point.

Figure 17.2-6 provides a graphical representation of the condition of the social license for the San Cristobal project over a 14-year time period from 1994 to 2008. Today, San Cristobal is a large zinc, lead, and silver mine in the southern Altiplano of Bolivia, operated by Minera San Cristobal (MSC), which is 65% owned by Apex Silver Mines Limited and 35% by Sumitomo Corporation. The quality of the social license was estimated initially from historical documents and the experience of persons who had been present throughout the life of the project using a basket of indicators and then verified through interviews with community members.

As can be seen in Figure 17.2-6 the quality of the relationship changed over time in response to various factors, which may be summarized as follows with reference to the numbers beside the graphical trace in the figure.

1. Rights to the mining concession are acquired by Mintec, a Bolivian mining consulting firm, which, together with permission from the community to access the surface, establishes formal legal status and permission to start work on the ground. The company rapidly builds social legitimacy with the local community by providing information and employment.
2. Geological indicators of widespread mineralization are identified. Mintec, and later ASC Bolivia LDC (ASC), an Apex Silver Mines Limited subsidiary that had acquired Mintec, steps up a dialogue with the community and provides additional benefits. Social and environmental baseline studies for an environmental impact assessment are initiated.
3. Clear indications of a very large mineral system are demonstrated through drilling. ASC believes that a mine can be developed in the near future. Accordingly, the company begins a process of consultation with the community of San Cristobal to relocate the population away from the mineral deposit. ASC empowers the community to manage essential aspects of the relocation such as selection of the new town site, design of houses and infrastructure, eligibility, and a benefit package. The community comes to feel that they are partners (co-owners) in the project—ASC has the mineral deposit, but the community has given its land to make the mine possible. Negotiations begin with the sister community of Culpina K for land for the tailings facility.
4. A comprehensive resettlement agreement is signed with the San Cristobal community. A land purchase agreement is reached with Culpina K. Trust reaches an all-time high.
5. The community of San Cristobal is relocated to the new town site together with the colonial church and cemetery.
6. The women, who were largely excluded from the negotiations and planning for the relocation, voice complaints about the houses: "They are not what we wanted." Culpina K residents start to think that they have made a bad deal.
7. The project is then transferred by ASC to MSC. Trust is eroded because the company has failed to deliver on commitments made in the resettlement agreement. Further, although the company has obtained necessary permits to construct and operate a mine, there are now doubts as to the feasibility of the project, and the company has drastically reduced the number of employees.
8. The project fails feasibility because of low metal prices. MSC closes all field operations. The communities are frustrated and trust is lost. Contacts between the company and the communities become infrequent. The company remains noncompliant with the terms of the resettlement agreement. Credibility is lost. The project remains legitimate in the minds of community members because they want the employment and the better future they hope it will bring.
9. Realizing the need to stabilize and strengthen the relationship with the community, the company initiates a program of assistance centered on employment for local people, agriculture, and tourism. Credibility is restored with delivery of the program.
10. A highly innovative program to encourage tourism is launched. Culpina K becomes heavily involved; San Cristobal, less so because it would rather have the mine.
11. An upturn in market conditions renders the project positive, and MSC announces the start of construction. Credibility peaks as the communities welcome the construction of "their" mine and the potential for employment during construction.
12. New management is installed to supervise construction that has no knowledge of the social history of the commitments to the communities. Contact between the company and the communities breaks down as the company drops meetings with the communities that involve top management. The communities feel deserted and disenfranchised because of a perception that they are not being respected and commitments for employment and training are not being honored. Credibility is lost almost immediately. Despite employment for almost all local people, social legitimacy drains away as the communities feel they have been overlooked in the construction phase and commitments dating back to 1999 remain unfulfilled. They still believe in "their" mine and mourn the loss of the partnership that existed at the time of the relocation of San Cristobal.
13. A contractor opens a road though community gardens outside of the agreed area of construction operations. For the community of Culpina K, this is an illegal act. Social legitimacy is compromised, and community relations collapse for a period with demonstrations and confrontation

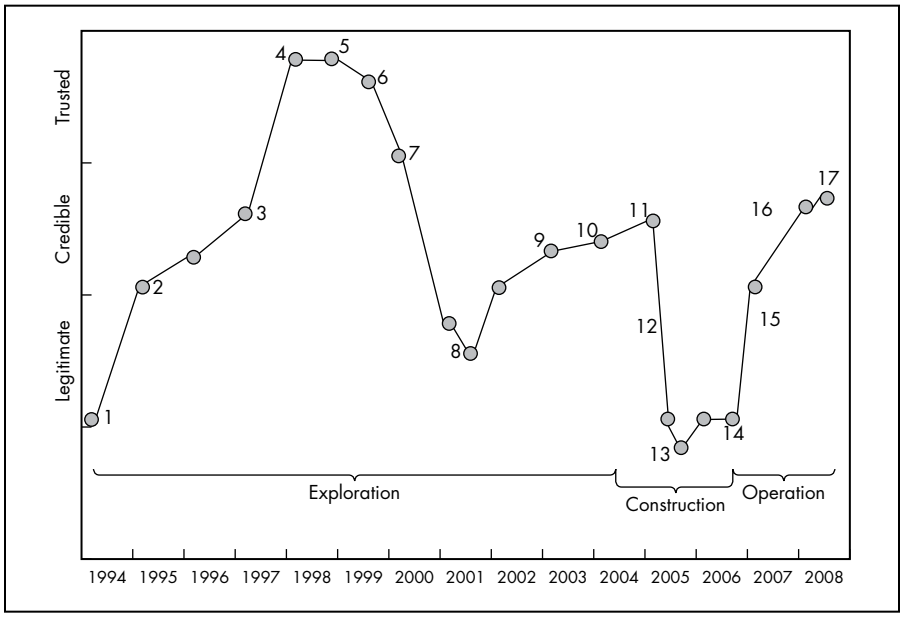

Figure 17.2-6 The ups and downs of social capital at San Cristobal mine

with the company. MSC is able to negotiate a letter of agreement that allows work to continue and begins a protracted process of negotiation for the acquisition of additional land for mine infrastructure facilities. Culpina K remains at a distance because of rising concerns that they will be adversely affected by the tailings facility.

14. Management comes to recognize the problems and risks created by the damaged relationship and takes action to improve the situation. The company proposes the formation of a community-based process for the design and management of community-development programs. The communities see this as an opportunity to take control of their own future and feel empowered. At the same time, MSC begins an accelerated program to comply with all prior commitments. The communities see progress and feel reassured. Construction ends; training and full-time employment is available to all. Dialogue is established with Culpina K around the issue of management of the tailings. Legitimacy is regained.
15. A management team is appointed to run the mine, replacing the construction team, which brings stability and quickly establishes a positive dialogue with the communities. All prior commitments have been met or are in a visible process of being met. An accelerated local employment program is initiated. Community-based planning for social and economic development is under way. Credibility is restored.
16. MSC responds to community concerns regarding the management of tailings by forming a joint monitoring committee with the community. Essential infrastructure improvements are made in San Cristobal and Culpina K. Credibility is strengthened. As "co-owners" of the mine, the communities make representations to the national government in support of the company in response to statements of increased taxes and threats of nationalization. Trust, however, remains elusive.
17. With the mine in operation and the communities fully involved in the management of their own development, in collaboration with MSC and local and regional government, there are early indications that trust could return to the relationship.

RELATIONSHIP BUILDING CHANGES BOTH SIDES

The Fiction of "Community" as an Entity

Up to this point, the term *community* has been used in a reified way, that is, in a way that grants it an identity and singleness of purpose that does not always exist. Many so-called communities are really aggregations of communities and/or kinship and interest groups. However, the concept of the social license to operate presupposes that all the families, clans, interest groups, and institutions in a geographic area have arrived at a shared vision for their future, or at least an agreed-upon set of priorities for today. This kind of cohesion is frequently absent. In such cases, it has to be built. That is why earning a social license to operate often involves the company in building social capital, also known as community building, capacity building, and institution strengthening.

Industries, and the companies in them, have to learn how to participate in the kind of community partnerships that earn a social license. Reciprocally, communities that want the benefits of participating in the mainstream economy have to develop the social structure that makes them capable of issuing a legitimate, credible, and trustworthy social license.

Communities Not Qualified to Issue a Social License to Operate

The key to a community's capacity to issue a meaningful social license is the pattern of social capital it has in its network structure. Without the right patterns of social capital, a community cannot stick to its commitment through the inevitable changes in local politics. Companies want a license that reduces the risk of investing in mining infrastructure. Figure 17.2-7A, B, and C illustrate three examples of how communities can have a social capital network structure that makes them unlikely to be capable of issuing the social license to operate that companies want.

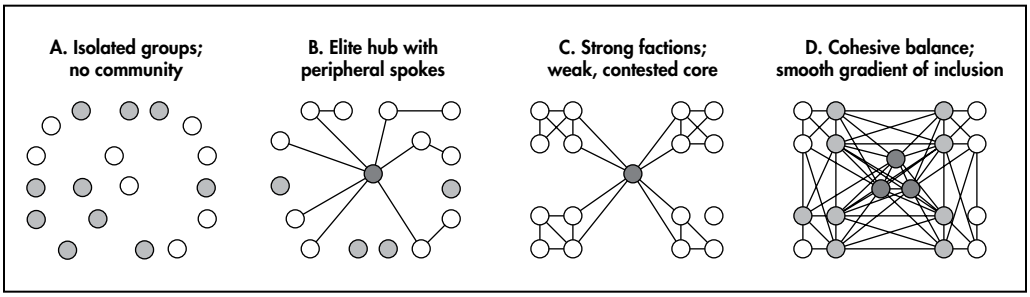

Figure 17.2-7 Four prototypical patterns of stakeholder network structure

Figure 17.2-7A shows a community with a severe lack of social capital. It has no core. It is an aggregate of groups that do not talk to each other. This is the pattern one would expect in a region after a natural disaster or war. There may be pockets of groups that deal with each other, but over the whole geographic region, or across all the stakeholders in the issue, there is little communication. No one can speak for the whole community, and therefore the community can neither issue nor revoke a social license to proceed. In this circumstance, companies usually fall back on the legal licensing process at the national level. Unfortunately, if the community subsequently comes together and finds a voice, that legal license can become worthless.

Another common hindrance to being capable of issuing a social license is the existence of an elite that purports to speak for everyone (see Figure 17.2-7B). The core has numerous relations of bridging social capital to peripheral groups. The peripheral groups have little social capital among themselves. Although dealing with this kind of structure is administratively convenient, there are dangers related to the elite's own legitimacy. Such elites are often tempted to put their own interests ahead of the interests of the whole community. Sometimes they stay in power by keeping everyone else divided, ignorant, or intimidated. Multinationals often fall prey to such groups when only the elites know the native language of the company representatives. Often they have been educated in the developed world and know the norms for doing business in the company's home country. The elites will say they can issue a social license, but once development gets underway, the objections of the excluded groups come to the surface. The company can then be lumped together with the elite as part of an illegitimate and corrupt establishment. This, of course, calls the social license into question.

Figure 17.2-7C shows another dysfunctional community structure. There is plenty of bonding social capital, but it is confined to tight-knit factions. To the extent that a core exists to speak for everyone, it is beholden to the leaders of the factions, be they mayors, war lords, clerics, or members of parliament. Because the factions are continually creating and destroying alliances in attempts to dominate the core, there is never a community with enough cohesion to ensure that any social license will be durable. The company can easily be drawn into the political machinations, either as a benevolent ally of one faction or an evil villain against which another faction rallies support.

Diagnosing Community Readiness to Issue

Companies that want a social license clearly need to know the patterns of the social capital in the network from which they expect to get the social license. Figure 17.2-7D is the ideal social capital structure for a stakeholder network. This type of community can make decisions that include everyone and that will work for everyone's benefit. It can stand behind the decisions for the long term but also has the flexibility to adapt its goals to changing circumstances.

Fortunately, social capital has been studied quite thoroughly in the social sciences for more than 15 years. Ways have been developed to quickly assess its patterns in a network, whether that is a geographic community or a wider set of stakeholders that includes national government departments and international NGOs. The basic approach is to interview the stakeholders about four areas of concern: (1) what their concerns are, (2) which other groups they consider to be stakeholders, (3) the quality of their relationship with the company, and (4) the quality of their relationships with other stakeholders. Data from interviews of this type provide a well-rounded basis for a stakeholder engagement strategy leading to a social license.

Ways to Approach Identified Problems

After a map of the social capital structure in the community is at hand, it is possible to determine where the effort should be focused. If the community looks like Figure 17.2-7A, it is necessary to start with basic communications among groups. If the community looks like Figure 17.2-7B, the first step is to make connections with the periphery groups and connect them with each other. If it looks like Figure 17.2-7C, efforts to strengthen the core are needed. A group of leaders from each faction must work together on a project long enough to develop a sense of shared purpose that is community-wide.

Each community has its own specific issues and problems that provide plenty of opportunities for bringing people together. Often the initial focus has to be setting community priorities and then identifying those that can be achieved in collaboration with the company. Wilson and Wilson (2006) offer numerous examples of initiatives that build social capital. These span diverse areas of operations from security to catering. Activities that build social capital rarely cost very much money. Usually they simply involve redirecting funds from an approach that ignores or damages the company's social license to an approach that improves and secures the social license. Sometimes they actually reduce costs, as occurs when the work to improve the capacities of local suppliers creates a stable of lower-cost local sources for goods and services previously imported from elsewhere.

Social License, Poverty Reduction, and Sustainable Development

The process of helping a community acquire the balance of social capital needed to issue a social license amounts

to strengthening the community to the point where it can be a strong, reliable partner in achieving whatever goals it sets for itself. This happens to be the same process that community development specialists follow in initiatives to reduce poverty. Social capital building and balancing initiatives have been shown to reduce poverty, but as Figure 17.2-7 indicates, the pattern of social capital has to be balanced (e.g., Figure 17.2-7D). In addition to a strong core, the overall pattern should integrate all subgroups to avoid isolation of the periphery. When these conditions are met, communities can benefit from the presence of a national or international corporation. The company can create or broker links to the larger economy outside the community. Such links are called *linking* social capital (Woolcock 1998). Through linking social capital, a community can gain access to more distant markets, for both its goods and its services (i.e., remittance income). Therefore, gaining and maintaining a social license employs the same set of activities that promote sustainable community development. Both goals depend on strengthening the community to the point where it can be a stable, committed partner in development initiatives.

TOOLS AND GUIDELINES

Companies use numerous tools and guidelines to help them do the things that earn a social license. These tools often bear labels related to "corporate social responsibility," "sustainability," or various more specific issues like corruption, transparency, or the environment. Leipziger (2003) reviewed hundreds of such codes, lists of principles, and guidelines. She reviewed more than two dozen of them in detail. Some of them reiterate many of the principles discussed above. Those that contain recommendations for specific steps and activities will not always work. Communities and circumstances are too varied to be amenable to any one-size-fits-all program. That is why the more general principles must take precedence over concrete recommendations. Although some guidelines sound too vague to be practical, it is actually the more specific elements that are less practical because they help only in some circumstances but not in others. Ultimately the social, cultural, and political dynamics of the individual community or communities that are neighbors to mining projects have to be understood, and tools and guidelines must be adapted to meet the characteristics encountered on the ground.

Exploration Practices

For explorers, *The Principles and Guidance for Responsible Exploration*, produced by the Prospectors and Developers Association of Canada (PDAC 2009a) together with the *e3Plus* on-line reference manual for good practice (PDAC 2009b) are invaluable aides to gaining legitimacy and credibility with local communities and hence acceptance and a conditional social license.

For projects that advance to feasibility and construction, the key sources of information for the management of social, socio-environmental, socioeconomic, and certain cultural matters are the Performance Standards on Social and Environmental Sustainability of the International Finance Corporation (IFC) of the World Bank (IFC 2006) and the Equator Principles (EPFIs 2006), a parallel set of guidelines created by the private-sector banks. While not created specifically for the mining sector, the IFC standards and a series of accompanying manuals are based on extensive practical experience that is of immediate relevance to mining projects. The IFC standards emphasize disclosure of information, consultation, participatory processes of investigation, and decision making with the community and other stakeholders; inclusion and protection of vulnerable and marginalized groups; respect for rights; participation in the benefits of mining; and so forth, all of which are actions that can create social legitimacy and, properly implemented, credibility for the company and hence a base for building trust.

Mine Operation from Construction Through Postclosure

Business for Social Responsibility (2003b) and AccountAbility and Business for Social Responsibility (2004) provide case histories and discussion of the social license together with practical advice on how a social license may be gained.

The principles and guidelines of the International Council on Mining and Metals (ICMM) provide a point of reference at the global level for good practice that aids acquisition of the social license (ICMM 2003). In addition, the ICMM has prepared a series of good-practice handbooks that offer practical advice on the management of various aspects of mining, including social and community development. At the same time, mining associations in a number of countries have developed guidelines optimized to national legal, cultural, and social norms; both Canada and Australia, for example, have developed such instruments.

The Mining, Minerals and Sustainable Development (MMSD) project identified a portfolio of initiatives that support gaining and maintaining a social license and are critical if mining projects are to make a contribution to sustainable development (MMSD 2002a). They include

- Supporting people (social capital) and investing in people (human capital),
- Supporting and strengthening existing governance structures (social capital),
- Facilitating continuous learning and improvement (human capital), and
- Helping local populations anticipate and take advantage of mine development to improve their quality of life (as defined by them) beyond the life of the project or mine (balancing human and social capital).

The MMSD project also created a framework for assessing a mining project's contribution to sustainable development, which includes material that can be used to design projects in a way that helps in gaining the social license to operate (MMSD 2002b).

As with the examples above, full implementation of the recommendations contained in these documents in ways that are sensitive to local social and cultural norms can significantly assist in gaining and maintaining the social license.

General Guidelines for All Types of Businesses

In the developed world, various existing political forces came together to create an ad hoc governance regime to regulate global corporations. The result of the ad hoc, piecemeal collaboration has been the emergence of some mechanisms for influencing corporate behavior. The influence strategies are each centered on a different set of stakeholders.

One of the most important stakeholder groups has been investors. The socially responsible investment movement applies investment screening criteria that have been promoted by the aforementioned loose coalition. In 2007, ethically screened investments accounted for US$4.93 trillion in assets

in United States and Europe alone (Social Investment Forum 2009). Prominent rating systems in the ethical investment field include the Calvert Social Index, the Dow Jones Sustainability Index, the FTSE4Good Index, and KLD's Domini 400 Social Index.

The same general influence mechanism has been called into play with lenders. The IFC has developed Performance Standards on Social and Environmental Sustainability, which are incorporated into the Equator Principles that have been adopted by most of the major commercial banks that finance mines. Companies seeking financing must pass independent assessments of their compliance with these standards for social and environmental performance.

In terms of employees and suppliers, there have been campaigns against child labor and sweatshops. The ILO has been very active in the area of mine safety. Its standards apply to governments, which in turn are supposed to enforce them on companies to whom it grants licenses.

The ILO 169 gives explicit instructions to governments to ensure that indigenous people are consulted before exploration and development of natural resources and that they share in the benefit that comes from resource development. This convention has a strong influence on corporate behavior even where governments are weak or absent, as is the case in many rural areas. The UNDRIP gives an even stronger instruction to governments to obtain the consent of indigenous people before any exploration or development of mineral resources.

Another approach is centered on consumers as stakeholders. Green and socially responsible consumer movements usually focus on specific product classes. The "dirty gold" and "blood diamonds" campaigns are aimed directly at the minerals industry.

The development of these influence channels has included the emergence of general codes and standards that spell out what is expected of companies. These expectations provide general guidance regarding how to earn a social license. Popular codes and standards that apply to all industries include the AA1000, the Global Reporting Initiative (GRI), and the venerable United Nations Universal Declaration of Human Rights (UNGA 1948).

The AA1000 was developed by the Institute for Social and Ethical AccountAbility (AccountAbility 2009). It consists of checklist-style framework for implementing changes in a company and a separate assurance process that verifies the company's adherence.

The GRI deals with standards for transparent reporting on nonfinancial matters. The most recent version was developed with input from thousands of companies from all parts of the world. It is a comprehensive checklist that was intended to apply to all industries. (GRI 2006). To help mining companies reduce the burdensome paperwork, the ICMM has published a guide for focusing on the parts of the GRI that are relevant to its sustainable development principles (ICMM 2005).

SUMMARY

The fundamental tools for building relationships between mining projects and communities are the values that permeate the actions of the company. These include

- Respect and inclusiveness;
- Transparency and honesty;
- Listening and empathy;
- Responsiveness and promise keeping;
- Goodwill, care, and protecting the interests of the other; and
- Clear rules and principled actions.

These are "soft" attributes that many mining company personnel find difficult to work with since they are not amenable to quantification in the same way as engineering and accounting. Nevertheless, they are keys to the creation of good, stable relationships and in many ways parallel the attributes of lasting personal relationships, friendships, and, indeed, a marriage.

ACKNOWLEDGMENTS

The authors thank Apex Silver for permission to present the history of the San Cristobal project; Juan Mamani, Javier Diez de Medina, and Margarita de Castro for providing the information on which the graphic history was first constructed; and the unknown community members who verified the data. The authors also acknowledge the support and intellectual contributions of Susan Joyce and Myriam Cabrera that led to the recognition of social legitimacy, credibility, and trust as the normative components of the social license to operate.

CHAPTER 17.3

Cultural Considerations for Mining and Indigenous Communities

Ginger Gibson, Alistair MacDonald, and Ciaran O'Faircheallaigh

THE GROWING IMPORTANCE OF INDIGENOUS CULTURAL CONSIDERATIONS

Article 1 of the International Labour Organization's (ILO's) Convention 169 defines indigenous peoples as

> (a) Tribal peoples in independent countries whose social, cultural and economic conditions distinguish them from other sections of the national community, and whose status is regulated wholly or partially by their own customs or traditions or by special laws or regulations; (b) peoples in independent countries who are regarded as indigenous on account of their descent from the populations which inhabited the country, or a geographical region to which the country belongs, at the time of conquest or colonisation or the establishment of present state boundaries and who, irrespective of their legal status, retain some or all of their own social, economic, cultural and political institutions (ILO 1989).

A cornerstone definition for the United Nations has been the "Cobo definition" of indigeneity, which highlights sacred attachment to and traditional ownership of land that has been appropriated by outsiders. This stands in contrast to people who self-identify as indigenous, which is the basis of the ILO definition.

The mining industry has not historically been required to closely analyze its potential impacts on indigenous cultures. This is no longer the case. The industry cannot afford the risks associated with the damage its activities can cause to indigenous culture. Nor can mining companies, in a highly competitive environment, ignore the potential of indigenous culture to add value to the enterprise.

More and more exploration and mining projects are located near indigenous communities whose culture is already under threat from dominant settler societies. The culture of indigenous communities, traditionally reliant on the land and its renewable resources, can be further threatened as they become exposed to and engaged with the mining industry (IFC 2007). Mining often becomes the new field of contestation between settler and indigenous cultures, as well as creating new relationships between the indigenous group and the distinct corporate culture of the modern mining firm.

Indigenous groups are not without levers to both shape these relationships and to impose sanctions on mining companies that refuse to acknowledge and respect their cultures. Many indigenous communities have gained enough power in recent decades to vigorously assert their rights to land, and have had these rights recognized through national law and international declarations and conventions such as the ILO's *Convention 169 Concerning Indigenous and Tribal Peoples* (1989) and the *United Nations Declaration on the Rights of Indigenous Peoples* (2007). This recognition has partly been driven by successful litigation and direct political action by indigenous peoples, often with the support of civil society groups. As part of this recognition of indigenous rights, cultural impact assessment of individual projects is now required in many regions. The Mackenzie Valley Resource Management Act in Canada's Northwest Territories, for example, requires environmental impact assessments (EIAs) to have regard to "the protection of the social, cultural and economic well-being of residents and communities of the Mackenzie Valley" (Government of Canada 1998).

Many of these indigenous cultures are resilient, vibrant, and resurgent. For example, in recent years, thousands of Aboriginal people from throughout Australia's Pilbara iron ore region have participated in annual ceremonial activities. Innu and Dene people of Canada are recapturing their cultural heritage through bushwalks and mass canoe trips (Zoe 2007). Indigenous communities have united to protect special cultural places and spaces. Another indicator of cultural resilience is that indigenous groups have increasingly challenged companies to make space for traditional cultural activities and values to be expressed at mine sites, to assist in protecting sensitive valued cultural components, and to adapt the corporate work culture of mining to the needs of indigenous people

Ginger Gibson, Adjunct Professor, University of British Columbia, Vancouver, British Columbia, Canada
Alistair MacDonald, Environmental Assessment Specialist, SENES Consultants Limited, Edmonton, Alberta, Canada
Ciaran O'Faircheallaigh, Professor, Politics and Public Policy, Griffith University, Brisbane, Queensland, Australia

(e.g., through alternative work rotations or respect for communal grieving) (Argyle Diamonds Ltd., Traditional Owners, and Kimberley Land Council Aboriginal Corporation 2004).

When cultural issues are not given appropriate consideration, the sanctions that indigenous groups impose on companies have become increasingly onerous. Companies who cannot show that they will not cause irrevocable damage may be denied the permits and licenses required to establish new projects. They may also be unable to secure mine financing if potential lenders perceive they are unable to manage cultural and social risks. Here are a few examples of downside risks resulting from inadequate community engagement or the presence of significant cultural impacts:

- Innu and Inuit landowners in Labrador, Canada, delayed the Voisey's Bay nickel project through court cases and activism because of the company's failure to prepare an environmental and cultural protection plan before starting exploration on indigenous lands (R. Gibson 2006).
- At Esquel in Argentina and Tambogrande in Peru (MacDonald and Gibson 2006), there was a fundamental lack of early and effective community engagement, and, as a result, insufficient effort to deal with indigenous concerns about adverse environmental, social, and cultural impacts. This led to a refusal by indigenous groups to grant companies a "social license to operate" (Joyce and Thompson 2000).
- Canada's federal government ultimately rejected a proposal for a modest drilling program in the remote Upper Thelon River basin when it became clear to the co-management board in charge of environmental assessment that the area held great cultural significance to the indigenous residents (MVEIRB 2007a).

(Note: The bulk of examples in this text are taken from the authors' experiences in Australasia and North America, but the tone is one focusing on expressing general concepts that emerge between indigenous communities and mining projects around the globe, and many of the general concepts, tips, and tools that can be applied in a variety of cultural contexts. However, there is no substitute for learning the site-specific cultural context and engaging culture holders in the cultural impact assessment process.)

Examples like these have done little to alleviate industry fears that dealing with indigenous cultures will consume valuable time, create new project costs, and open a Pandora's box of new risks for mining projects. Geologists, mining engineers, and other project managers have historically lacked training in cross-cultural engagement. This lack of experience can heighten a perception that cultural engagement is the first step in either a total rejection of their proposed project, a drastic reduction in its operating scope, or the imposition of restrictions that cost a great deal of money and reduce the life of any potential project.

Such a perception is both inaccurate and damaging to mining companies and their shareholders. In reality, the majority of potential cultural impacts are manageable at modest cost if they are clearly identified and appropriately addressed, and particularly if this occurs early in project life. Further, cross-cultural engagement can generate substantial value for the enterprise. For example, Canadian diamond mines have worked with indigenous groups to devise a 2-week-in/2-week-out work rotation schedule that maximizes the amount of time hunters can be out on the land. Any rotation greater than 2 weeks was considered too long, given that a herd of caribou can move through an area in weeks and be too far from communities to harvest by the time workers returned. In this case, the cultural practices and communal desires of the potentially affected culture groups were integrated into project planning. The result has been a win–win situation for the companies and the communities, with a more-committed work force for the companies, and an indigenous work force able to balance traditional and wage economies (G. Gibson 2008).

In areas largely populated by indigenous people, cross-culturally sensitive workplaces can add value by increasing indigenous employee retention rates. Unlike many nonindigenous mining employees who migrate or "commute" to remote mine sites, local indigenous people have a long-term commitment to live in the regions where mines are located. If they can be recruited and retained by mining companies, this can significantly reduce work-force turnover, which in turn can reduce company expenditure on staff recruitment, training, relocation, and severance, and enhance work-force cohesion and morale. In addition, resources committed to upgrading the skills of indigenous workers can generate higher returns for the corporation, as their ties to their "home place" make them less likely to move to other operations elsewhere, taking their new skills with them. Use of local labor can also reduce the costs involved in transporting workers into remote sites and providing them with camp accommodations. Companies may incur additional up-front costs in recruiting and training indigenous workers but, especially if a longer time frame is adopted in assessing returns, this investment can generate significant net gains (Barker and Brereton 2005; Barker 2008; Harvey and Gawler 2003; NWT and Nunavut Chamber of Mines 2005; SIWGMI 1996; G. Gibson 2008). Cross-culturally sensitive work environments can also minimize downtime and costs associated with turnover among indigenous and nonindigenous employees, reducing management–employee conflict and minimizing costly disruptions to the work environment.

Respectful cross-cultural engagement is essential if companies are to gain access to traditional indigenous knowledge, an outcome that can generate considerable value for the firm. Traditional knowledge is sometimes envisioned by developers as an input useful only during initial project planning, and as a legal requirement of the formal EIA process. Experience shows that these resilient cultures and their knowledge constitute a valuable resource that companies can draw from throughout the life of the mine. Cultural knowledge can be a valuable environmental planning and early warning tool for mining companies. Indigenous peoples are often in a unique position to assist mining companies in minimizing negative environmental impacts and in returning mine sites to acceptable environmental standards (O'Faircheallaigh 2010). One critical resource possessed by indigenous people is time depth in relation to information on the existing environment ("baseline data"). Typically, mining companies only start collecting baseline data some 2 to 3 years before project construction is planned to commence. Because environmental conditions can be highly variable over time, a few years' data may not provide a sufficient basis on which to develop an understanding of environmental dynamics. Indigenous peoples draw not only on decades of experience in observing environmental conditions on their traditional lands, an understanding of which is vital to their subsistence activities, but also on generations of knowledge handed down to them. Thus, their participation is essential in achieving a full and accurate understanding of

existing environmental dynamics, which in turn is the foundation for effective environmental protection (Nadasdy 2003; Usher 2000).

The intimate and ongoing contact that many indigenous people have with their ancestral lands and waters also allows them to quickly detect ecological changes that may signal problems with a mine's environmental management system, helping to avoid potential damage and quickly take remedial actions. A range of more specific indigenous knowledge can also greatly assist effective environmental management. This can, for example, include understanding of animal behavior as essential in designing effective wildlife monitoring and management regimes.

The knowledge and skill of indigenous people can also be mobilized to make major technological shifts that increase productivity. As an example, using elders' knowledge of sea ice re-freeze conditions and time requirements to build a floating bridge, Inuit workers decreased wait times for shipping of ore from the Voisey's Bay mine in Labrador (I. Paine, personal communication).

In all of these cases, the requisite traditional knowledge may only be readily accessible if a respectful and trusting relationship, including strong ground rules for the protection of cultural knowledge, is established between the developer and knowledge holders.

Positive cross-cultural engagement can also allow companies to

- Demonstrate their corporate social responsibility, a major benefit in an industry with an often problematic public relations image;
- Develop the effective communication and understanding of the indigenous party (and vice versa) essential for negotiating, interpreting, and implementing agreements between indigenous communities and mining companies; and
- Obtain certainty of land tenure and permits in a timely manner.

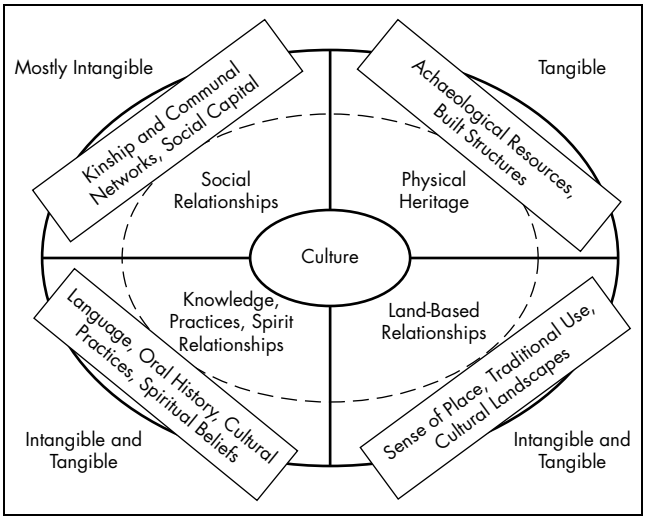
Against this background, mining companies, small and large, have to learn how to deal with indigenous expectations that impacts on culture will be managed, and with the increased leverage exercised by indigenous people. Avoidance of cultural impact identification will only delay risks until a time in the future when greater financial losses will accrue because increased project investment has occurred. Industry associations are certainly taking heed that cultural issues merit closer consideration to both take advantage of upside benefits and avoid downside risks. As an example, the International Council on Mining and Metals has published ten principles of sustainable development, including the requirement that operations should "uphold fundamental human rights and respect cultures, customs and values in dealings with employees and others who are affected by our activities" (ICMM 2003). Also, the Prospectors and Developers Association of Canada has developed e3 Plus: A Framework for Responsible Exploration that includes expectations of "respecting and protecting local culture and traditions" (PDAC 2009).

Cultural impact assessment and the expectation that companies will achieve effective cross-cultural engagement with indigenous people are thus both "on the table." Despite the importance of cultural factors—their growing legal recognition, the demands of indigenous peoples around the world that they be considered before developments proceed, and the business case for positive engagement—culture quite often remains the "elephant in the living room" of mining project development. Everyone knows it is there and it is awfully hard to ignore, but dealing with it effectively is another matter. While some companies are making serious efforts to respectfully engage with indigenous cultures, common barriers to effective cross-cultural engagement and doing good cultural impact assessment still include

- Narrow interpretations of "culture," usually to the detriment of "intangible" dimensions of culture;
- Weak initial cross-cultural engagement often associated with lack of preparation and lack of in-house expertise;
- Power differentials and incompatible cultural values between settler society, indigenous groups, and mining companies;
- Emphasis on the technical/scientific/quantitative over the oral/traditional/qualitative in formal EIAs;
- The complex variety of contributing factors to cultural change;
- Lack of agreement on what constitute appropriate indicators of cultural impact;
- Lack of preexisting thresholds of acceptable change for cultural indicators;
- Companies not wanting to take on pseudo-governmental sociocultural protection roles; and
- Lack of formal legal requirements for implementation of cultural protections.

These are not insurmountable challenges; they can be overcome by changing attitudes with additional guidance and more effective approaches to cultural engagement and impact assessment, both at the corporate head-office level and by company managers "on the ground."

The purpose of this chapter is to identify some of the key issues that must be addressed, and principles and methods that can be used, during engagement between indigenous communities and mining companies. It seeks to help ensure that the current gaps in cultural impact assessment and community engagement practice can be overcome, relationships are respectful and appropriate, the benefits of cross-cultural reciprocity can be fully realized, and adverse impacts on indigenous culture can be avoided throughout the life cycle of an operation and at the various sites of cross-cultural interaction.



The sections that follow define culture, discussing intangible and tangible cultural assets; scoping, which requires engaging culture holders and understanding the potential impacts a project may have on culture; the collection and analysis of appropriate data and prediction of likely impacts and their significance; and the identification and implementation of appropriate mitigation, the means by which potential adverse impacts can be avoided or minimized and, equally importantly, benefits to (and of) culture can be maximized.

CONCEPTS OF CULTURE

Before exploring how mining development can impact indigenous culture and vice versa, it is necessary to know what culture is, who holds it and where, and how the values and priorities of indigenous cultures and mining's corporate culture tend to differ.

Tangible and Intangible Cultural Assets

The study of indigenous cultures as they relate to mining has often focused on the protection of historic artifacts that may be

Source: Adapted from Candler 2008.
Figure 17.3-1 Tangible and intangible cultural assets

physically damaged by development. This "stones and bones" approach to cultural impact assessment ("heritage resources impact assessment") is practiced largely by archaeologists and other physical anthropologists, and has helped identify and protect the material manifestations of past occupation—features such as historic sites, gravesites, middens (refuse caches), rock and cave paintings, and scatterings of stone tools as well as dwellings or ceremonial sites and trails (King 2002; O'Faircheallaigh 2008). Each of these features leaves a physical clue as to how the earlier generations lived and traveled. They focus attention on the *tangible* signs of a culture's past.

Culture is, of course, much more than stones and bones; it is a living, continually adaptive system, not a remnant of the past. It is also highly complex, which makes precise or exhaustive definition of the concept impossible. A simple, general definition of culture is "a way of life; a system of knowledge, values, belief, and behavior, passed down between generations." As early as 1871, Sir Edward Tylor defined culture as "that complex whole which includes knowledge, belief, art, morals, law, custom, and any other capabilities and habits acquired by man as a member of society" (Tylor 1920).

Although it may be difficult to define it precisely, it is possible to identify some key elements of culture. Aside from the physical manifestations most often analyzed and protected during a heritage resources impact assessment, culture also includes values and worldviews, and the tools through which they are communicated—symbols, language, and behavior. It includes communally held knowledge, spiritual practices and beliefs, traditions and traditional pursuits, social relationships, and a common understanding of humankind's connection to the natural environment. These are among the *intangible* assets of a culture group. Manifestations of intangible cultural heritage include oral traditions, language, performing arts, ritual and festive events, knowledge concerning nature and the universe, traditional craftsmanship skills, traditional social practices, spirituality, and sense of place (UNESCO 2003; Andrews and Buggey 2008).

Common elements of culture, and particularly of indigenous cultures, are identified in Figure 17.3-1.

Common languages, stories, myths, songs, conversation, traditional activities, and art are used to communicate and transmit culture from generation to generation. Often in indigenous communities, the stories, knowledge, and practices that are critical to living well are transmitted as people are out on the land, engaged in the traditional economy as they pick berries and plants, hunt, trap, and fish. In these primarily oral societies, historical and mythological events are often recorded in landscape features. Literally for them, "the land is like a book" (Dene Elder Harry Simpson, quoted in G. Gibson 2008). As young people travel on the land to significant places, they engage with their elders, leaders, and families, strengthening their bonds and knowledge, while they come to know their history through storytelling at the significant sites of their people. The shared stories ensure that the younger generation acquires appropriate cultural information about traditions, way of life, and values.

The key thing to remember for those involved in cross-cultural engagement is that impacts on culture can come not only from changes to "things you can touch" or from physical effects on tangible and visible heritage resources, but they can also come from changes to "things that touch you"—intangible cultural assets that while perhaps not visible from without, are felt from within and are vital to cultural retention and maintenance.

Domains of Culture: Who Holds It and Where?

It is essential to understand the "domains" of culture—the places, spaces, and other planes of interaction where culture is transmitted, regenerated, and altered. Culture is acted out, transmitted, and received between the self, the family, and social networks; within and between communities; between different cultural groups; and within the context of an increasingly global popular culture. In many indigenous cultures there is an ongoing struggle between the norms and values realized through the practice of traditional ways such as subsistence harvesting and the values of a dominant settler society.

Culture has a spatial component as well. All cultures have a "home place" and members have a shared sense of place. For the mining company's corporate culture, the home place may be the corporate head office or the mine site. Indigenous cultures have ties to the physical habitations they reside in, just like settler communities do, but indigenous cultures may hold a much stronger, even symbiotic, relationship with their wider traditional lands.

For indigenous people the land itself is often a key repository of knowledge, an interpretive tool, and a key locator of meaning and history. There is growing international recognition (MacKay 2004; UNDESA 2004) that the ability to live on, care for, and use resources from their ancestral lands is central not only to the economic and social well-being of indigenous people but also to their very survival. Land is critical

- To physical sustenance;
- For social relationships that are bound up with relations to land;
- For law and culture, which are interwoven with use of the land and its resources; and
- For spirituality and religion, which have as their basis beliefs about the creation of the land, the way in which creation spirits continue to occupy the land and influence contemporary life, and the way in which ancestors and future generations are tied to the current generation through the land.

Indigenous knowledge of the land is tied to knowledge of past events related to people first by their ancestors and

then passed by them to their own descendants. Quite literally for indigenous people, "wisdom sits in *places*" (Basso 1996, emphasis added).

Wisdom resides in spaces too. Places are sites. Spaces are routes, relational lines between points on the map. They are larger than a single place, and they can also represent a larger meaning as *cultural landscapes*. Cultural landscapes have been defined as "landscapes that are lived in" and that bring attention "to the way people within the landscape live, their traditions and everyday life" (NWT Cultural Places Program 2007). Even where there are no visible signs of human usage, there may be historic events, culture hero stories, or significant usages of an area.

> These kinds of activities can give cultural meaning to natural features in the landscape, such as hills, rocks, caves, water, trees, animals and plants. Natural features remind people of stories about events in their history and of how important animals, plants and spirits have always been for the people of their community (NWT Cultural Places Program 2007).

In a cultural values assessment for the proposed Sahyoue-Edacho National Historic Site in Canada's Northwest Territories, the importance of this cultural landscape was described as follows:

> These areas represent the relationship between the Sahtugotine and their land; the landscapes of Sahyoue and Edacho blend the natural and spiritual worlds of the Sahtugotine, creating a living web of myth and memory…[they] remain important places not only for subsistence, but also for spiritual renewal and a sense of cultural identity (Janes and Hanks 2003).

Cultural landscapes are the embodiment of cultural heritage at a grand scale, incorporating individual sites of heritage resources into a broader network of stories and collective memory tied to the land, essential to defining the people similarly tied to that land (Rose 1996). Buggey (2004) argues that a cultural landscape expresses an indigenous group's "unity with the natural and spiritual environment. It embodies their traditional knowledge of spirits, places, land uses, and ecology. Material remains of the association may be prominent, but will often be minimal or absent."

It is this lack of tangible presence that can be a problem for the outsider, both in coming to understand the values and priorities of an indigenous group and in determining the significance of impacts on cultural assets during impact assessment. The value of different cultural assets cannot be discerned from without; it must be determined from within, at least with the assistance of the indigenous peoples themselves.

In general, three types of "values" are associated with cultural assets:

1. *Use value* is associated with continuing utilization of an area. For example, an area may be important because it is used currently by culture holders on a day-to-day, seasonal, or annual basis for practice of the traditional economy.
2. *Bequest value* is associated with any cultural assets the holder desires to pass on unchanged to future generations and the satisfaction and peace of mind associated with this knowledge.
3. *Existence value* (sometimes known as wilderness value) is the benefit attributable to knowledge that an environmental resource exists, even in areas that are not used and likely will never be used by the individual. These values can be important in situations where indigenous groups are unable to access parts of their traditional lands for extended periods of time because, for instance, they are distant from settlements.

Often places carry multiple layers of meaning, deepening their value to culture holders. Cultural landscapes such as the Upper Thelon River basin in the Northwest Territories may be all the more important and sensitive because they hold use, bequest, and existence/wilderness values. For the Denesoline people, the area is "the place where God began." It is critical habitat for wildlife including the vitally important barren ground caribou herds. It is viewed as a place with which the Denesoline desire continued connection in its current, relatively pristine status to sustain their cultural history, traditional activities, and spiritual base into future generations (Lutsel K'e Dene First Nation 2008). The Upper Thelon River basin is also a highly valued conservation and ecotourism area (one of the largest forested areas north of the tree line), valued for its existence/wilderness value both among Canadians and internationally. This serves as a reminder that while impacts from mining may be primarily felt by those closest to the development (indigenous peoples), there may be impacts on other cultures associated with special places.

The existence and bequest values associated with special places and spaces belie using quantitative indicators like the existence of known physical heritage resources or intensity of current use for traditional activities as the only measuring sticks. Some places take much of their value from the peace of mind people enjoy from knowing they are not being disturbed. Other places are important not (or not only) because they house valuable renewable resources, but because they hold power and resources that should be avoided except in times of great need or in very specific circumstances, as, for instance, in a particular ceremonial context (NWT Cultural Places Program 2007). Some places may require avoidance by all people at all times, or should be visited only by particular people who hold specific knowledge, because they can be dangerous to the ignorant or the uninitiated. In many parts of Australia, specific places are variously considered dangerous to men or to women, or to any individual who has not completed specific initiation ceremonies, or to anyone who is not accompanied by custodians who can perform rituals to render the visitors safe. Aboriginal attempts to restrict access to such places are designed not only to protect them from damage, but also to protect non-Aboriginal people who would otherwise suffer serious injury by visiting them inappropriately (O'Faircheallaigh 2008).

Indigenous culture holders take their guardianship of spiritual and cultural places and spaces very seriously, and there may be severe repercussions for their failure to protect them. For instance, the destruction of an important women's cultural site by the Argyle diamond mine in Western Australia in the mid-1990s had serious social consequences for its female custodians, although they fought strenuously to stop the development (Dixon and Dillon 1990).

Culture is not only practiced on the land, it is practiced in the home and in the community. Cultural change is not limited to alterations on the land, but also occurs when social relations change, or when practice of language and other tools of cultural maintenance or one's sense of self, place, and community are altered (Basso 1996; G. Gibson 2008).

Understanding Cultural Differences

The work sites of operating mines, although they are often envisioned as "culture free" areas (Trigger 2005), are themselves one of many cross-cultural "mixing zones" associated with mining in indigenous communities (see Figure 17.3-2). Cultural differences are also felt during initial community engagement, around the negotiating table when agreements are being developed, and during the mine planning and formal cultural impact assessment processes.

Indigenous culture interacts with the institutional culture that prevails in mining camps and companies (Heyman 2004). The mining company can be distinguished by its different sites of operation: the operating mine site is quite distinct from the parent company in managerial style and strategic priorities. A parent company may watch over many operating mines and shepherd old mines out of existence. The management and corporate culture of the individual mine is concerned with the ore bodies on site, the understanding of which changes frequently and often expands as the ore body is newly delineated and made real through development and extraction.

The operating mine is characterized by key values, hierarchical relationships, strict lines of authority and communication, and prescribed policies for managerial and human resource systems. Key values of an operating mine are maximizing productivity and site safety (G. Gibson 2008). A head office's primary and overall responsibility is to maximize economic returns to company shareholders. The means to these culturally prioritized ends may conflict with the primary driver of indigenous culture: to protect the values imbued in the land under which the mineral resource lies.

"People" priorities may differ as well. Cross-cultural leadership qualities, social science skills, and human relations acumen are not necessarily valued prerequisites in mine management, as long as the individual has a track record of productivity. This can and has led to conflicts between indigenous workers and their settler culture managers (G. Gibson 2007, 2008). Indigenous workers are expected to assimilate into the occupational site, discarding, at least temporarily, their own practices and values in favor of those of, primarily, the institutional culture, and secondly, the settler society. As one senior manager put it, workers have to "take off their kimonos" and participate in the "industrial bubble" (Trigger 2005). Participation in the mine site can powerfully affect how individuals are able to reproduce and express their own values and practices (G. Gibson 2008). Exposure to a new workplace in an isolated fly-in/fly-out work camp where the dominant culture is defined by the employer not only exposes the indigenous person to new values and world views of people from settler cultures, but also to the institutional culture of the modern mining workplace. Common differences between the corporate culture of the mining work site and indigenous groups are outlined in Figure 17.3-3.

The difficulties for indigenous workers in adapting back and forth between the industrial production culture and the home community can create major challenges

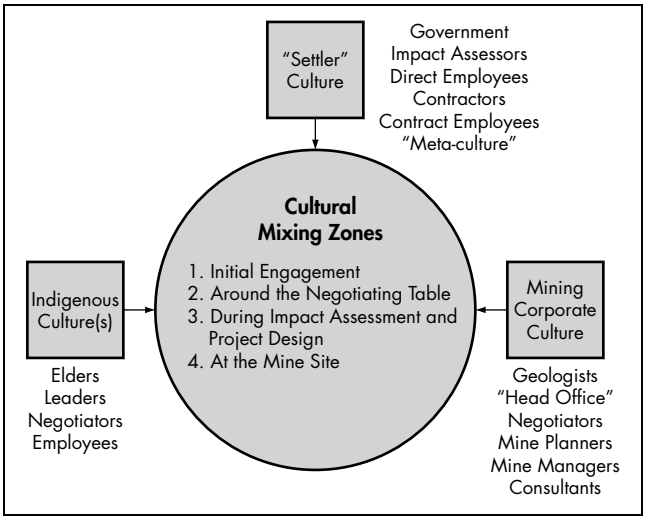


Figure 17.3-2 Cultural "mixing zones" associated with mining activities

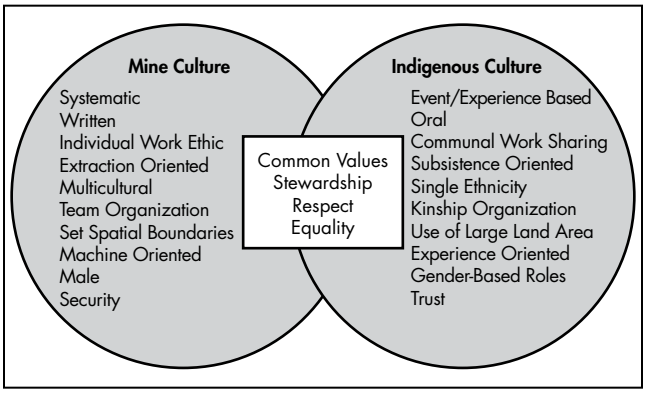

Figure 17.3-3 Comparing values

(O'Faircheallaigh 1995; Barker and Brereton 2005). Attempts to divorce the "workplace" culture from the "home place" culture lead to problems such as cross-cultural disputes and high turnover rates, often associated with increased familial tensions as well as workplace conflict. G. Gibson (2007, 2008) identified the top 10 cross-cultural conflicts encountered between indigenous people and mine managers at the diamond mines in northern Canada, a few of which are discussed here:

- In an area such as the open pit, it takes constant shifting, training, and machine jumping to gain the skills necessary to understand the full range of machines in the area. People who move up in the mines have been afforded these opportunities by their pit managers, given the time to train, and often have a few characteristics the manager sees as necessary. They may be aggressive and self-promoting. These characteristics and values may run contrary to the nature of an indigenous person.
- When a non-kin member of a family dies, corporate-leave policy may constrain managers from allowing a worker to attend the funerals of other than immediate relatives. In a society where kinship is defined by different rules, an indigenous person may need to attend funerals as part of a communal grieving custom.

Table 17.3-1 Elements of cultural difference that may be exposed during a cultural impact assessment

Factor	Mining Culture	Indigenous Culture
"On-the-ground" evidence of culture in area proposed for mining	Found archaeological sites	Stories, trails, use patterns (current and historic), density of place names, archaeological sites and potential for unfound sites, cultural landscapes
Prioritized cultural impact consideration	"Bones and stones"	Tools/images/objects/ stories in combined place memory; innate values of the land
Value focus in cultural impact assessment	Current use value and bequest value associated with physical heritage resources	Historic and current use; bequest value and sometimes intrinsic existence values
Geographic scope of cultural impact assessment	Places and sites that will be physically altered or otherwise directly affected by the proposed development	Places, sites, spaces, cultural landscapes and relationships between them and people, home community, lived experience
What constitutes "heritage resources"?	Heritage resources as physical artifacts only	Heritage resources also include culture holders' shared history and experiences, knowledge of the land and resources, and ways of knowing and transmitting knowledge
Role of intangible cultural resources in cultural impact assessment	Minimal; view that vulnerability of things like language and time spent on the land is linked to cultural change beyond scope of project-specific cultural assessment	Project-specific cultural impact assessment should consider contribution of proposed development to potential erosion of cultural maintenance tools in context of cumulative change

Cultural differences must first be identified before there can be any successful coexistence and cross-cultural engagement of the many cultures on site. Only then can human resources policy be adapted to fit these unique cultural needs (work-site cross-cultural conflict mitigation strategies are discussed later in this chapter).

Obviously, the work site is not the only place where mining companies and indigenous communities interact. Common sources of tension between corporate/settler culture and indigenous cultures in other cultural mixing zones include

- Prioritization by companies of the written word and technical expertise over oral discussions in plain language, often characterized by company use of overly wordy and complex documents, presentations, and other materials about the development;
- Different canons of proof, with Western, "scientific" knowledge being privileged, and characterization of traditional knowledge and oral history, often provided by elders, as "hearsay" or "anecdotal" information without scientific support;
- Access to and control over information, including sensitive traditional knowledge;
- Misinterpretation of cultural signals (e.g., silence in settler society may indicate agreement, while for an indigenous society it may mean nonsupport);
- Conflict between settler laws and traditional indigenous laws, with corporations seeking to rely exclusively on the former;
- Lack of incorporation of ceremonies required prior to, during, and after meetings, breaking the land and agreements; and
- Different understandings of formal arrangements like impact benefit agreements as either final "set in stone" legal settlements (from the mining companies' perspective) or as the starting point for an ongoing, open, and adaptable relationship (from the viewpoint of the indigenous people) (G. Gibson 2008).

Many of these cultural differences are exposed during early community engagement and subsequent cultural impact assessment. Cultural differences not only govern how people interact but also how they perceive the environment and potential for impacts from mining projects. Table 17.3-1 provides a comparison of values in relation to key factors involved in a cultural impact assessment.

Some understanding of the cultural attributes of each other is essential prior to entering a formal relationship. Gaining a contextual knowledge of the community is essential so that relationships are based on mutual understandings of priorities and reasons behind actions. Without this in-depth knowledge, misinterpretation and a lack of trust can emerge. For example, concerns are sometimes raised about whether indigenous culture holders invent, fictionalize, or otherwise augment their histories to make potential cultural impacts appear more severe. This concern surfaces when an impact emerges in the last moment in an environmental assessment. This misperception is linked to the fact that the nature of information sought in order to understand culture is often highly sensitive. Depending on the cultural values of the potentially affected group, it may be hurtful or improper to custodians and to the wider indigenous community for cultural information in the form of traditional or local knowledge to be divulged, and so information may only be released at the very last moment when it becomes clear that to do so is the only way to protect a place. A conflict between the desire of formal impact assessment to quantify cultural assets and their value, and the desire for indigenous groups to retain control over the sensitive cultural knowledge and expression of value of their cultural resources often emerges. Sometimes cultural resource issues are simply too sensitive for public disclosure (King 2004; O'Faircheallaigh 2008). This is often the case with indigenous people who are concerned with the impact of mining activities on spiritual or religious sites. To divulge information about a site may actually put knowledge holders or the place itself, as well as recipients of the knowledge, at risk. This explains the reluctance to divulge it unless knowledge holders become convinced that protecting sites requires releasing information about them, even though revealing their location or significance may reduce their future safety.

EFFECTIVE EARLY COMMUNITY ENGAGEMENT

Early and appropriate community engagement can create a respectful relationship between parties and assist in proper identification of cultural issues that may arise from a project in a specific location, a process referred to as *scoping*. To scope

properly, the developer needs to understand the unique cultural context in which the project is proposed and how mining activities have tended to impact indigenous cultures in this or other similar environments.

There is no broad-brush approach that can be used to understand indigenous peoples' lives. Each indigenous community will be unique, with issues, concerns, and an underlying context that will emerge only through engagement. At the outset of a project, developers need to develop a basic understanding of the cultural context in which they are operating and the unique vulnerabilities and resiliencies of the people involved. Developers need to be aware of

- The historic background of the community;
- The relationship between community members and the environment;
- Demographic characteristics of the community;
- Demographic subgroups within the community who are particularly vulnerable to adverse cultural impacts and are underrepresented;
- Internal (traditional laws and governance) and external (state) political and legal structures and customs;
- The community's relationship with regional, territorial, and federal governments;
- Existing community goals and aspirations for social and cultural well-being, as expressed, for instance, in development plans or proposals for protected areas;
- The cultural values that shape the perspectives of community members; and
- Vulnerabilities and strengths of the community, (e.g., strong language and other cultural programs) and trends in levels of subsistence activity.

Developing this contextual knowledge requires a substantial and early commitment of resources but has important benefits. It assists in accurate issue identification, which allows identification of the proper scope and scale for the required impact assessment. It also helps to identify locally and regionally relevant mechanisms and processes that are already in play to support and protect valued cultural components, such as the regulatory and legislative context for identifying and managing cultural impacts. Regulations on burial sites, cultural items, sacred sites, religious freedoms, and archaeological sites will also need to be understood (King 2004; Parker and King 1990).

Sources of contextual cultural information include

- Land-use plans and supporting documentation;
- Literature on protected areas in the vicinity, which often include some description of cultural values and specific spaces identified as requiring special protection;
- Documentation in relation to prior EIAs in the region in question;
- Published anthropological or sociological literature about the people and places involved;
- State and federal government departments responsible for indigenous populations' health and well-being, and cultural protection;
- Community-specific engagement protocols;
- Museums or cultural institutes dedicated to the study of the indigenous culture, which among other resources often house archaeological databases identifying physical heritage resource locations and areas of high heritage resource potential;
- Ethical guidelines for traditional knowledge collection and dissemination (e.g., MVEIRB 2005a); and
- Existing traditional knowledge reports, which may have certain confidentiality restrictions.

It is prudent to identify and use all available secondary (desktop) sources of information before committing to any dedicated primary (fieldwork) cultural impact assessment. Besides creating a useful contextual understanding to help avoid misunderstandings during initial engagement, this can also help avoid the "consultation fatigue" often cited by indigenous communities. Despite the obvious differences among indigenous communities, there are also remarkable consistencies in the issues they raise in relation to proposed developments. Therefore, it may be useful when determining the "cultural risk profile" of a development to consider case studies of similar developments in other indigenous environments. Table 17.3-2 identifies some of the activities a developer may want to undertake prior to formal engagement with a community.

Table 17.3-2 Checklist of recommended activities prior to and during early community engagement

☐ Identify what land access agreements will be required in the area of the proposed development, and identify any overlapping land claims by different culture groups.
☐ Identify relevant community plans, regional land-use plans, and other planning documents. Identify whether the proposed development conforms to these plans.
☐ Use community engagement handbooks and talk to community liaison specialists before developing a consultation strategy. Consider whether a consultant or local expert from the cultural region is required.
☐ Identify which potentially affected communities and culture groups should be consulted initially.
☐ Identify whether each identified community, or the region as a whole, has specific policies or protocols that dictate how developers should conduct early community engagement, or for the collection and protection of traditional knowledge.
☐ Conduct desktop research on the social, economic, and cultural environment of communities that may be affected by the proposed development.
☐ Identify appropriate community contacts.
☐ Produce a preliminary in-house list of potential impacts and public concerns that may be raised (see the "Impacts of Mining on Indigenous Cultures" section later in this chapter). Use information about the proposed development, research on past developments in the potentially affected region, case studies of similar developments, and existing developments in the region as source material for this list.
☐ Distribute a plain-language description of the proposed development to potentially affected communities.
☐ Be familiar with cultural impact issues commonly brought up by indigenous community members, be ready to listen to whether and how these concerns relate to the proposed development, and be prepared to respectfully consider issues that may not seem to you to be directly relevant to the proposed development.
☐ Take responsibility for keeping detailed meeting minutes, be ready to provide them to the community consulted for verification, and establish a flexible and appropriate mechanism for follow-up communications with communities.

Source: Adapted from MVEIRB 2007b.

Early community engagement can be essential in minimizing the type of misunderstandings that can damage, even irrevocably, a project in traditional indigenous territory. Important contextual information about the cultural group in question may in some cases only be unearthed during discussions with key contacts in the communities. The key here is to make sure that contact is "appropriate," meaning it is made through the proper channels according to relevant community engagement protocols. To bypass these protocols, which are set up by the culture holders to protect their interests, can get the engagement process off to a bad start.

Rio Tinto's (Rio's) Marandoo iron ore mine in the Pilbara region of Western Australia offers an example of the costs associated with failure to address cultural heritage protection early and in cooperation with indigenous custodians. The developer complied with the provisions of Western Australia's Aboriginal Heritage Act, but traditional owners believed this legislation offered little by way of effective protection and wished to negotiate stronger protective provisions. After Rio failed to establish a productive engagement with them during exploration for the project, the traditional owners undertook a number of legal actions designed to frustrate Rio's plans and slow development. While Rio eventually overcame these hurdles and secured project approvals, the action of traditional owners resulted in a delay of more than 2 years. This not only led to higher capital costs but meant that Marandoo came onstream too late to take advantage of an expected spike in iron ore prices, and Rio incurred significant losses as a result. Another result was, according to a Rio executive, "a low point in Aboriginal relationships for the company…[and] a legacy of deep distrust and bitterness in the [Aboriginal] communities" (Eggleston 2002). The experience contributed to a fundamental policy shift at Rio Tinto, with the company undertaking a major initiative to establish productive relationships with all indigenous communities located adjacent to its mine sites (Eggleston 2002; O'Faircheallaigh 2006).

IMPACTS OF MINING ON INDIGENOUS CULTURES

A second key task for managers is to understand how a project might impact culture. Many developers enter an area without fully understanding the likely impact of their activities on indigenous culture. This requires both a basic understanding of how mining projects have been known to impact indigenous culture, and specific knowledge of both the proposed development and the cultural context it is proposed to be situated in.

Common Impacts of Mining on Indigenous Cultures

At a workshop in Perth, Australia, in May 2008, EIA practitioners from around the world identified the cultural impacts that most concerned them in relation to mining. The results are indicated, along with the authors' own experiences, in Table 17.3-3 (updated from Gibson et al. 2008). The list is by no means is definitive.

Cultural impacts from mining activities occur to places and people. For example, the first layer of impact may be direct and tangible damage to heritage resource sites through construction, blasting, and earthmoving. As a result, the physical record of a culture group's past occupation may no longer be marked into the landscape (Angelbeck 2008). This destruction can in turn indirectly reduce the ability of people to practice rituals, ceremonies, and traditions, as well as add to disconnection from nature (Pilgrim et al. 2009). The space might also be a fundamental source for food, shelter, clothing, medicine power, or a wellspring for much less tangible but equally important cultural resources (Angelbeck 2008). These changes can have cascading, potentially devastating impacts on a group's cultural history, traditional practices, and sense of place. These cascading impacts are more likely to occur if there are cumulative effects from other human activities contributing to pressures on indigenous cultural resources. Thus, destruction of the land can damage and even destroy cultures that remain closely tied to their environments, which in turn can lead to mental, psychological, and social pathologies (Pilgrim et al. 2009).

Impacts on culture, like all impacts, occur through these direct, indirect, and cumulative processes. Direct impacts are ones specifically caused by the development in question, such as the aforementioned mine construction requiring destruction or removal of physical heritage resources. Indirect impacts are changes caused or contributed to by a development through a chain of events. For example, increased employment of indigenous people at a large mine may reduce their reliance on, and interest in, spending time on the land conducting traditional

Table 17.3-3 Common cultural impacts related to mining projects

Valued Cultural Component(s)	Impact Concern
Cultural heritage resources	• Physical loss of heritage resources and associated spiritual loss
Cultural landscapes and other special spiritual spaces/places	• Visual impacts redefining the way a place/landscape is "seen" in culture (inappropriate use or alteration of landscape can create loss of value and meaning regarding what places on the land can teach us about life)
Culture and land tenure	• Social organization may be tied closely to the system of land tenure, which may also reflect transmission of rights, property, and gender relationships. Changes to land tenure through mining or changes in property ownership may interfere with these relationships.
Overall relationship to land and traditional activities on the land (including practice of traditional economy)	• Sense of disconnection from traditional lands and wellspring of cultural well-being • Less time on the land conducting traditional practices can cause cascading impacts on well-being across a variety of categories (everything from poor diet to erosion of language and ways of learning) • Often linked to perceived and real physical degradation of habitat and lower harvesting success for key wildlife species • Less time in kinship relationships that are critical to transmission of knowledge
Values and belief systems	• "Culture free" working conditions can erode cultural values or lead to alienation • Large-scale in-migration can alter cultural norms and values • Spiritual/religious change, loss of faith in traditions
Methods of cultural transmission (including language, oral history, intergeneration relations, social networks)	• Contributions to changes in social structures leading to cultural loss (e.g., decline of intergenerational culture transmission) • Contribution to cumulative loss of indigenous language, even to extinction • Linked to changing political structures and power relations (e.g., elders vs. politicians or business-people as leaders)
Sense of self; sense of place; overall well-being	• Loss of sense of control over one's own fate • Health impact outcomes caused by cultural impacts (e.g., increased suicide, alcohol and drug addiction, poor diet)

pursuits. This can in some cases contribute to loss of connection to the land, reduction in intergenerational knowledge transfer, and other damage to maintenance of traditional culture. Alternatively, increased employment at a fly-in/fly-out mine may provide the added income and free time required to spend time on the land, creating an increase in practice of the traditional economy and beneficial cultural outcomes (O'Faircheallaigh 1995). The lesson here is twofold:

1. The term *impact* simply means "change." Impact outcomes are not inherently unidirectional. They can be beneficial or adverse, or either for different people, depending on the cultural context and the way people react to change.
2. Pathways by which impacts occur may be simple and involve single-chain cause–effect relationships (e.g., a bulldozer physically destroying an artifact), or they may involve complex causal chains with a variety of contributing factors along multiple pathways (e.g., less practice of traditional economic activity caused by a combination of increasing involvement in wage economy, fewer harvestable animals, changing demand for country food, and decreasing time on the land). The incorporation of culture holders in predicting both initial changes and their eventual outcomes may be required to create a realistic picture of the most likely impact outcomes in a specific cultural context.

Mine developments do not occur in cultural, economic, or social vacuums where they are the only cause of change. Cultural change is always occurring, and for multiple reasons. A common argument is that the most dominant forces of change in modern industrial society are beyond the capacity of individual developers to manage. This is true. Television, for example, brings into the homes of indigenous people the values and world views of dominant societies. Developers are not being asked to take full responsibility for the cumulative effects of these multiple contributors to cultural change. They are expected instead to recognize the pressures these cumulative effects may be placing on valued cultural components, as part of understanding the local operating environment to which the developer needs to adapt. The "weight of recent history" (Gibson et al. 2008) may need to be considered, as many indigenous communities have been bombarded with the negative effects associated with intrusions by settler cultures. Cumulative effects are often measured through trends in language retention rates, time spent on the land, and traditional harvesting levels. Equally important may be the more-qualitative measures of change that can only be captured by talking to the culture holders about their sense of place, their attachment to special sites and cultural landscapes, and their hopes and fears for the future.

It can be argued that impacts must be interpreted through the filter of the culture holders themselves. Impact significance is socially defined, and these social perceptions are linked to the values of the culture holder. Consider a situation where a defined cultural landscape of importance to an indigenous group is to be used for an open-pit mine. In absolute terms, the physical footprint of the mine and associated infrastructure may account for 1% of the cultural landscape. But that 1% may represent some of the most important hunting grounds and encompass an important spiritual site, and its importance is therefore much greater than its area would suggest. In addition, impacts on that 1% may affect the perceived value of a much wider area. Indeed, in some cases the destruction of one site can impact the values associated with the entire cultural landscape and have even further ramifications—the inability of traditional owners to protect a site may change relationships within the community. In addition, if certain sacred sites are destroyed, rituals and ceremonies may no longer be practiced, which will have far-reaching ramifications for cultural transmission.

The nature of cultural impacts may change over the mine life cycle. During initial exploration, concerns may focus on the cultural appropriateness of using a certain area for any sort of industrial development (MVEIRB 2007b). During mine development, increased activity on the ground may cause increased concern about immediate destruction or damage to specific physical heritage resources, spiritually important landscape features, and key wildlife species. There may also be increased concern about the effects on culture of increased in-migration, of increased indigenous involvement in the wage economy, and of associated changes to the traditional economy. During mining operations, concerns may focus on changing social network structures and familial tensions associated with long-distance commuting (Barker and Brereton 2005) or on workplace cross-cultural conflict (G. Gibson 2008).

Determining a Project's Potential for Cultural Impacts

Determining the potential cultural impacts of a particular mining development requires project- and culture group-specific analysis. Only by examining both the "site" (the project) and the "situation" (the cultural context within which it is embedded) can the developer answer these important questions:

- How much further work is required to fully understand potential cultural impacts?
- What should that work focus on?

The proper identification of impact issues allows a refining of the level of detail required and of the focus of cultural impact assessment work. For example, it makes no sense to conduct additional heritage resource assessments in areas where they have already been conducted or where all parties agree they are unlikely to be found. The exercise becomes especially fruitless if the real issue for the community is the potential for high levels of in-migration to exacerbate pressures on traditional culture. Therefore, although scoping for cultural impact assessment can be done in-house by the mining company, it is preferable to involve indigenous culture holders (e.g., through key contact interviews, focus groups, scoping sessions, or meeting with leaders or other groups) in the initial identification of potential impacts.

A range of warning signs is related both to the nature and scale of the proposed development and the cultural context. The following lists identify some attributes to consider when determining the likelihood that a project may cause or contribute to adverse cultural impacts. The first list identifies characteristics of a proposed project that are indicative of a higher impact potential on culture. The second focuses on aspects of the physical and human environmental context surrounding the proposed development. Again, these lists are far from exhaustive, and context-specific variables will emerge during dialogue between parties.

Site, or project, attributes associated with higher cultural impact potential may include situations such as the following:

- The physical and impact footprint of the project is large (e.g., in terms of the extent to which land, air, water, and wildlife may be adversely impacted).
- New or improved transportation access routes are involved.
- The land management status of an area would need to be changed.
- New, complex, or controversial technology is necessary.
- A high level of in-migration to a region is required.
- Long-distance commuting for all workers is required.
- The land use will lead to irrevocable visible changes (e.g., large-scale open-pit mining).
- It is a brand new development (known as a greenfield).

Situational, or cultural, contexts include the following:

- Indigenous communities/traditional lands/trails are nearby.
- Proposed or existing protected areas are in the vicinity.
- There is known or high potential for physical heritage resources or spiritual sites.
- More than one indigenous group is using the area.
- Wildlife intensity is high in the area, traditional pursuits are widely undertaken, and traditional harvesting is an important part of the economy.
- The area contains unique/rare landscape forms.
- The location is important to indigenous oral histories; that is, there is a high density of indigenous place names in the area.
- People practice agriculture in the region and have local forms of land tenure that is not recognized by the government.
- Other past, present, or reasonably foreseeable future developments contribute to cumulative effects in the area.
- Potentially affected communities are already dealing with the intensity of preexisting social, economic, or cultural problems.

The likelihood of major impacts and the level of effort required to manage them will grow as the number of attributes increases.

DIGGING DEEPER: DATA AND METHODS FOR DETERMINING CULTURAL IMPACTS

This section deals with data collection, impact identification, and predicting the significance of the determined impact. While each cultural impact assessment needs to be developed around the specific cultural context and expectations of the case at hand, there may be guidelines for social and cultural impact assessment from the jurisdiction where the work is being done or from prospective lending agencies (e.g., MVEIRB 2007b; MVEIRB forthcoming; IFC 2007).

In considering levels of effort for cultural impact assessment, a distinction is made between basic, moderate, and comprehensive. Consider, for example, a situation where the only potential cultural impacts identified during scoping are the physical disruption of heritage resources.

- Where there is a low risk of adverse impacts, a *basic* cultural impact assessment may require a summary of existing data on heritage resources and heritage resources potential, and inclusion of respected local knowledge holders to understand the impacts.
- Where there are no known heritage resources but medium-to-high potential for unfound heritage resources, a *moderate* impact assessment may require archaeological studies on the project site and development of a site-specific heritage resource protection plan(s).
- Where there are known heritage resources and high potential for unfound resources, a *comprehensive* impact assessment may require incorporation of traditional knowledge studies alongside local archaeological studies, a regional heritage resources cumulative effects assessment, and identification of a regional heritage resource protection plan, in concert with the responsible government authorities and indigenous groups.

For projects with potential impacts on less-tangible elements of culture, for example, whether they be effects on broader cultural landscapes, key wildlife species and traditional harvesting, or contributions to effects on language retention, a similar distinction from basic to comprehensive can be determined based on the results of scoping. In essence, a basic assessment looks to confirm that significant adverse impacts are unlikely, through secondary data collation and dialogue with potentially affected parties. A moderate assessment is used where there might be significant adverse impacts that require, at a minimum, adaptive management plans to be in place in case they do occur. A comprehensive assessment is based on the premise that adverse cultural impacts are likely, that there may be cumulative effects beyond the scope of the project that need to be factored in, and that aggressive mitigation and a dedicated monitoring system for project effects must be set up by the parties involved.

The discussion in this section assumes that the project in question has at least a moderate additional cultural impact assessment requirement.

Involving Cultural Resource Experts and the Culture Holders

Many approaches can be used to help understand impacts on indigenous cultures, including

- Traditional land-use studies (e.g., Tobias 2000);
- Traditional ecological knowledge studies;
- Physical anthropology or archaeology studies;
- Collection of oral histories from elders and other traditional knowledge holders;
- Linguistic and kinship studies;
- Place names research and other ethnogeographic studies;
- Cultural landscape studies;
- Land-use planning, including proposals for protected areas;
- Focus groups, interviews with key contacts, and town hall sessions geared toward identifying valued cultural components and concerns for them;
- Analysis of statistical trends in appropriate cultural indicators, usually collected by a bureau of statistics or similar body (e.g., land usage, language proficiency); and
- Community wellness surveys including indicators of cultural resilience and vulnerability.

Effective cross-cultural engagement and cultural impact assessments require input from trained practitioners, just as mining requires application of engineering and geological skills. The concept of a cultural impact assessment itself is often perceived as being "soft" or "fuzzy," a mistake compounded by the fact that this emboldens nonexperts to try to become practitioners without any training. As a result, the

right professionals are often not brought on board to assist with community engagement and cultural impact assessment. Often, the engineer or geologist who seems best suited to consulting with communities—in other words, those with some empathy and communication skills—are given the added task of understanding culture, writing about it in an impact assessment, and finding mitigation strategies to avoid damaging it. The lack of engagement of anthropologists, linguists, or traditional knowledge specialists can lead to real problems down the road through misunderstandings and lack of rigor.

Technical experts alone are not enough. When it comes to documenting archaeological and other tangible impacts, there is no replacement for the expertise of archaeologists and cultural anthropologists, but their work should incorporate (or itself be used to augment) the local expertise of elders and traditional knowledge holders. Although archaeologists can determine the presence of ancestors via marks of their physical passing, they may not be aware of mythological events that have been worked into indigenous imaginations and cultural landscapes. When defining the cultural importance of a place or space, there is no substitute for the words of the culture holders themselves.

Despite this, companies often commission consultants to do desktop studies that include little or no engagement of culture holders themselves and rely entirely on archaeological evidence. This focus on desktop studies has led to an emphasis on summarizing available statistical and physical data to the neglect of the rich oral and indigenous narratives that can emerge locally. These narratives are laden with context and predictive power. Elders, leaders, spiritual healers, and cultural resource experts within a region can help to identify sacred areas, or values that are at stake in a region, and only local people can verify the meaning and extent of impacts on the cultural environment.

The developer should keep in mind that most indigenous communities want to maximize the control they have over cultural impact studies, especially ones that deal with sensitive traditional knowledge about land use, spiritual places and spaces, and other aspects of their culture. Research shows that control over cultural maintenance is linked to population health among indigenous groups. Chandler and Lalonde (2007) show how Aboriginal communities in British Columbia that have strong showings in eight indicators of control over "cultural continuity" (e.g., control over education, cultural facilities) have lower suicide rates than communities that lack control over cultural continuity. Lack of control over aspects of culture can be an impact in itself, one the developer should avoid exacerbating. However, there are often few financial or technical resources available for potentially affected communities to properly engage in studies of cultural impacts during EIA processes. The developer's role may be to assist in funding such studies rather than imposing them on the group from outside.

The parties should, early in their relationship, establish mechanisms for ensuring substantial indigenous control over research processes and cultural information. A basic start might be to give communities the authority to select archaeologists and other nonindigenous technical staff. Further, communities should be in charge of the information flow surrounding cultural heritage identification and protection. In Australia, for example, it is standard practice for indigenous organizations to enter into "cultural studies agreements" or "cultural heritage protocols" that

- Establish agreed processes for cultural heritage work;
- Allow for recognition of indigenous intellectual property in cultural heritage and indigenous control of sensitive information; and
- Provide for provision of reports that meet the developer's need for project permitting, yet avoid inappropriate disclosure or use of information.

Public consultation that occurs during a formal EIA requires specific engagement with expert knowledge holders, but these people may not be able to share knowledge with all indigenous community members, let alone the nonindigenous public. For example, women may only be able to pass knowledge on to young women during their puberty rites, and to pass knowledge to any men would be to violate norms and rules (O'Faircheallaigh 2008). Given the potential for information to be sacred or secret, early consultation should be undertaken with communities before public consultation, so that protocols can be arranged for control, content, and flow of sensitive information (King 2004).

Counting What Counts: Collecting and Analyzing the Right Data

The developer should have identified valued cultural components, the cultural assets people most want to protect and enhance. Appropriate ways to study changes to these cultural assets now need to be determined. Table 17.3-4 identifies some potential indicators for consideration when conducting a cultural impact assessment on mining projects.

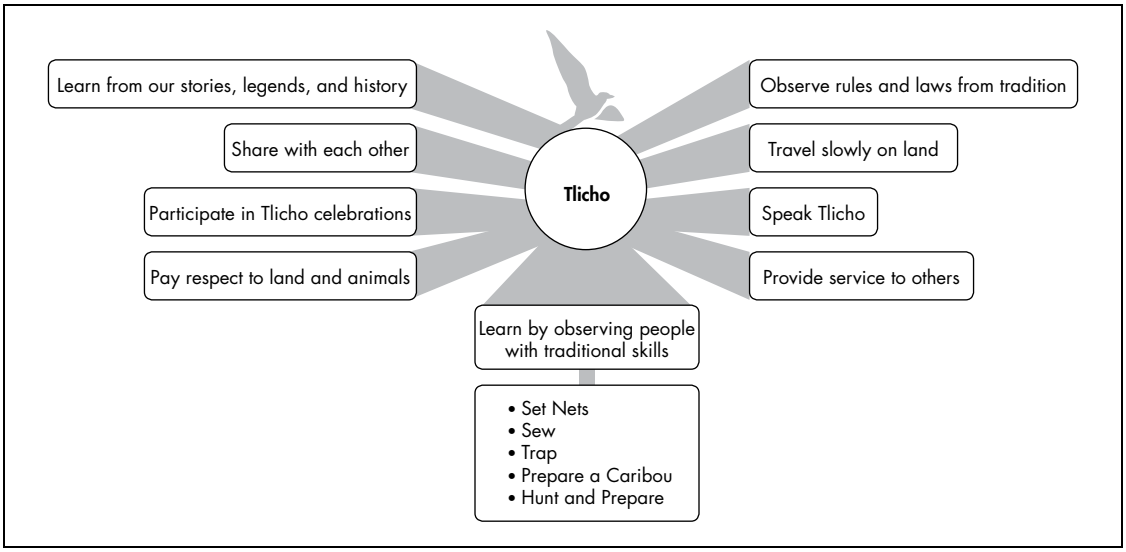
Quantitative tools should be used where appropriate to augment qualitative approaches and vice versa. While quantitative indicators (e.g., percentage of language speakers) can surface some trends, the meaning and culturally relevant issues will only emerge from locally situated narratives. Community experts and outside experts can tend to weigh significance differently, prioritize certain issues, and account for change in culturally specific ways. As a result, it is important to include local experts in the definition of the appropriate issues, indicators, and narratives of impact and change. In some cases, quantitative indicators will be developed with and vetted by an appropriate cross section of the residents of potentially affected communities prior to the developer adopting them during any formal impact assessment process. Thresholds of acceptable change for all valued cultural components must also be established, and they cannot be effectively developed without community input. The same applies to qualitative narratives of the impacts and significance of these impacts.

As mentioned earlier, impacts on tangible culture, especially physical heritage resources, are the ones most often studied during a formal environmental impact assessment, and impact assessments for mining projects have largely tackled the concept of culture through a technical, "scientific" lens. As a result, only a limited range of indicators (almost entirely quantitative) have emerged to "capture" the concept of what constitutes culture and to assess potential cultural impacts (e.g., number of historic sites, numbers of traplines, language retention rates). Qualitative means of measuring cultural change have largely been neglected, often because they are difficult and time-consuming to measure, in part because relevant data are not available from published sources. Another reason for the limited use of qualitative data is a bias in the EIA business (of which cultural impact assessment is but a part) against what some professionals and EIA professionals

Table 17.3-4 Example valued cultural components, criteria, and indicators

Valued Component(s)	Indigenous Group Goal/Priority	Criteria or Indicator
Heritage resources	Protecting heritage and cultural resources	• Historic properties, including buildings, sites, structures, and signs • Cultural items, such as sacred objects and funerary items • Archaeological resources • Sites, features, or artifacts that are old (the specific required age is often determined by archaeological resource protection acts the developer needs to be familiar with) • Archaeological, historic, and scientific data that is usually found in association with archaeological resources and historic properties but may exist independently • Sacred sites
Cultural landscapes and other special spiritual spaces/places	The aesthetic, cultural, archaeological, and/or spiritual value attributed to places	• Reported time spent on the land for transmission of practices, language, oral histories • Types of cultural uses of and associations with the potentially affected area • Place names • Continuity of traditions • Relationship of site to other cultural sites in the landscape
Land tenure	Maintenance of traditional economic structures and forms of land tenure	• Landownership or traditional patterns of agriculture
Overall relationship to the land and traditional activities on the land (including practice of traditional economy)	Continuity of knowledge and practice	• Recreational and traditional economy that involves access to the land • Valuation of alternative land uses (i.e., tourism vs. hunting vs. industry) • Percentage of country food in diet • Number of traplines, or traditional use registered or known in area
Values and beliefs	Protection of indigenous culture in occupational sites and at home site	• Cultural norms, values, and beliefs that might be impacted at work sites
Methods of cultural transmission (including language, oral history, inter-generation relations, social networks)	Maintenance of traditional language, education, laws, and traditions; maintenance of cultural ties	• Practices: rituals, religious rites, and ceremonial activities • Percentage speaking indigenous language at home • Percentage retention of education, laws, and traditions • Density of relationships and networks in the culture
Sense of self, sense of place, overall well-being	Ability to influence decisions on critical cultural issues	• Percentage of gambling, reported crimes, substance abuse • Reports of sense of control over decision making

regard as "anecdotal" evidence. The stories, oral histories, and words of the culture holders are often discounted in favor of evidence that is easier to quantify.



When cultural practices are quantified (e.g., language, hunting, trapping, and food consumption), the indicators may be used as inappropriate proxies for what culture *is*, so that when one is not practicing this activity, one is not a "cultural" being. Local accounts of culture are usually about much more than participation in "traditional" practices. Elders will often tell complex stories that relate to values, roles, and relationships that are reinforced in meetings, at church, and in daily activities. These things cannot be reduced to numbers. They are complex concepts that are only reflected and reinforced through talk and practice. What holds the group together is more than participating in activities and speaking the language; it is also engaging and reengaging relationships to other people and animals, both past and present. Forces that interfere with unity, relationships, and the continuity of roles are what elders often define as threats or impacts (G. Gibson 2008). This reveals the importance of surfacing both qualitative and quantitative measures and narratives of impact.

A downside of focusing exclusively on quantitative data is that it can tell you *what* is happening, but rarely if ever can it tell you *why* change is occurring, especially on intangible assets of culture. Researchers tend to use available quantitative data on valued cultural components to get a sense of status and trends, looking for cultural "hot spots"—those valued cultural components that are in decline. Researchers then dig deeper using qualitative assessment tools to get at the reasons behind the phenomena.

A community's issues and concerns are often best surfaced through in-depth interviews, focus groups, or community meetings. Some training and knowledge of local context and politics is required to be effective. Talking to the wrong person about sensitive issues and places (e.g., a member of a family who does not use a certain area) can result in inaccurate information and inadvertently even raise tensions within the community.

In identifying appropriate criteria and indicators of cultural impacts and cultural resilience, it is important to consider not only readily available statistical data on culture collected by settler government agencies, but also community-based data and analysis. Figure 17.3-4 reveals the kinds of criteria for cultural transmission that an elder (in this case, a group of Tlicho elders from Canada's Northwest Territories) might raise with respect to the possible impacts from a proposed development. These are the criteria of cultural preservation that are often raised in a collective setting—the next step is connecting these criteria to the key issues and concerns that emerge from the proposed project. For example, if these are the areas the community most values and wants to enhance, the question of how mining can embrace these aspects might be addressed. Thus, Canadian mines operating in indigenous territory can bring in elders to tell stories, encouraging spiritual and cultural celebrations on site.

While these criteria do not lend themselves to quantification (e.g., it makes little sense to count the number of stories told over a year), the collective reflection in community settings on the issues and practices helps to imagine mitigation measures for a proposed development. Such community-based initiatives are more likely to be focused on criteria, stories, and indicators deemed most relevant to cultural health and maintenance by the culture holders themselves (G. Gibson 2008). Community-based initiatives may also have the added

Source: G. Gibson 2008.

Figure 17.3-4 Community-defined criteria of cultural preservation

benefit of linking data collected to goal statements or thresholds of acceptable change that can assist in the determination of whether additional impacts will be significant. Where thresholds are discussed, there is the possibility of then defining when and how action will be taken, if significant changes come to pass.

Impact Prediction and Significance Considerations

A robust and defensible picture of potential impacts must be developed before effective mitigation strategies can be identified. Consider a situation where the question at hand is, What is the potential for impacts on heritage resources from Development X?, yet no on-the-ground archaeological studies have yet been conducted. How can a credible answer be derived?

The absence of physical evidence cannot be assumed in this case to be "evidence of absence" in terms of a location's cultural importance. In this case, different sources on the area's cultural resource potential can be consulted. Government officials responsible for assessing heritage resource potential across the jurisdiction, traditional land users, elders, and other traditional knowledge holders can be consulted to establish warning signs of the potential presence of unfound heritage resources or other cultural assets, which may include identification of

- The prevalence of trails, important hunting locations, meeting places, or historic habitations in the vicinity of the proposed development;
- Historic and current use of the area;
- Identification of heritage resources found around, rather than within, the project area;
- The role of the place and paths to it in the oral history of the culture, including density of place names;
- The ranges of important wildlife;
- Types of landforms, water bodies, and other physical characteristics that make it more likely to be used for cultural purposes;
- Whether the location fits into a larger cultural landscape, and how it relates to the whole; and
- The expressed desire by the culture holders to protect the location as it is, as seen, for instance, in public statements of concern, or attempts to withdraw the area from development or find other legal protections.

Using multiple indicators of cultural impact potential triangulated by several sources allows for an estimation of the importance of the area to a culture including, but not limited to, the presence of physical heritage resources. And this initial estimation can be accomplished in some cases without requiring a costly heritage resource impact assessment.

After cultural impact potential is identified, determination of cultural significance must be embraced as a social rather than a technical process. Because culture is a complex and always evolving human phenomenon, it is essential to focus not only on what impacts culture can absorb (a technically estimated threshold of *manageable* change), but also on what the culture holders are willing to take (a socially derived threshold of *acceptable* change). Therefore, when the time comes to assign significance to an impact on culture, a central voice should be that of the culture holders (Winds and Voices Environmental Services Inc. 2000). They are the primary experts on what will change or potentially be affected, because the significance of a site or space may not be apparent to the outsider, to a developer, assessment body, or regulatory agency. As the MVEIRB put it when deciding that a de facto burial ground under Great Slave Lake was not an appropriate location for exploration drilling:

> The Review Board relied on the most reliable and accurate experts it could when making its determination about cultural impacts—the Aboriginal cultural groups themselves. Cultural impacts are best identified and addressed when relayed by the holders of the cultural knowledge, the community members themselves (MVEIRB 2005b).

In indigenous cultures where oral history is the canon of proof (Andrews and Buggey 2008), the evidence of traditional knowledge holders such as elders and other land users,

Table 17.3-5 Factors to consider when determining cultural impact significance

Significance Factor	Questions the Assessors May Want to Consider
Nature of impact	• Which valued cultural components does the impact threaten? How does it threaten them? What pathway would it occur by? Knowledge of pathways of impact that can be blocked or managed by mitigation is essential to minimizing or eliminating impacts.
Situational context	• What is the evidence for use, bequest, and existence values associated with the potentially affected area? • How sensitive are the valued cultural components to change—will a little bit of change fundamentally alter the values associated with the place? • Is the place or landscape one of many similar important places or is it the "one and only"? • Is there the potential for cascading impacts from this cultural change? • Are there cumulative effects that need to be considered from other developments? • Does the area that will be impacted have multiple uses by many different groups? • How vulnerable or resilient are the valued cultural components that may be affected? What is the current status and trends for indicators related to them? Less-resilient elements of culture, if they are deemed important by culture holders, should be prioritized for mitigation.
Trade-offs	• Will there be beneficial effects to offset adverse effects? Will the beneficial effects be on the same valued components or different? For example, economic growth at the expense of cultural decline may require mitigation that takes financial capital and converts it to cultural assets. • Are there any activities or values associated with the location to be impacted that will be inevitably constrained, altered, or eliminated if the development proceeds?
Capacity to manage and social acceptability	• Will any identified thresholds of acceptable change be approached or breached if the development proceeds? Are there thresholds already breached that increase the significance of any additional changes? Does the predicted change exceed the existing capacity of the community and government services to absorb the change? • Are there management plans in place and can they handle the likely increased change?
Geographic area and distribution	• How many communities, culture groups, areas of cultural importance, and valued cultural components will be impacted by this development?
Likelihood	• Is there a greater than 50% chance the impact will occur? Does the estimated magnitude of the change make a 50% likelihood too high to consider? What is the estimate based on and what assumptions were used? Who made the estimation? Are there people who disagree with it?
Impact equity	• Are certain cultural groups or subgroups within a culture more likely to be impacted? For example, elders, people who rely on the traditional economy and live on the land, women, and youth, in that order, are often more likely to be impacted by adverse cultural change.
Public concern	• Is there a high level and wide cross section of the culture group (and others) expressing concern about the proposed activity?

affirmed by other culture holders, is not anecdotal evidence but rather the lived reality.

In assessing the authenticity of a claim about cultural impact, it is telling to look at the range of culture holders who will attest to the significance of the affected cultural site, space, or activity. Thus, significance is clearly established if an impact surfaces again and again in interviews, community meetings, focus groups, or public hearings.

A range of factors may be considered in weighting cultural impact significance, as identified in Table 17.3-5.

The situational context is often more important than the project context for determining the potential for significant adverse cultural impacts. The scale and meaning of cultural impacts cannot be foretold solely on the basis of project size. Just as severe water quality issues can emerge from the smallest of mines if acid mine drainage occurs, so too can a cultural impact from a small drilling program be significant if it is in a location of high sensitivity. Further, impacts on one part of a cultural landscape may have wider and more profound impacts on the whole, regardless of the scope or scale of the activity that causes the impact. Both of these issues were addressed in an MVEIRB decision to recommend rejection of an exploration drilling program in the Upper Thelon River basin of Canada's Northwest Territories:

> The Review Board is of the view that the degree of biophysical impact on the area is not always commensurate with the magnitude of the cultural impact experienced by the people who value it. The scale of the project is not the main consideration in this case. The project is small, but the issues are much bigger because the proposed development is located in a landscape of such vital cultural importance. In this case, the Review Board heard that this development, regardless of its size, cannot be reconciled with the values placed on the area where it is proposed (MVEIRB 2007a).

Because of rare instances like those noted here where developments are not allowed to proceed, the term *significance* can create fear in the minds of developers because there is an impression that significance is all about *whether* a project should proceed ("go" versus "no-go" zones). It is not always possible to mitigate, and as a result, indigenous groups will in some cases accept nothing but complete rejection of a project. Nonetheless, such outright rejection is the extremely rare exception rather than the rule. Significance determination is almost always more about helping to determine *how* a project should proceed, under what conditions, and with what level of cultural protection. Far from being "project breakers," most adverse impacts on culture initially deemed significant can be dealt with through proactive, cost-effective mitigation. The next section examines how appropriate mitigation measures can both minimize adverse impacts and maximize benefits to all parties.

CULTURAL IMPACT MITIGATION AND CULTURAL ENHANCEMENT STRATEGIES

General Considerations

Mitigation measures to avoid, reduce, or compensate for adverse cultural impacts and to enhance cultural resilience run

the gamut from complex re-routing of the proposed activity to small, day-to-day accommodations at the work site. For example, the type of food, the norms for recreation, the support for workers unfamiliar with the wage economy, the involvement of community-based elders and spiritual leaders and healers, and the naming of features within the site can all become a focus of cultural enhancement measures (Barker and Brereton 2005; G. Gibson 2008).

In many jurisdictions legislation nominally designed to protect indigenous heritage affords few if any enforceable tools to protect the complex and varied constituents of culture. This is particularly true for impacts on less-tangible elements of culture, such as cultural landscapes, which are often only given commemorative designations without attendant substantive land-use restrictions (NWT Cultural Places Program 2007), and impacts on cultural maintenance factors like language preservation. In the absence of formal statutory legal requirements, developers face two choices: They can negotiate effective mitigation measures with indigenous groups or they can face the risks of project delay and ultimately abandonment created by these groups as they use direct action and alternative legal or regulatory mechanisms, such as EIAs, to help make up for the absence of legislative protection.

It is in the interest of developers to prioritize cultural impact mitigation, not only because it helps companies gain the required social license to operate from the cultural group, but because successful mitigation, and cross-cultural engagement more generally, offer other substantial benefits. For instance, it can help make the work environment a welcoming one for indigenous people alongside the settler culture work force, which minimizes costly turnover and time spent on workplace conflict resolution. It can also help to demonstrate the corporate social responsibility expected by shareholders, funders, and the general public alike.

Finding appropriate means to minimize impacts on culture from a mining development requires asking

- What is the likely impact outcome?
- What are the pathways/triggers by which this impact might occur?
- How can this outcome be avoided, minimized, or compensated for (in that order of prioritization)?
- Does the proposed mitigation deal with the root of the problem (pathway/trigger)?
- What alternative mitigations are available and what are the advantages and disadvantages of each? What is the best mitigation option?
- Is the proposed mitigation acceptable to the impacted group?
- What have the cultural holders themselves proposed for avoidance, minimization, or compensation?

Mitigation should focus on altering the triggers of adverse change so that valued cultural resources are, at a minimum, not eroded and, at best, enhanced. Effective mitigation prioritizes elimination of the impact, but if this cannot be done, then impacts are controlled or minimized. Compensation should always be the last resort. One of the main reasons why impact avoidance or minimization is much preferred to compensation is that it is extremely hard and usually inappropriate to place a monetary value on cultural assets. Another is that monetary compensation can in some cases actually exacerbate other social, economic, or cultural impacts on indigenous communities rather than minimize them (Gibson and Klinck 2005). If the pathways by which culture is eroding are sought out, however, targeted investments of compensatory funds can go directly into avoiding root causes or bolstering cultural resilience strategies, such as bush camps, funding for traditional harvesters to get out on the land, documentation and dissemination of elders' knowledge and stories, and grade school cultural curriculum development.

Looking beyond adverse impact mitigation, developers can obtain substantial benefits by seeking to incorporate indigenous culture into the everyday life of mining projects. In particular, this can help create a workplace conducive to indigenous recruitment and retention, with major economic benefits for the mining company (O'Faircheallaigh 2010).

Specific Examples

Different types of mitigation measures should be established and managed at different stages of project development. For example, early consultation may serve to identify areas that are sacred, and the developer may remove these areas from its development plans. Cultural protection provisions may also be recommended in EIA reports issued by regulators and attached to licenses and permits. Mitigation commitments should be sought early and redefined as necessary as the development and relations between parties mature, and when potential impacts emerge via the monitoring systems established.

Table 17.3-6 comprises a range of mitigations that have been used in projects. However, mitigation will always have a site-specific element, and so new measures will emerge tailored to the local context.

In evaluating the strength of cultural heritage protections of a large number of agreements, O'Faircheallaigh (2008) identified two key criteria: the level of protection sought; and the activities, processes, and resources applied to ensure that this level of protection is actually realized on the ground. In relation to the first, he identified five distinct and alternative levels of protection. At one extreme, sites or areas of significance may be damaged or destroyed by project development without any reference to indigenous people. At the other, there is an unqualified requirement to avoid damage to cultural heritage, even if this involves major changes to project design and/or a decision not to develop specific ore bodies. In relation to activities, processes, and resources, he identified six key areas. In this case the criteria do not represent alternatives but are cumulative; that is, the more of them that are present, the more likely it is that the level of protection sought will actually be realized. The six key areas are

1. Provisions that maximize indigenous control of site clearance and heritage management processes;
2. Provision of financial and other resources to support cultural heritage identification and management;
3. Measures to enhance an indigenous community's general capacity for cultural heritage protection;
4. Explicit protection of any cultural knowledge provided by indigenous people as part of the cultural heritage protection regime;
5. Provisions that allow traditional owners to temporarily stop project activities to protect previously unknown sites; and
6. More general measures designed to support a *system* of cultural heritage protection.

O'Faircheallaigh (2008) found that the highest levels of cultural heritage protection were required in only one-fifth of

Table 17.3-6 Cultural and social measures from environmental assessments and contractual agreements

Area	Principles and Options
Cultural heritage protection	• Principle of avoiding damage, then minimize and compensate as last resort • Measures to avoid damage to cultural sites • Description of meaning of damage to, or interference with, site/object • Site clearance guidelines including time frame for site clearance reports • Prohibitions on interference with cultural spaces and archaeological sites • Indigenous access to areas that contain sacred sites (e.g., traditional owners at the Rio Tinto Argyle diamond mine in Western Australia have access to areas of the mining lease that contain such sites) • Employment of local cultural heritage protection monitors • Monitoring guidelines • Protocols for site or object management • Confidentiality of culturally sensitive information • Consequences if mining party defaults • Process or compensation for site/object damage
Cultural landscapes and other special spiritual spaces/places	• Protection of sacred sites • Continued practice of rituals to maintain site or protect visitors from harm
Culture and land tenure	• Protection or creation of alternative sites or livelihoods for agriculturalists
Overall relationship to the land and traditional activities on the land (including practice of traditional economy)	• Compensation for lost revenues from trapping and fishing caused by damage to equipment, loss of animals, including direct loss if animals are not in area or if there is increased cost associated with additional travel • Assistance in location of new areas • Rotation change such as moving from a 3-day rotation schedule to a 2-week rotation schedule to allow for time out harvesting on the land
Values	• Measures to control interactions of "outside" workers from large accommodation camps with small, primarily indigenous communities • Family and community support (e.g., money management, training) • Counseling in locally appropriate way and in own language for worker and for entire family • Flexible human resource policies that acknowledge different models of kinship • "Country" or "bush" food kitchens, and the ability to prepare food in the culturally appropriate style • Provisions for country food on the main dining menu • Possibilities or spaces for the practices, rituals, and spirituality of the indigenous peoples
Methods of cultural transmission (including language, oral history, intergeneration relations)	• Site visits by elders and conduct of ceremonial activities on site (e.g., the cultural practice of mantha, a ritual done to protect workers at the Argyle diamond mine or naming of landscape features using Aboriginal place names) • Special leave for culture and for family or community crisis • Creation of community–corporation relationship mechanisms such as family visits and out-on-the-land trips • Language-promotion activities • Community involvement in defining, monitoring, and analyzing cultural impact
Social networks	• Family accommodations and spousal visits • Develop family separation, life skills, drug and alcohol or gambling addictions programs; prepare people for lifestyle associated with development or rotation schedule management • Policies on consumption and use of alcohol and drugs • Training for and access to computers and availability of phone and computer access to family
Sense of self, sense of place, overall well-being	• Cultural exchanges of senior managers and senior indigenous leaders • Cultural sensitivity training for all incoming senior managers to ensure awareness and sensitivity to culture • Funding traditional knowledge studies—information collection and dissemination in an appropriate manner and led by the cultural group • Broader support for cultural activities (e.g., support for cultural activities) • Antiracism training and gender sensitivity training • Flexible work schedules and equal time on and off of rotations • Cross-cultural training workshops

the agreements he evaluated. This suggests that negotiated agreements are only able to achieve protection in some cases, given that the bargaining power of some indigenous communities is limited. Where the community is well-resourced and politically powerful, there is often a strong ability to use agreements to achieve cultural heritage protection. In other cases, indigenous peoples will need to use all available avenues for protection.

O'Faircheallaigh's research also highlighted the fact that even where a system is created for cultural heritage protection, there is often a systematic failure to implement it effectively. There are many reasons for this failure to implement agreements, such as changing circumstances, lack of resources, failure to review and renegotiate mechanisms over time, failure to anticipate all the issues that emerge, and inappropriate allocation of responsibility or authority for cultural heritage protection (O'Faircheallaigh 2003). This highlights the need to focus carefully on the mechanisms and resources needed to ensure that cultural heritage protection provisions continue to operate and work as previously envisioned.

Mining companies must develop, in collaboration with affected indigenous groups, specific measures to mitigate cultural impacts and support cross-cultural engagement, and ensure that these are not put in place solely to secure project

approval but are maintained over the longer term. This requires substantial and ongoing commitment by senior management of the time and financial resources required to support indigenous participation and implementation of protective measures.

Workplace-specific mitigation is an essential element of any cultural impact management plan. Some of the measures that increase workplace satisfaction include antiracism training, gender sensitivity training, and policies on harassment, racism, and cultural leave for bereavement (G. Gibson 2008). In addition, the nature and length of a rotation will be of critical importance (Shrimpton and Storey 2001, 1989); an equal rotation (e.g., 2 weeks on and 2 weeks off) is often the most sustainable for families and workers. Exit interviews with Aboriginal miners at the Century mine in north Queensland found that appropriate support and mentoring for workers was essential (Barker and Brereton 2005). The commitment involved in providing this support is well justified in terms of the role it plays in securing an ongoing license to operate, in avoiding the serious investment risks that can occur if indigenous heritage is damaged, and in terms of the value that can accrue to the enterprise from the positive effects of cross-cultural engagement.

CONCLUSION

Using the tools outlined in this chapter will help developers get past the fear of the unknown and embrace the opportunities presented by cultural impact assessment and cross-cultural engagement. A mindset change is at least as important as a new toolkit. It is critical to remember that finding an adverse cultural impact does not in most cases mean a project will not proceed, and that avoidance of thorough and early cultural impact assessment is much more likely to create a high-risk situation than avoid one.

A good cultural impact assessment can do more than merely provide evidence for the EIA processes. Corporations can gain public prestige both by effectively engaging with indigenous communities and by supporting strong community-based identification, management, and protection of cultural assets. Cross-cultural engagement can also generate substantial value for enterprises by, for instance, allowing them to gain access to stable, skilled work forces that are committed to the regions in which minerals are developed.

Cooperative indigenous–company action to enhance culture can also generate benefits for indigenous culture holders. It can provide opportunities for indigenous people to document and appreciate their own history and culture. Where potential impacts on sacred land are being studied, the stories, songs, and practices that are central to this place may be archived and rejuvenated for younger generations of indigenous people.

The following general rules can make cross-cultural engagement and cultural impact assessments effective, risk-minimizing, and benefit-maximizing processes for all parties.

Key considerations for effective cross-cultural engagement:

- Proceed with caution and prudence. Don't rush in.
- Follow community engagement protocols.
- Be ready to put on the shoes of the "other"; identify and respect differences between your culture and that of the group you are interacting with. Suspend your disbelief early—just because a place has no cultural value or meaning to you, it does not follow that it has no meaning to others.
- Talk to indigenous people and their organizations well in advance of actions that may have impacts; provide information early, fully, and in a form that makes sense to people. Recognize that withholding information is itself a major cause of negative sociocultural impacts.
- Don't assume your own interpretation of what will or will not generate impacts is soundly based in the indigenous context.
- Share control and work cooperatively. For most indigenous people, a process someone else controls is a process they don't trust.
- Provide resources for communities to engage; communities are not in a position to do so, and it is an investment that will yield dividends.
- Use all available avenues, not just the formal EIA process, to engage with communities on cultural issues.
- Do not view cross-cultural engagement as a discrete stage in project life, or simply as one of a series of regulatory hurdles. See it as an integral part of all activities, like health and safety.

Key considerations for effective cultural impact assessment:

- Do early work—acclimatize to the indigenous culture, and understand what mining can do to culture.
- Include traditional knowledge as much as possible, but respect culture-group-defined protocols around gathering, control, and distribution of culturally sensitive information.
- Avoid the "fear factor"; realize that project-threatening impacts are relatively rare. Treat cultural impact assessment instead as an opportunity for proactive relationship building, not as a regulatory hurdle.
- Get beyond "bones and stones"; identify both tangible and intangible valued cultural components.
- See beyond the site to the situation; learn about cultural context.
- Recognize that wisdom sits in places, spaces, and people—all merit attention.
- Adopt the proper scope and scale for your project's cultural impact assessment based on robust scoping.
- Use experts where necessary and appropriate degrees of rigor.
- Don't study for study's sake; exhaust your analysis of existing data sources before starting additional fieldwork.
- Gradually ramp up effort, investment, and specialist advice as the project develops and potential impacts expand.
- Project size is only one factor in the equation—do not assume that the biophysical impact footprint is the only driver of cultural impact potential.
- Support and augment qualitative data with quantitative data, and vice versa.
- The culture holders themselves must play the key role in defining cultural impact significance.
- Consider whether community-defined thresholds of acceptable change are likely to be exceeded for valued cultural components, and work with other responsible parties to minimize additional impact loads.
- Recognize that the work site itself is not culture-free, and develop mitigation to avoid cross-cultural conflict.

CHAPTER 17.4

Management of the Social Impacts of Mining

Daniel M. Franks

INTRODUCTION

The value of a "social license to operate" is increasingly recognized within the mining industry. Unmitigated negative social impacts have the potential to result in negative publicity, increased litigation, and reputational damage, or to delay, prevent, or close down mining in existing and prospective areas as a result of community concerns. On the other hand, the positive impacts associated with mining projects can be welcomed by communities and governments. Assessment and ongoing management of environmental impacts are relatively common fixtures in the mining industry, as evidenced through formal environmental impact assessment processes and environmental management plans. Only more recently have approaches emerged to link social impact assessment with ongoing management and to proactively respond to social and community issues.

This chapter outlines techniques and processes that assist first in identifying and responding to social issues during planning and then in guiding and monitoring projects during operation through to postclosure. The term *management* is used in this chapter to refer to the coordination of activities in responding to social impacts and social risks. Effective management requires an understanding of social issues, which can be gained through ongoing assessment. Through both assessment and management, the design and implementation of mining activities can be shaped to enhance environmental and community outcomes.

Social impact assessment and management are the responsibility of dedicated community relations practitioners at most mining operations. In addition, however, there is a need for mining engineering professionals to be familiar with such approaches, since effective management requires integration across all aspects of the operation. In recent years, mining companies have increasingly come to recognize the value of using management systems to manage all aspects of their operations. Commencing with the introduction of quality systems and environmental management systems based around key international standards (ISO 9000 and ISO 14000, respectively), the trend now is to bring these specialized areas together into integrated management systems. It is essential that the management of social issues be part of this trend and not considered in isolation from the other parts of the business.

This chapter begins with a discussion of the social impacts of mining and then looks at each of the phases of social impact assessment and management that make up current practice in the field (Figure 17.4-1). These phases are consistent with an adaptive management framework or the plan-do-check-act cycle. Adaptive management emphasizes continuous improvement through an iterative process of planning, implementation, monitoring, and adjustment. The phases of social impact assessment and management include (1) the scoping and formulation of alternatives, (2) profiling and baseline studies, (3) predictive assessment and revision of alternatives, (4) management strategies to avoid and mitigate negative social impacts and enhance positive impacts, (5) monitoring and reporting, and (6) evaluation and review. The chapter concludes with lessons that can inform technical and management roles. Through greater awareness and consideration of social impacts and risks, mining engineering professionals will find their projects are more acceptable to communities and have a greater prospect of success.

SOCIAL IMPACTS AND RISKS

A social impact is something that is experienced or felt (real or perceived) by an individual, social group, or economic unit. Social impacts are the effect of an action (or lack of action) and can be both positive and negative. Social impacts can vary in type and intensity, and over space and time. Examples of social impacts associated with mining operations include employment effects; changes to social services, such as health and childcare or the availability and cost of housing; and cultural change, such as changes in traditional family roles as a result of the demands of mining employment, or even the breakdown of traditional economies due to the introduction of a cash economy. Environmental impacts also have social implications. Mining activities can result in changes to community amenities, health, or the availability and quality of water and land (Table 17.4-1).

Impacts can be direct, such as the impact of noise and dust, or result from indirect pathways, such as road fatalities

Daniel M. Franks, Research Fellow, University of Queensland, Sustainable Minerals Institute, Centre for Social Responsibility in Mining, Brisbane, Australia

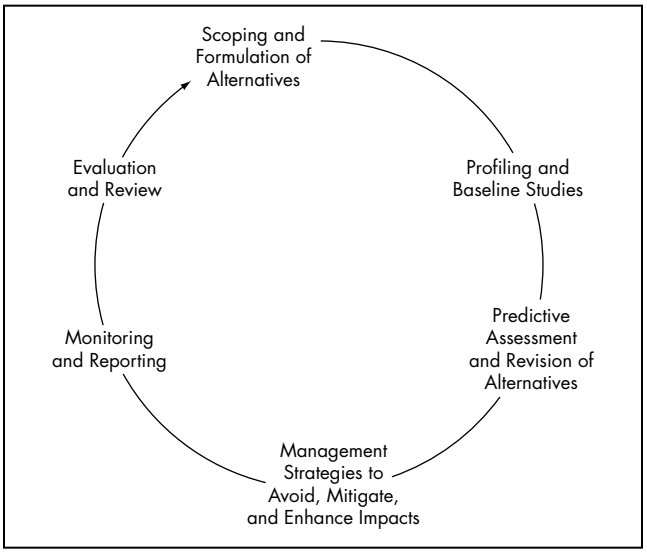

Figure 17.4-1 Phases of social impact assessment and management. The phases should be applied to each stage of the mining life cycle as part of an adaptive management cycle.

resulting from increased traffic in a nearby town servicing a mine. Impacts often accumulate and interact such that they trigger or become associated with other impacts. Cumulative impacts arise from the compounding activities of a single operation or multiple mining and processing operations, as well as from the interaction of mining impacts with other past, current, and future activities that may not be related to mining (Franks et al. 2009a).

A social risk is the potential for an existing or planned project to have an impact on individuals or groups or, conversely, to be impacted by them. Like impacts, social risks are both positive and negative because of the potential for mining to generate social and economic opportunities, such as economic and community development and employment.

The fear of an action can often be as important a generator of impact as the action itself. Perceptions of impact, opportunity, or risk are subjective, and public understandings do not necessarily correspond with scientific perspectives. There are a number of reasons for this. Nontechnical factors, such as personal value systems, previous experience, levels of trust in information sources and methods, and openness to change, all influence the way individuals and communities perceive and respond to change.

PHASES OF SOCIAL IMPACT ASSESSMENT AND MANAGEMENT

Social impact assessment (SIA) is a process for understanding the social issues associated with development. SIA is focused on how to identify, avoid, mitigate, and enhance outcomes for communities and is most effective as an iterative process, rather than a one-off activity at the outset of mining (Vanclay 2003; Becker and Vanclay 2006). Social impact management refers to systems and strategies undertaken during the implementation phases of a development (including exploration) to monitor, report, evaluate, review, and proactively respond to change. Together, SIA and impact management provide a very effective tool to address impacts, if the team conducting the work are well integrated with the overall management of the entire operation.

Not all social impacts are predictable. Because communities and the external environment are dynamic, an element of uncertainty will always be present. Similarly, not all impacts can be avoided or mitigated. However, SIA can provide insights, focus attention, and identify key issues as perceived by stakeholders to predict and anticipate change, and social impact management can assist in proactively responding to the intended and unintended consequences of mining developments.

SIA and impact management are most effective when undertaken across the life cycle of mining and resource processing, encompassing all of the activities from exploration, construction, extraction, and processing, through to postclosure, as well as including recycling and waste management. The varied social impacts across the mine life-cycle phases and the extraction and resource processing stages demand a varied range of approaches to assessment and management. For example, the exploration phase often entails a need to carefully manage community expectations, a challenge in maintaining continuity, and a risk that the outcomes at this early stage can greatly influence the future of relations. At the construction phase, there is invariably a large influx of temporary contract workers into a region that may pose challenges for communities; at closure, impacts are generated by the withdrawal of economic activity and employment, and management requires long-term planning to support alternate futures. Similarly the nature and scale of impacts, and thus the scale and scope of assessment and management, will vary with the type of extraction. Opencut pits involve the removal, processing, storage, and rehabilitation of large amounts of material that can pose risks to waterways or affect the visual amenity of a region; underground mines can create subsidence at the surface, which can affect other land users; heap leach and in-situ leach operations can pose risks to groundwater that may be used by other people and industries; and the various stages of processing will demand varied inputs and create by-products and hazardous materials that can pose risks to communities. The form and level of assessment and management is determined by the significance and scale of the action, as well as by the sensitivity of the community, the location, and its environment.

SIA is a common requirement of regulatory approval processes at the project approvals phase for mining and processing stages in many jurisdictions. These SIAs may be independent or integrated within environmental impact assessments. Beyond this regulatory requirement, SIAs are undertaken by mining operations in response to an actual (or potential) major change in the project or impact on a community—for example, in preparation for closure or for a major expansion. Social impact assessment can also address any particular issues faced during exploration, resettlement, temporary scale-down of operations, or a community development program. Assessments are most useful when maintained and periodically updated as "living" documents to inform decision making. Social impact management approaches, such as community reference panels, social management plans, grievance mechanisms, and community development initiatives, are increasingly required by government legislation, as well as by industry and corporate policies/standards.

The following sections introduce and describe each of the phases of SIA and impact management. Consistent with an adaptive management approach, many of the techniques mentioned may be useful in several of the phases. For example,

Table 17.4-1 Common changes induced by mining activities that can lead to social impacts and risks

Social and Cultural Change	
Population and demographics	In-migration, out-migration, workers' camps, social inclusion, growth or decline of towns, conflict and tensions between social groups
Social infrastructure and services	Demands on and investment in housing, skills (shortages and staff retention), childcare, health, education, and training
Crime and social order	Corruption, domestic violence, sexual violence, substance abuse and trafficking, prostitution, change in social norms, pace of change for vulnerable communities
Culture and customs	Change in traditional family roles, changing production and employment base, effect of cash economy, reduced participation in civil society, community cohesion, sense of place, community leadership, cultural heritage
Community health and safety	Disease, vehicle accidents, spills, alcohol and substance abuse, pollution, interruption to traditional food supply, awareness and treatment programs
Labor	Health and safety, working conditions, remuneration, right to assemble, representation in unions, labor force participation for women
Gender and vulnerable groups	Disproportionate experience of impact and marginalization of vulnerable groups (e.g., women, disabled, aged, ethnic minorities, indigenous, and young), equity in participation and employment
Human rights and security	Abuses by security personnel (government, contractor, company), social disorder in camps, suppression of demonstrations, targeting of activists, rights awareness programs
Economic Change	
Distribution of benefits	Employment, flow of profits, royalties and taxes, training, local business spending, community development and social programs, compensation, managing expectations, equitable distribution across state/regional/local/ethnic/family groups, cash economy
Inflation/deflation	Housing (ownership and rents), food, access to social services
Infrastructure	Demands on, and investment in, roads, rail, ports, sewerage, telecommunications, power and water supplies
Socio-Environmental Change	
Pollution and amenity	Air (e.g., dust), water (e.g., acid and metalliferous drainage, cyanide, riverine and submarine waste disposal), noise, scenic amenity, vibration, radiation, traffic, government capacity to monitor and regulate
Resources (access/competition)	Land, mobility, water (groundwater, river, ocean), mineral resources (artisanal and small-scale mining), cultural heritage, forest resources, human, postmining land use
Resettlement	Consent and consultation for resettlement, compensation, ties to land, adequacy of resettlement housing and facilities, equity, postsettlement conditions, livelihoods
Disturbance	Disruption to economic and social activities (including by exploration), consultation for land access, frequency and timing, compensation
The Process of Change	
Community engagement	Consultation, communication, participation, empowerment, access to decision makers, transparency, timing, inclusiveness—particularly for vulnerable and marginalized groups—respect of customs and authority structures, reporting
Consent	Indigenous sovereignty/title (free, prior, and informed consent), community consent
Participation	Planning, development of programs, monitoring, selection of alternatives and technologies, operational aspects
Remedy	Grievance and dispute resolution, acknowledgment of issues, compensation, mitigation
Agreements	Equity, timely honoring of commitments, issues with delivery, duress, clarity of obligations, capacity and governance (including government capacity to respond to and manage change)
Community development	Participation, adequacy, appropriateness, capacity to facilitate, consistency, prioritization

management approaches such as community reference groups can be effectively used to identify issues during scoping. To avoid duplication, the techniques will be discussed in the phase in which they are most commonly used. Table 17.4-2 presents a variety of social research methods and impact assessment techniques that are often, but not exclusively, applied at the scoping and predictive assessment phases.

Scoping and Formulation of Alternatives

When developing a new project, planners are usually faced with a number of alternative options. Impact assessments provide an opportunity to investigate these alternatives in greater detail to assist decision makers in choosing the most appropriate option.

The scoping phase sets the parameters for the later phases of assessment and management by determining the scale, timing, and focus of the assessment, ascertaining who is likely to be impacted and identifying the actions that are likely to result in impacts.

Scoping will begin by defining the purpose of the assessment and identifying background material that may influence the assessment. This includes regulations and legislation, government and corporate policy and programs, standards, and operating procedures. After these have been taken into account, the next step is to identify project stakeholders.

Early public involvement is crucial to identifying attitudes and perspectives, harnessing local knowledge, and defining processes for further public involvement (more information on the identification of stakeholders appears in "Profiling and Baseline Studies"). With the assistance of stakeholders, the actions that are likely to result in impacts and the extent to which these impacts may be felt can be initially identified. Case studies of related actions may assist in this regard, and any gaps in knowledge should be recorded.

Alternative options should be formulated for later analysis and an initial appraisal of the impacts of these alternatives undertaken. Impacts can be prioritized, in consultation with stakeholders, to narrow down the analysis

Table 17.4-2 Common social and economic research methods and assessment techniques

Method	Description
Literature review	A critical summary of current knowledge on a topic drawn from an existing body of literature.
Interview	A method of primary data collection that consists of in-depth questioning. Interviews may vary according to the type of informant, the type of medium (telephone or face-to-face, individual or group), the setting and recording, and the type of questioning (structured, semistructured, and unstructured).
Focus group	A group interview method where a facilitator poses questions to generate discussion among participants.
Survey/questionnaire	A form with questions used to solicit information from a statistically significant group of respondents. Surveys may be used in SIA to provide data on the characteristics and opinions of a population and may vary according to the choice and wording of questions, the type of instrument (e.g., mail-out, telephone, or face-to-face), the sample size, and sample frame.
Stakeholder analysis	A stakeholder is anyone who can affect, or is affected by, an action. Stakeholder analysis consists of the identification of stakeholders, analysis of their underlying attitudes and motivations, a determination of which stakeholders are most significant, an understanding of their networks and relationships, and the development and implementation of an engagement plan.
Social and economic profile	A process to collect relevant primary and secondary data about a community. The profile is a detailed description of the community, environment, and economy of a region and provides insight into values, priorities, and trends.
Social baseline	An appraisal of the current state of a community or social group including a consideration of trends.
Case study/comparative analysis	Detailed analysis of an example, often used to identify patterns and causal relationships. Case studies can be developed from multiple sources of information and can be supplemented by data gathering.
Cultural heritage mapping	A process for identifying and recording the meaning ascribed to landscapes by cultural groups.
Ethnography	The description of human societies, usually informed by field methods that include interviews, participant observation, and surveys.
Impact pathway analysis	A process-mapping exercise used to predict the pathway of impacts resulting from an action. The method prompts insights into the direct and indirect impacts of actions and their interaction. Also known as change mapping.
Social risk assessment	A participatory technique to identify, prioritize, and respond to the social risks and opportunities faced by an organization or communities. Through a facilitated workshop, key stakeholders determine the consequence and likelihood of each identified risk and develop controls to avoid, mitigate, or enhance priority risks. Also known as social risk and opportunity analysis.
Scenario analysis	A tool used to anticipate change under different plausible future situations. Scenario analysis assists the development of a proactive policy response through the testing of assumptions.
Trend analysis	The collection and analysis of historical and contemporary data to inform the prediction of the future.
Cost–benefit analysis	An economic technique that compares the costs and benefits, usually quantified in monetary terms, for scenarios with and without an action.
Cost-effectiveness analysis	An economic technique that compares the cost-effectiveness of alternative options for achieving an outcome. It is used to identify the alternative with the lowest direct financial cost.
Input-output analysis	An investigation of the relationships and interdependences of an economy through an analysis of the flow of resources. It considers the inputs to industry, transfers between sectors, household consumption, and the outputs of goods produced.
Choice modeling	An experimental technique used in economics to frame trade-offs between different options. The technique estimates the value of options by revealing how respondents are willing to trade them. Information is usually gathered through surveys.

and investigation of the later phases to address key issues of relevance. Cumulative impacts should be considered during this prioritization stage. Although an issue may appear acceptable when considered in isolation, the impact may have greater significance when combined with the impacts of other overlapping activities.

Future and simultaneous proposals should be considered during the scoping phase. Methods range from collation of known projects (announced, approved, or under construction) and government forecasting to industry surveys of potential future activities. Efforts to forecast potential future developments can demonstrate that the proposal is serious about (and investing in) regional futures. Issues of commercial confidentiality have been overcome in other resource provinces through the use of anonymous industry forecasting surveys, usually undertaken by a peak industry body. Such information can also help the industry negotiate with government on future infrastructure needs and priorities.

The output of the scoping phase may be the definition of the objective, scope, scale, priority issues, and terms of reference for the phases of assessment and management to follow.

Profiling and Baseline Studies

Social profiling consists of understanding the communities and stakeholders potentially impacted by the activity through social and economic research. Profiling involves analysis of the social and economic characteristics of a region at a given point of time. Baselines are an appraisal of the state of a community or social group before an activity takes place. Baseline studies provide a benchmark against which potential impacts can be anticipated and change measured. They are also valuable for building mutual understanding. The foundational

information and understandings provided by profiling are useful across all of the phases of extractive projects. Leading companies now routinely require their operations to undertake such studies and update them at regular intervals, particularly when there is any significant change to the scale or shape of a project or community. For example, Anglo American PLC has developed its own Socio-Economic Assessment Toolbox process to assist and encourage their operations to regularly review social impacts at different stages through the life of the project. Through regular review of profiles and baseline studies, or by approaching profiling as a "living" output, longitudinal trends may be observed over time and a more accurate picture of the change processes will be developed.

Knowing the community assists in anticipating how people might respond to change. Actions, even well-meaning ones, that are not socially, culturally, or environmentally grounded in the people and places (potentially) affected by a development, invariably result in poor outcomes. Understanding communities involves an analysis of their relationships and networks and the values that may shape attitudes and behaviors.

Stakeholder analysis is a common profiling technique that may be useful across a number of phases. A stakeholder is someone that has, or potentially has, an interest in an issue—any entity that is affected by, or can affect, a project. Stakeholders can be individuals, groups, neighborhoods, or organizations. Stakeholder analysis consists of the identification of stakeholders, analysis of their underlying attitudes and motivations, a determination of which stakeholders are most significant, an understanding of their networks and relationships, and the development and implementation of an engagement plan. Targeted consultations (or focused plans) may need to be developed for each stakeholder, especially vulnerable groups. Stakeholders have varying degrees of power, legitimacy, and interest in an issue or a project. They may include communities located in the vicinity of mining operations, employees, shareholders, financial institutions, indigenous peoples, nongovernmental organizations, trade unions, and governments and their departments. Stakeholders also include people within resource companies that may be important to the planning, development, and implementation of the action.

Profiling can be assisted by establishing meaningful avenues of two-way dialogue with stakeholders. Dialogue can reveal stakeholder histories and decode cultural meanings and symbols. Knowing the operations or proposed activity is a crucial, but often missing, element of profiling. This step requires an understanding of how the various elements of the proposal fit together and how the work groups involved in planning and implementation make decisions.

Profiling includes analysis of demographic patterns and trends; population characteristics; ethnicity and culture; the local economy; the labor market; land-use and ownership patterns; social and political organization; family and community organization; matters involving health, nutrition, and disease; community infrastructure and services (housing, health, childcare, etc.); expectations and concerns community members have about the project; community needs and desired futures and the capacity to meet these needs; and the vulnerability of social groups.

After a review of secondary information, and the identification of knowledge gaps, a program for the collection of primary data is developed. It is important to know the purpose for the collection of each piece of data. The accumulation of vast amounts of information of marginal use can be overwhelming and leave little time to do analytical work. Methods of primary data collection include quantitative, qualitative, participatory, and technical methods, such as interviews, focus groups, literature reviews, and surveys and case studies, among others.

Predictive Assessment and Revision of Alternatives

In this phase, likely impacts are identified and predicted, and their scale and significance evaluated, using technical and participatory methods. Impact prediction is an opportunity to analyze issues in more detail and to undertake broader consultation and engagement. A number of techniques can be used in social impact assessment to inform this phase (Table 17.4-2). The choice of methods will depend on the nature of the activity and the phase within the mining life cycle. The focus of the analysis will be informed by the prior scoping and profiling phases, and the baseline data will form a foundation for anticipating and predicting risks and impacts. Predictive assessment usually requires the collection of additional data.

Where possible, analysis should consider associated facilities, policies, or programs, such as roads, power transmission lines, and community development initiatives. Predictions should both describe how the proposed activity will contribute to the existing situation and assess the capacity of environmental and social systems to absorb impacts. The methodology and level of confidence should also be clearly explained, as well as any gaps in knowledge.

The outcomes of predictive assessment and analysis are usually prioritized by their scale and level of significance (sometimes as a matrix). They are used to provide feedback to engineers and project developers in order to modify and revise the project, as well as to enable them to decide which proposed project alternative best achieves the objectives of the project while still enhancing social outcomes and avoiding negative impacts.

As part of the trend toward integrated management systems, most mining companies have now adopted extensive risk-management processes that encompass many different elements. It is common to find consequence tables in risk-assessment procedures that include both environmental and community dimensions (Barclay et al. 2009). Social risk assessment, also known as social risk and opportunity analysis, is a technique that can be undertaken during the predictive assessment phase, but it may also be periodically employed to identify and update key social risks and opportunities, and to respond with appropriate strategies, during the impact management phases. Social risk assessments usually involve a workshop of key stakeholders (internal and/or external to the organization) and may be focused on the social risks and opportunities faced by the company or communities. The key tasks are to

1. List the potential social risks and opportunities that may affect (a) the company, and (b) the community;
2. Think about the causal factors for each of the risks/opportunities identified;
3. Make an assessment of the likelihood of the risk/opportunity occurring;
4. Make an assessment of the consequence if the risk/opportunity were to materialize;
5. Prioritize the risks and opportunities based on the assessment; and

6. Develop controls (ways to mitigate or enhance) for the most significant risks and opportunities (Evans et al. 2007).

The outcomes of such a social risk-assessment process should be captured as part of the overall "risk register" for the project. Social risks can be among the highest priority category for mining projects.

Management Strategies to Avoid, Mitigate, and Enhance Impacts

In many circumstances, there is a lack of integration between SIA and the ongoing management of social and economic issues after a project commences or after an operation closes. This can happen for many reasons. SIAs are often conducted by external consultants to serve the regulatory need for independent analysis. In such cases, there can be a lack of continuity between impact assessment and relationship development with community and stakeholders. Another possible reason for a lack of integration is that impact assessment might be the responsibility of a small team, most likely in the community relations section, whereas management requires coordination across all aspects of the operation.

It is important that the outcomes of SIA be embedded across all aspects of the business, similar to the way that health and safety have been embraced at a corporate level in recent years. Social impact management can be formalized into management systems, typified by various series of the International Organization for Standardization, site plans, agreements, development of standard operating procedures for high-risk issues, and systems to handle complaints and grievances. Examples of management procedures to address social issues include formal complaint handling systems, cultural heritage management plans, human rights and cultural awareness training (linked to human resources systems), and local sourcing and purchasing policies.

For some impacts, particularly cumulative impacts, the most effective approach may not be to target a particular impact generated from mining but to invest "off-site" to ameliorate or enhance impacts generated by other activities. At the broader level, there are four approaches to the management of impacts. These are to (1) mitigate or enhance the impacts of past and existing activities; (2) mitigate or enhance the impacts of the project or activity under consideration; (3) mitigate or enhance the impacts of potential future projects; or (4) consider whether and how these projects or activities should proceed (Duinker and Greig 2006).

This section has introduced a number of strategies for ongoing management. There is a great deal of overlap between the strategies outlined here and the practice of community relations, community development, and community engagement. The following discussion details a sample of approaches including social management plans, scenario planning, community reference groups, community development and social investments, networking and working groups, and complaints and grievance handling mechanisms.

Social Management Plans

Social management plans (also known as "environmental and social management plans," "social and labor plans" or "environmental and social action plans") summarize the findings of the impact assessment; they outline the measures adopted to enhance positive impacts and to avoid, mitigate, and (as a last resort) offset and compensate negative impacts (Franks et al. 2009b). In addition, the plans provide estimates of the timing, frequency, duration, and cost of management measures. They also establish monitoring and reporting procedures (discussed later in greater depth).

Social management plans are usually developed in partnership with regulatory agencies, investors, and the community; they identify the responsibilities of each party in the management of impacts, opportunities, and risks. Management plans also provide an opportunity to link activities with local and regional planning processes and, if developed with reference to the management plans of other operations, can assist in addressing cumulative impacts. They also provide the facility to coordinate project activities with service and infrastructure planning by government.

The plans may explicitly refer to capacity-building activities, where the institutional or community capacity to undertake such activities is lacking, and may include details of community development and social investments. Finally, social management plans outline the procedures for how social issues will be addressed in site management systems and plans, the processes for ongoing public participation and information disclosure, and the mechanisms for handling community grievances and feedback. Measures that are the responsibility of other parties are recorded and form a basis for ongoing partnerships (Franks et al. 2009b).

Scenario Planning

Scenario planning can assist organizations in preparing for unplanned activities. Scenario analysis is a tool to anticipate change under different plausible future situations. It assists the development of a proactive policy response through the testing of assumptions. If conducted with communities, scenario planning can help to inform the public of risks and manage expectations. For example, the boom-and-bust nature of the industry can increase the risk of premature or temporary closure and downsizing of operations. The effects of mine closures (where impacts are generated by the absence of activities) can be a significant challenge for regional communities and economies. Planning for closure should proceed well before an operation starts, and measures should be put in place to prepare communities and companies for such an eventuality, which will most definitely occur (however large the deposit or valuable its product).

Community Reference Groups

Community engagement is an important component of social impact management. It involves activities such as the communication of the project proposal to stakeholders; the incorporation of stakeholder views in order to modify project details; the ongoing involvement of stakeholders in community boards and reference groups; and stakeholder participation in the submission of ideas for, and implementation of, community projects.

Regardless of the form of engagement, it is important to be upfront and straightforward with stakeholders when communicating the potential impacts of a project. False impressions can distort expectations and become an ongoing point of contention and a breach of trust when the true nature of impacts becomes clear (Franks 2009).

Community reference groups provide a forum for ongoing consultation and engagement. Representation can include groups such as youth and aged organizations, local business,

tourism, health, welfare, policing, and education, in addition to environment, government, and community groups. Broad representation helps to ensure that a range of issues are covered, (although reference groups should be kept to a manageable size). For community reference groups to be at their most effective, there needs to be strong mechanisms for feedback to the broader community to provide an opportunity for input and to report on outcomes.

Community Development and Social Investments

A key strategy adopted by mining companies to manage social impacts involves programs to support community development. These may include health and education programs or support of organizations such as schools, clubs, and societies. It is important to focus and coordinate investments to target community priorities and identified needs. Community development may be prioritized by the outcomes of the scoping, profiling, and predictive assessment phases and, more importantly, through community participation. Partnerships are often the best way to facilitate local capacity-building and development programs, social services, and infrastructure (Kemp 2003, 2010). Partnerships with organizations, service providers, governments, other mining companies, and peak industry bodies can be effective in mobilizing greater resources, leveraging investments, and coordinating activities. Many mining organizations prefer an approach where community-led initiatives are supported by industry. This approach seeks to build the capacity of communities and their organizations to undertake activities and avoid overdependence on mining companies. Examples of community trusts include BHP Billiton's Minera Escondida Foundation in Chile and Rio Tinto's Coal and Allied Community Trust in Australia.

Networking and Multistakeholder Working Groups

Informal and formal networks can provide important opportunities to exchange experiences at the operational and strategic level to better manage the impacts of activities. Professional networking is an opportunity to exchange ideas and advice, as well as to communicate approaches (both successes and failures). Formal networking arrangements, such as forums of mine managers and professional staff, provide an ongoing opportunity to discuss common issues and coordinate activities. Examples include the Central Queensland Mining Rehabilitation Group, which is a forum for sharing experiences about environmental management on mine sites in central Queensland, Australia, and the Muswellbrook Mine Managers forum, which is a regular meeting between the general managers of multiple coal mines and local government in the Hunter Valley, Australia.

Multistakeholder working groups are an opportunity to facilitate partnerships around a particular goal. Working groups can share strategic information, develop and coordinate solutions, undertake research into best practice, and facilitate cross-sector communication. Multistakeholder working groups are well placed to focus on the management of social issues at a regional scale.

Complaints and Grievance Handling Mechanisms

Complaints and grievance handling mechanisms are becoming more common at the operational level within the mining industry as a means to actively respond to community concerns. A grievance is a concern, issue, or problem that is usually expressed through a complaint or protest by individuals or groups. According to Kemp and Gotzman (2009) grievance mechanisms include

- A dedicated pathway (or pathways) and processes of engagement for handling grievances;
- Procedural elements, such as a documented procedure outlining steps to be taken to handle community grievances;
- Records, such as complaints/grievance logs and data, evidence of communication about the process, and documentation of outcomes;
- Dedicated resources, such as human and financial resources, as well as formally defined responsibilities for grievance handling;
- Evidence of dialogue with aggrieved parties and/or use of alternative dispute-resolution techniques (negotiation, mediation, arbitration, etc.) where direct dialogue is not possible or has little potential (through normal channels) of leading to a resolution of issues; and
- Substantive outcomes, such as improved organizational practice and relationships, and conflict resolution (validated by aggrieved parties).

Monitoring and Reporting

The monitoring and reporting phase involves collection, analysis, and dissemination of information on social impacts, opportunities, and risks over time. This phase can (1) assist in refining assessments, (2) track the progress of social impact management approaches and identify changes needed (adaptive management), (3) assess the return that a company is getting on its community investments, (4) report to communities on how they are being impacted, and (5) facilitate an informed dialogue around these issues.

Monitoring

Social impact monitoring can be challenging for many reasons: time lags between actions and outcomes, difficulty in isolating impacts, difficulties in obtaining and comparing data, differences in the way people experience impacts, the risk of information overload for managers, and the complexity of the way impacts interact. Not all impacts can be separated and analyzed independently because they do not exist in isolation of the social and ecological context. It is important, therefore, to have ongoing points of intervention and monitoring.

Monitoring should be undertaken over meaningful time scales and spatial extent. Regional monitoring can help to address the cumulative impacts of multiple actions (Franks et al. 2009a). Monitoring should also be designed to facilitate community participation. The participation of community members can assist many aspects of monitoring, including the collection of data, participation in the development of indicator frameworks, or multistakeholder monitoring organizations. Meaningful participation can assist in building public confidence and trust in the monitoring and resolution process.

Monitoring consists of a number of discrete activities. These include the following:

1. Decide what to monitor. Prioritization can be based on community engagement and the profiling, assessment, and impact management phases. It is important to monitor outcomes, not just effort and activity.
2. Define targets, limits, and thresholds. What are the desired and undesired outcomes? Thresholds refer to

scientifically defined points where undesirable changes result if exceeded. Limits consider what may be acceptable to the community as determined through consultation and participation, with targets being designed as the desired future outcomes.
3. Select indicators. What would indicate that change is occurring or has occurred?
4. Establish measures. What data are preferred, what data are available, how will data be collected, and how often will it be collected?
5. Report and interpret data. Identify and verify trends (or nontrends), interpret trends (attribute change), and communicate results.

The collection of irrelevant information can be avoided through planning and prioritization, and the measurement load can be minimized through the appropriate design of administrative systems and the use of existing data whenever possible. Qualitative data can provide exceptionally useful information if the methodology employed is consistent and robust.

Reporting

Sustainability reporting has become a significant activity for the mining industry to communicate performance at the operational and corporate levels. Reporting consists of the documentation and communication of information on numerous activities and outcomes. In recent years there has been a trend toward standardized reporting requirements, such as the Global Reporting Initiative (GRI). The GRI is a sustainability reporting framework that requires reporting on the economic impacts on project stakeholders and systems; environmental inputs, outputs, and expenditure; labor practices; human rights; and social risks to communities. The GRI has developed, in collaboration with the International Council on Mining and Metals, a mining and metals sector supplement that details specific disclosures and indicators for the industry (GRI 2010). The Extractives Industry Transparency Initiative (EITI) is another such approach. The EITI is a global standard for transparency in oil, gas, and mining that is implemented by both businesses and governments. EITI requires industry to publish all of the payments made to governments, such as through royalties and taxes, and for governments to disclose the revenues they receive from resource developments (EITI 2009).

The documentation of social decisions and agreements (internal and external to the operations) is a key aspect of reporting that is often overlooked. The nondelivery of agreed outcomes is a salient issue at many operations. Nondelivery can create unaccounted-for future liabilities, breach trust with communities, and damage the reputation of the operation.

For some operations and issues, reporting is best addressed at a regional scale. In circumstances where multiple mining operations are located in close proximity to a single town or community, there is often an absence of information that provides a comprehensive overview of industry investments, activities, aggregate impacts, and the state of the environment. Collective reporting to the community on the economic, social, and environmental performance of the industry may be more effective at communicating the overall contribution of the industry and the totality of activities and impacts (Brereton et al. 2008; Franks et al. 2009a). Regional organizations and industry bodies are best placed to coordinate such efforts; however, the absence of a representative organization is not necessarily prohibitive.

Evaluation and Review

The final phase of social impact assessment and management is to evaluate and review the assessment and management processes. An active process of evaluation and review—and importantly, the adjustment of actions—are fundamental features of adaptive management and should be integrated into each of the previous phases. The reconciliation of impacts predicted during the assessment phase with the actual impacts experienced during implementation will assist in refining and improving future approaches. Structured review should be built into ongoing programs, policies, projects, and agreements in order to reflect contemporary conditions.

LESSONS FOR THE EFFECTIVE MANAGEMENT OF SOCIAL IMPACTS

This section summarizes key lessons that can inform mine managers, engineers, and technical professionals to effectively manage the social impacts of mining. It is important to note that communities are complex and, at times, difficult to predict, that local context is paramount, and that the transferability of approaches is often not straightforward. At the same time, consideration of these issues will assist mining professionals to design and implement projects that are more acceptable to communities and therefore have a greater prospect of success.

1. Engage with community stakeholders and build relationships through understanding and goodwill. Be upfront and straightforward about potential risks. Establish meaningful and timely avenues for two-way dialogue, and use this to understand stakeholder histories, relationships, and networks, as well as the values that shape attitudes and behaviors. Assist stakeholders to articulate community concerns and visions. Listen to and design the project or activity within the parameters of such perspectives. Be responsive and adaptive; respect customs and political and authority structures; and, where appropriate, gain informed consent.
2. Align and integrate the outcomes of assessment and monitoring into site management systems and plans. Ensure company-wide understanding and respect of community expectations, concerns, and future visions. SIA and impact management are only effective to the extent that the responsible staff and the outcomes are well integrated into the overall management of the entire operation.
3. Draw on specialist skills and social and economic research to build knowledge and understanding. The use of specialists, however, should not come at the expense of integrating understandings into the organization, nor should it confuse accountability or responsibilities. Relationships with community stakeholders are most effective when stakeholders feel the people they are dealing with have the authority to make decisions and changes.
4. Build the capacity of stakeholders. Tailor community development activities to enhance independence and postmining legacies.
5. Monitor what matters. Design monitoring in such a way that the community's concerns are identified and acted on. Acknowledge and remedy (past) issues and grievances,

and fulfill outstanding commitments. Use appropriate systems to record issues and to coordinate and deliver outcomes.
6. Continuously review activities and programs, and periodically update assessments as "living" documents.
7. Assess and manage social impacts and risks across the life cycle of mining and resource processing activities, including all of the activities from exploration through to postclosure, as well as recycling and waste management. The scale and focus of activities will vary depending on the stage, and local and operational context.

The processes of social impact assessment and impact management detailed in this chapter will assist in identifying key stakeholder issues, predicting and anticipating change, and embedding these understandings into ongoing systems and strategies to proactively respond to the consequences of mineral exploitation. Trust is an important feature of managing social impacts. Mining companies may not originate from the region, or be familiar with the local culture, customs, and lifestyles, but nevertheless they have the power to transform the environment and society. As outsiders, mining companies may be viewed with suspicion by communities and must earn community trust. Even well-meaning actions, when not socially, culturally, or environmentally relevant, may result in poor outcomes. However, by proactively responding to community issues, facilitating meaningful participation, and shaping mutually beneficial futures, mining companies can avoid conflict with communities and the associated costs.
