Pathogens are present in untreated domestic wastewaters as well as in runoff waters from animal sources. These organisms range from submicroscopic viruses to parasitic worms visible to the unaided eye and represent important components of water quality. Table 12.1 lists some of the most prevalent human pathogens associated with domestic wastewater. These pathogens are divided into five groups: viruses, bacteria, fungi, protozoans, and helminths. The density of these organisms in raw wastewater varies geographically.

Viruses are submicroscopic, nonliving particles of genetic material that are enclosed in a sheath. Viruses cannot divide and reproduce alone, but they can infect host organisms and reproduce to very large populations at the expense of the host organism. Over 100 virus types are known to occur in human feces, with minimum infective doses as low as one organism for some species. Bacteria are universally present in human feces, with normal populations of about $10^{11}$ organisms per gram (Leclerc *et al.*, 1977). Although most of these organisms live symbiotically with their hosts, a number of species are known human pathogens and occur with great frequency in infected individuals. Human parasites derived from wastewater-related infections include protozoa and helminths. Two common protozoan parasites are *Entamoeba histolytica* and *Giardia lamblia*, which both cause diarrhea in infected humans. The phylum *Aschelminthes* (cavity worms) includes all parasitic worms incapable of adult life without a host organism. A number of helminths, including tapeworms and flukes, are found in infected humans and can be spread through wastewater pathways. For a summary discussion of environmentally transmitted pathogens, see Maier *et al.* (2000).

The efficiencies of conventional treatment technologies that reduce pathogens to noninfective levels have been studied thoroughly, and wastewater treatment plants regularly add processes to accomplish necessary removals (Metcalf and Eddy Inc., 1991; Crites and Tchobanoglous, 1998). The most common add-on disinfection processes are chlorination, ozonation, and ultraviolet irradiation.

Because of its low cost and proven effectiveness, chlorination has been the disinfection method of choice for many years. However, negative side effects of effluent chlorination have become apparent in the past two decades. Residual free chlorine harms a variety of aquatic organisms and causes chronic and acute toxicity to microorganisms and fish. Also, when it comes in contact with organic compounds in wastewater or receiving waters, free chlorine forms trihalomethanes and other organochlorine compounds known to be carcinogenic. These findings have resulted in the increased use of dechlorination techniques and in the development of the ozonation and ultraviolet disinfection technologies.

Animals are also a source of pathogenic organisms. Farm animals produce feces with high numbers of bacteria. Cows, sheep, pigs, and poultry produce $10^5$–$10^7$ fecal coliforms per gram, and $10^6$–$10^8$ fecal streptococci per gram. Cats, dogs, mice, and chipmunks produce similar concentrations (Maier *et al.*, 2000). Waterfowl and other wetland birds also contribute coliforms to the wetland environment and may do so in great quantities during migratory concentrations. Beavers, muskrats, and other warm-blooded wetland animals are also producers of enteric pathogens. Beavers have been implicated in transmission of *Giardia*. About half the animals in Colorado were found to be infected and shedding $10^8$ cysts per animal per day. Ninety-five percent of muskrats in this study were found to be infected with *Giardia* (Erlandsen, 1995).

Natural treatment technologies have the potential to reduce populations of enteric pathogens because of natural die-off rates and hostile environmental conditions. Wetlands have been found to reduce pathogen populations with varying but significant degrees of effectiveness. This chapter reviews the pathogens typically found in wastewater and describes the effect that treatment wetlands have on the pathogen populations passing through them.

## 12.1 INDICATOR ORGANISMS AND MEASUREMENT

Measurement of human pathogenic organisms in natural and wastewaters is expensive and technically challenging. Consequently, it has been customary to first look for indicator organisms that are easy to monitor and correlate with populations of pathogenic organisms. No perfect indicators have been found, but the coliform bacteria group has long been used as the first choice among indicator organisms. Typical indicator organisms are listed in Table 12.2.

In the United States, total coliforms were the first approved indicator organisms. These coliforms include bacterial species that are rod-shaped, stain gram-negative, do not form spores, are facultatively anaerobic, and ferment lactose with gas production in 48 hours at a temperature of 35°C. Because many members of the group are not limited to fecal sources, methods have been developed to differentiate organisms of fecal origin. Fecal coliforms are separated from total coliforms by their ability to ferment lactose with gas production in 24 hours at a temperature of 44.5°C.

**TABLE 12.1**
**Some Human Pathogens Typical of Domestic Wastewater**

| | Pathogen | Illness |
|---|---|---|
| **Viruses** | Adenovirus (31 types) | Respiratory disease |
| | Enteroviruses (67 types) | Diarrhea, respiratory disease, polio |
| | Hepatitis A | Infectious hepatitis |
| | Norwalk agent | Gastroenteritis |
| | Rotavirus | Diarrhea |
| | Reovirus | Gastroenteritis |
| | HIV | AIDS |
| **Bacteria** | *Campylobacter jejuni* | Diarrhea |
| | *Escherichia coli* | Diarrhea |
| | *Legionella pneumophila* | Fever, respiratory tract infections |
| | *Leptospira* (150 spp.) | Leptospirosis |
| | *Salmonella typhi* | Typhoid fever |
| | *Salmonella* (~1,700 spp.) | Salmonellosis |
| | *Shigella* (4 spp.) | Diarrhea, dysentery |
| | *Vibrio* spp. | Cholera, diarrhea |
| | *Yersinia* spp. | Yersiniosis |
| **Fungi** | *Aspergillus fumigatus* | Aspergillosis |
| | *Candida albicans* | Fungal infections |
| **Protozoa** | *Balantidium coli* | Diarrhea, dysentery |
| | *Cryptosporidium parvum* | Diarrhea |
| | *Entamoeba histolytica* | Diarrhea, dysentery |
| | *Giardia lamblia* | Diarrhea |
| **Helminths** | *Ascaris lumbricoides* | Roundworm |
| | *Clonorchis sinensis* | Bile duct infection |
| | *Diphyllobothrium latum* | Fish tapeworm |
| | *Enterobius vericularis* | Pinworm |
| | *Fasciola hepatica* | Liver fluke |
| | *Fasciolopsis buski* | Intestinal fluke |
| | *Hymenolepis nana* | Dwarf tapeworm |
| | *Necator americanus* | Hookworm |
| | *Opisthorchis* spp. | Bile duct infection |
| | *Schistosoma* spp. | Schistosomiasis |
| | *Taenia* spp. | Tapeworm |
| | *Trichuris trichura* | Whipworm |

An even narrower group, *Escherichia coli*, is being used more frequently as an indicator organism, because it can readily be separated from the rest of the fecal group, and because several strains are capable of causing severe human health problems. However, as these bacteria also originate in other warm-blooded animals, *E. coli* is not diagnostic of human fecal contamination alone. The coliform groups in general have an indicator disadvantage in that they may regrow in aquatic environments.

The fecal streptococcus group is used to confirm the origins of fecal contamination. A high ratio of fecal coliform to fecal streptococcus (FC/FS > 4) is regarded as an indication of human origin, whereas a low ratio (FC/FS < 0.7) is indicative of animal pollution (Clausen *et al*., 1977). However, the validity of this separation has been subject to question (Gerba, 2000). Fecal streptococcus is found in the feces of humans and other warm-blooded animals including birds and mammals. These bacteria are found frequently in waters receiving fecal contamination and are not believed to multiply in natural or polluted waters and soils. Because fecal streptococci bacteria seem to survive longer than fecal coliforms in receiving waters, they are used as a second indicator of fecal contamination. Because bacterial die-off affects the ratio, it is only applicable to fecal pollution within 24 hours of discharge.

It is generally recognized that fecal coliforms are not suitable indicators of viral contamination in surface water receiving domestic waste because some viruses are more resistant to chlorination and environmental deactivation than bacteria (Kraus, 1977; Gersberg *et al*., 1987; Gerba, 2000). Bacteriophages (viruses that infect bacteria, such as coliphage MS-2) have been used as viral indicators in wetland treatment systems (Gersberg *et al*., 1987; Schuerman *et al*., 1989).

Enumeration of bacteriophages is technically simpler and more rapid than enumeration of the target pathogenic viruses. Also, MS-2 is nearly the same size as enteroviruses and is more resistant to ultraviolet (UV) light, heat, and disinfection than most enteric viruses. In a free water surface (FWS) study at San Jacinto, California, Chendorain *et al.* (1998) added cultured MS-2 virus to the wetland influent wastewater to determine die-off rates.

## 12.2 PATHOGEN REMOVAL PROCESSES

The observed net removal of pathogenic organisms in treatment wetlands is the result of a variety of processes, some that remove pathogens and some that introduce pathogens. Generally speaking, removal mechanisms are much more prevalent than reintroduction mechanisms, and most constructed wetlands demonstrate large net removals of pathogenic organisms down to a nonzero background concentration ($C^*$).

### Solar Disinfection

UV radiation is a potent agent for killing bacteria in FWS wetlands. An exponential relation is commonly used to describe the inactivation in disperse batch cultures:

$$N = N_o e^{(-k_i I t)} \tag{12.1}$$

where

$I$ = intensity of UV light in solution, J/m$^2$·d
$k_i$ = inactivation rate coefficient, m$^2$/J
$N_o$ = initial number of dispersed organisms
$N$ = surviving number of dispersed organisms
$t$ = time, d

However, most organisms are present in association with wastewater particulates, rather than in a dispersed phase (Emerick *et al.*, 2000). Consequently, UV inactivation rates are lowered from shielding of the organisms by the particle structures. Equation 12.1 is still applied, but rate constants are much lower than for dispersed-phase populations. Emerick *et al.* (2000) found little variation in rates for fecal coliforms across 11 treatment technologies, with $0.022 < k_i < 0.054$ m$^2$/J for activated sludge, trickling filter, aerated, and facultative pond effluents.

The UV wavelengths that are absorbed by microorganisms, and hence are effective in disinfection, comprise the range 240–280 nm (Crites and Tchobanoglous, 1998). Lamps used for in-line disinfection of wastewaters are designed to provide radiation in this range. The effectiveness of the radiation depends on water quality factors, such as optical absorbance and suspended solids content. Typical UV dosages are 100–850 J/m$^2$ to provide suitable disinfection of fecal coliforms to the range between 1,000 and 23 CFU/100 mL (Crites and Tchobanoglous, 1998).

In a natural system, such as a pond or an open-water wetland, sunlight provides a source of ultraviolet (UV) radiation. However, the fraction of the incoming solar radiation that is in the UV range is small, typically less than 1%. Therefore, solar inactivation rates based on total solar radiation are much smaller than those determined for UV lamp sources, and these are designated $k_S$. For example, Davies-Colley *et al.* (1999) present pond water data for *E. coli* for which $k_S \approx 0.7$ m$^2$/MJ, which is about 100,000 times lower than for a UV lamp. Salih (2003) determined a similar value for *E. coli*, $k_S \approx 1.5$ m$^2$/MJ. Davies-Colley *et al.* (1999) also demonstrated that dissolved oxygen and pH had important influences on rates of inactivation. These authors inferred that both direct hit radiation damage and photooxidation were caused by incoming radiation.

The overall solar inactivation rate for a shallow water body (pond) is further reduced by the lack of penetration of light (Mayo, 1995). The top few centimeters of a stabilization pond get the required radiation, but deeper sections do not. Accordingly, the solar inactivation rate constant is approximately inversely proportional to the pond depth:

$$k_S = \frac{k'_S}{K_L h} \tag{12.2}$$

where

$h$ = water depth, m
$k_S$ = overall solar inactivation rate coefficient, m$^2$/J
$k'_S$ = intrinsic solar inactivation rate coefficient, m$^2$/J
$K_L$ = light attenuation coefficient, m$^{-1}$

Mayo (1995) reported values of $0.012 < hk_S < 0.016$ m$^3$/MJ for five stabilization pond studies. Additionally, high-rate ponds (0.2–0.3 m depth and a few days' detention) have been shown to have $k_S = 0.0675$ m$^2$/MJ (Davies-Colley *et al.*, 2003) and $k_S = 0.083$ m$^2$/MJ (Craggs *et al.*, 2004).

Bacteriophages are also susceptible to UV radiation. Jolis (2002) gives a range of inactivation rate coefficients of $0.0054 < k_i < 0.0106$ m$^2$/J for irradiation from UV lamp sources. This slower rate is reflected in higher UV lamp dosages needed to inactivate viruses, typically six to eight times higher than for coliforms (Crites and Tchobanoglous, 1998). As for bacteria, natural systems receive solar radiation that contains small amounts of UV, which is effective in inactivation of bacteriophages. Davies-Colley *et al.* (1999) provide pond data for an F-DNA phage ($k_S \approx 0.7$ m$^2$/MJ) and for an F-RNA phage ($k_S \approx 0.6$ m$^2$/MJ). The inactivation of phages by sunlight has been found to be a good rate analog for the inactivation of human pathogenic polio, echo, and coxsackie viruses (Fujioka and Yoneyama, 2002).

Solar disinfection depends on the sunlight reaching and penetrating into the water column. Dense vegetation intercepts sunlight in the wetland environment and diminishes the potential for solar disinfection. This negative effect is putatively present for emergent and floating plant communities. It may or may not be present in submersed algal or macrophyte communities where subsurface oxygenation may occur. The presence of enhanced amounts of dissolved

oxygen (DO) fosters the photooxidation route of disinfection and may compensate for reduced penetration of UV radiation (Davies-Colley *et al*., 1999; Sun *et al*., 2003).

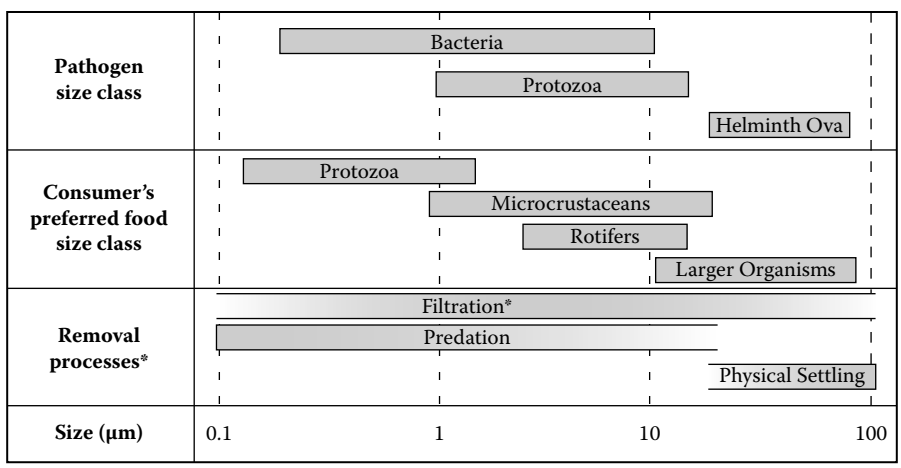
However, when pond performance is compared to vegetated wetland performance for fecal coliform reduction across large numbers of both types of systems receiving varying numbers of pathogens, little difference can be seen in the general level of reduction (Kadlec, 2005e). Other mechanisms of organism mortality and removal, beyond just solar disinfection, become operative in the wetland environment.

## Predation

Most pathogens are food for nematodes, rotifers, and protozoa (Decamp and Warren, 1998). Among these, rotifers and flagellated and ciliated protozoa have been implicated as important contributors to the reduction of bacteria in treatment wetlands (Panswad and Chavalprit, 1997; Laybourn-Parry *et al*., 1999; Proakis, 2003; Stott and Tanner, 2005) as well as in natural aquatic systems (Menon *et al*., 2003). While pathogenic organisms span a wide size range (0.2–100 μm), so do the associated predator/grazing communities (Figure 12.1). They are found in secondary wastewaters in considerable numbers; for instance, Fox *et al*. (1981) reported up to about 50 rotifers per liter in such effluents (Figure 12.2).

Proakis (2003) determined that rotifers consumed enterococci at the rate of about 600/h when the bacterial density was approximately $10^6$ per 100 mL. From this rate, it was determined that rotifers, at a density of ten per mL, could suitably disinfect stormwater in a 1.2-hour detention in a marsh. The next question, then, is about concentrations of predators that can be expected in the wetland waters.

Decamp and Warren (1998) found that the ciliate *Paramecium* consumed more than 100 *E. coli* per hour when the bacterial density was approximately $10^8$ per 100 mL. This was interpreted to require 20 *Paramecium* per mL to remove about $2 \times 10^6$ *E. coli* per 100 mL in eight hours' detention. This concentration of *Paramecium* was comfortably within the observed concentration range in the SSF wetland from which the protozoa were taken.



Heterotrophic nanoflagellates (HNAN) were found to dominate the protozoan community in both lagoons and grass filters treating sewage (Laybourn-Parry *et al*., 1999). Ciliates contributed to only about 10% of the grazer populations. The grass filters harbored more numbers (approximately $10^8$ per 100 mL) of these bacterial predators than the lagoons (approximately $10^7$ per 100 mL).

The overall effect of grazing on bacterial numbers in aquatic systems was quantified by Menon *et al*. (2003). Grazing by protozooplankton was responsible for more than 90% of the overall mortality rate of both fecal and autochthonous bacteria in the river Seine. For example, whereas in the presence of protozoa the overall first-order volumetric mortality coefficient was $34 \times 10^{-3}$ h$^{-1}$, it was $2 \times 10^{-3}$ h$^{-1}$ in the absence of protozoa.

Grazing is generally higher at higher temperatures (Laybourn-Parry *et al*., 1999; Menon *et al*., 2003), but temperature coefficients for wetland environments are not available. The aforesaid studies indicate a strong potential for pathogen removal through predation in constructed wetlands. They do not, unfortunately, allow quantification of this removal mechanism. Whereas predation/grazing is an important removal mechanism (especially in FWS wetlands), it is not the only removal mechanism. Settling and filtration also play important roles in pathogen reduction, and these removal mechanisms have a cumulative effect in treatment wetland systems.

## Settling and Filtration

A measurable proportion of wastewater microorganisms are found either associated with particulates or as aggregates of

*Note: Filtration processes are system dependent.

**FIGURE 12.1** Pathogen and predator size chart.

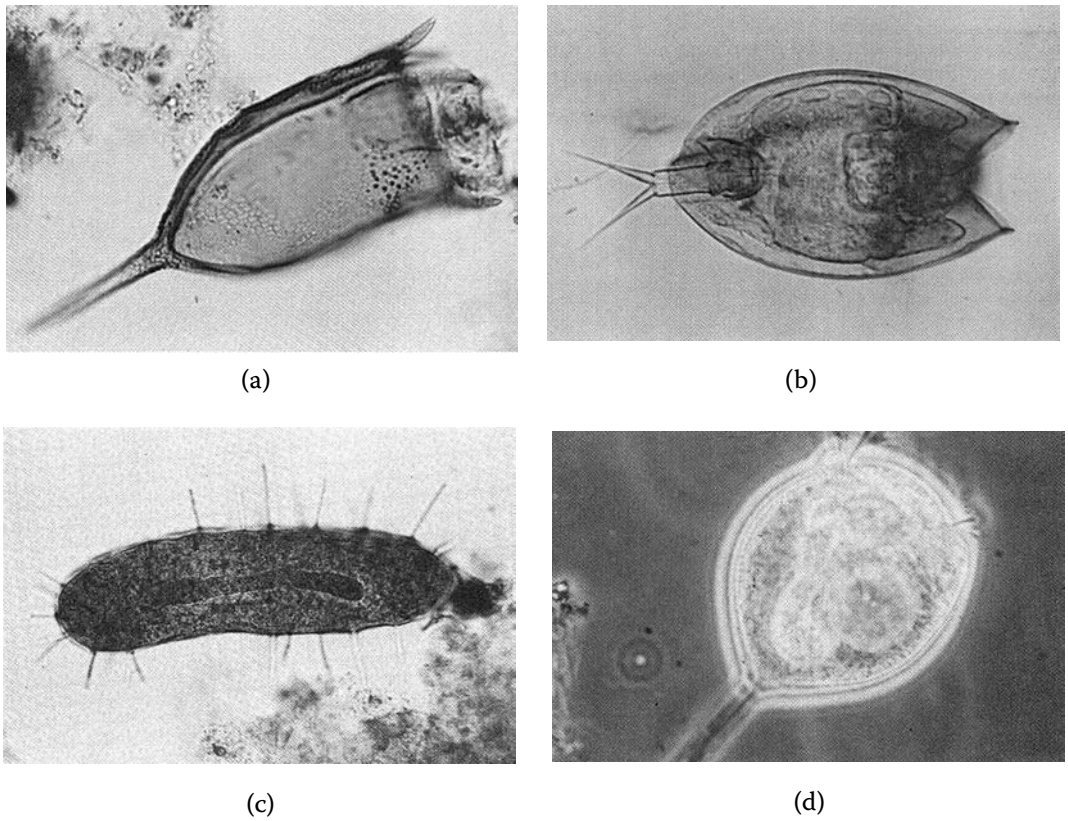


**FIGURE 12.2** (a) Rotifer *Keratella* spp. 200 µm. (b) Rotifer *Lepadella* spp. 100 µm. (c) Protozoan *Discophrya* spp. 80 µm. (d) Protozoan *Vorticella* spp. 65 µm. (From Fox *et al.* (1981) *Sewage Organisms: A Color Atlas.* Lewis Publishers, Boca Raton, Florida. Reprinted with permission.)

many organisms. For the activated sludge process, the fraction of particles with associated coliform ranges from <1% to 24% (Loge *et al.*, 2002). This fraction declines with the residence time (mean cell residence time) of organics in the activated sludge process. The loss of coliform organisms inside the activated sludge process has been speculatively attributed to predation by protozoans (Loge *et al.*, 2002). Organisms associated with particles are far less susceptible to UV or solar disinfection, presumably because of shielding effects (Emerick *et al.*, 2000).

Bacteria may clump together to form aggregates. These are highly amorphous and porous, but the internal voids are apparently filled with exopolymeric material (Li and Yuan, 2002). Sedimentation of these particles contributes to their removal from the water column, with removals of 25–75% due to gravitational sedimentation in conventional treatment plants (Metcalf and Eddy Inc., 1991). Tests of algal settling ponds produced 40% removal of *E. coli* by sedimentation (Davies-Colley *et al.*, 2003).

In the wetland environment, submersed plant parts and their associated biofilms form "sticky traps" for particles, including all sizes of microorganisms (see Chapter 7). These biofilms are capable of trapping considerable numbers of organisms (Flood and Ashbolt, 2000; Stott and Tanner, 2005). Such biofilms are enhanced in quantity by larger quantities of submersed surfaces and exposure to light. There may be an optimal plant density that allows light and provides the necessary surfaces for biofilm growth.

### Mortality and Regrowth

Bacteria, protozoa, helminths, and viruses typically do not survive longer than about 30 days in freshwater environments and about 50 days in soil environments (Crites and Tchobanoglous, 1998). Similar survivals might therefore be predicted for wetlands, but there are many site-specific factors and processes which may materially increase or decrease survival.

A part of the overall removal of pathogens consists of the death or inactivation of organisms for reasons other than radiation damage or predation. This has been called the *dark death rate* (Khatiwada and Polprasert, 1999b). Mortailty has been found to be approximately 25% of the overall removal rate in ponds (Craggs *et al.*, 2004), with a similar fraction in a *Typha* FWS wetland in Thailand (Khatiwada and Polprasert, 1999b). However, care must be taken to separate sedimentation and filtration from mortality in this dark death rate. For instance, Khatiwada and Polprasert (1999b) estimated that only 6.5% of the overall fecal coliform removal rate was due to temperature-modulated death of organisms.

There is no definitive study of the temperature effect on mortality of bacteria in wetlands. Estimates of temperature

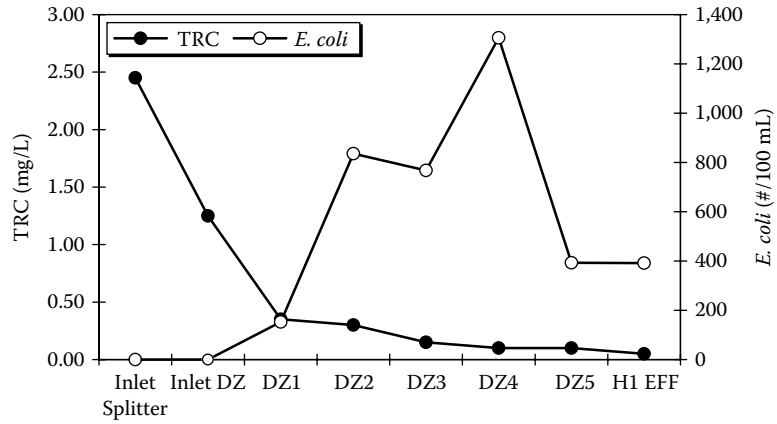

**FIGURE 12.3** Longitudinal profiles of total residual chlorine (TRC) and *E. coli* through Tres Rios Hayfield, Arizona, wetland H1.

coefficients (θ) for ponds range from 1.000 (no effect) to 1.070 (strong effect).

Very low temperatures may result in freezing conditions. Ice formation followed by a thaw drastically reduces the populations of pathogens in water. For instance, Torrella *et al*. (2003) found that only 1.2% of fecal coliforms survived four days of freezing, but more coliphages survived. However, care must be taken in enumeration, because organisms may be viable after freezing, but unculturable in routine tests (Parker and Martel, 2002). Further, many bacteria survive the snowmaking process. Less than one log loss was measured for fecal streptococcus due to snow formation and melting (Parker *et al*., 2000).

To complicate matters even more, some indicator organisms are capable of regrowing and multiplying in an aquatic environment. All members of the coliform group have been observed to regrow in natural surface water (Gerba, 2000). Such regrowth is fostered by high concentrations of organic matter and by elevated temperatures. This phenomenon is recognizable when disinfected wastewater is introduced into treatment wetlands, and bacterial populations increase along the direction of flow (Figure 12.3).

## Reintroduction

Indicator organisms can be produced by sources other than incoming wastewaters. This is particularly true for the coliform group, which may originate from many different warm-blooded animals that frequent wetlands. As an example, consider the performance of the Orlando Easterly FWS Wetlands (Figure 12.4). Incoming fecal coliforms are very low, but animal (bird) populations are high, especially near the outlet. Background geometrical annual averages range from 50 to 142 per 100 mL. Monthly values show an exceedance frequency of 40% of the permit limit of 100 CFU/100 mL. The five-year median fecal coliform was 64 CFU per 100 mL and FS was 106 CFU per 100 mL. The ratio FC/FS was 0.6; thus, the presumption may be made that the source of contamination is animal rather than human (criterion = FC/FS < 0.7). In this case, the treatment wetland has been measured to have very large bird populations, which also supports the concept of reintroduction of pathogens from avian populations (U.S. EPA, 1993a; U.S. EPA, 1993d).

These naturally-caused bacterial populations are generally low, but they may be variable and seasonally high because of wildlife activity patterns. Total and coliform bacteria have been measured in natural wetlands that receive no wastewater. For example, Fox *et al*. (1984) measured between 109 and 456 CFU/100 mL of fecal coliforms in cypress wetlands in Florida that were not receiving any external water inputs. Fecal coliform concentration in lake water passing through a wetland in Montreal, Quebec, increased from 40 to 110 CFU/100 mL (Vincent, 1992). Because natural sources of coliforms and fecal streptococcus bacteria are found in all wetlands open to wildlife, outflow indicator bacteria populations in treatment wetlands cannot be consistently reduced to near zero unless disinfection is used.

Subsurface flow (SSF) wetlands provide much less wildlife habitat than FWS systems; however, their use by wildlife cannot

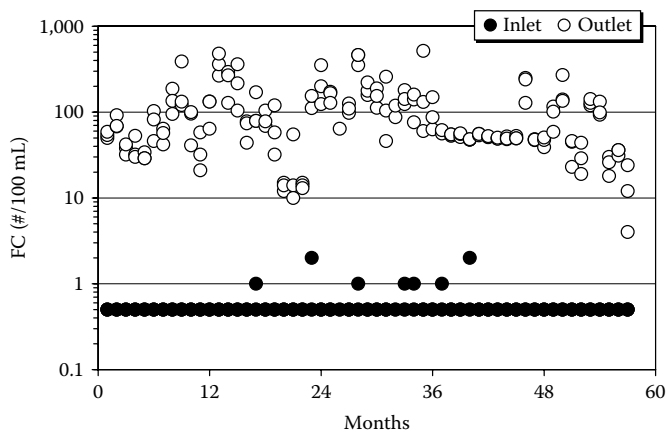

**FIGURE 12.4** Fecal coliforms entering and leaving the Orlando Easterly Wetland, in Florida during 1993–1997. The incoming wastewater is disinfected, with only a few detections of the indicator organisms. The balance of the nondetect samples are plotted as half the detection limit of 1.0 per 100 mL. (Unpublished data from city of Orlando.)

be excluded. For instance, a HSSF wetland in Arizona, fed with disinfected potable water, produced on an average, effluent concentrations of 130 total coliforms (CFU/100 mL) and 22.3 fecal coliforms (CFU/100 mL). This reintroduction of indicator organisms was attributed to wildlife use of the system. Because wildlife use of SSF wetlands has been observed on many occasions (Wallace *et al.*, 2001), it is to be expected that these treatment wetlands will also deliver a nonzero background concentration ($C^*$) for indicator organisms. However, wildlife use is so restricted that backgrounds are likely of little consequence.

## 12.3 FECAL COLIFORM REMOVAL IN FWS WETLANDS

The most common indicator organism group is the fecal coliform group and consequently the wetland database is largest for this group. Further, several attempts have been made to extract quantitative generalities about the removal of this indicator group in FWS treatment wetlands.

### First-Order Removal Models

The complexity of the suite of processes responsible for reducing indicator bacteria in FWS wetlands is considerable, with the many interacting processes described previously. Although some attempts have been made to combine these into a single removal model (Mayo, 1995; Bahlaoui *et al.*, 1998; Khatiwada and Polprasert, 1999b), data have been insufficient to provide robust calibrations of combination models. Information on light exposure and penetration, vegetative cover, and predator density is typically lacking. Therefore, at this point in the evolution of treatment wetland technology, only very simple global removal models may be considered.

### Model Structure

First-order models have been used to describe reductions of indicator bacterial populations in lagoons and wetlands:

$$\text{First-order (volumetric)} \quad \left(\frac{C_o - C^*}{C_i - C^*}\right) = \left(1 + \frac{k_V \tau}{N}\right)^{-N} \qquad (12.3)$$

$$\text{First-order (areal)} \quad \left(\frac{C_o - C^*}{C_i - C^*}\right) = \left(1 + \frac{k_A \tau}{Nh}\right)^{-N} \qquad (12.4)$$

$$\text{Plug-flow limit} \quad \left(\frac{C_o - C^*}{C_i - C^*}\right) = \exp\left(-\frac{k_A}{q}\right) \qquad (12.5)$$

where

$C_i$ = inlet concentration, #/100mL
$C_o$ = outlet concentration, #/100mL
$C^*$ = background concentration, #/100mL
$h$ = water depth, m
$k_A$ = areal rate coefficient, m/d
$k_V$ = volumetric rate coefficient, $d^{-1}$
$N$ = number of TIS
$\tau$ = nominal detention time, d

The first question that arises is whether to use Equation 12.3 or Equation 12.4, the former being volume-specific and the later being area-specific. In the situation of unvegetated systems, von Sperling and Mascarenhas (2005) provide an unequivocal answer: no difference was found in doubling the depth (80 cm versus 40 cm) and thus doubling the detention time for *E. coli* removal. The implications are that $k_V$ is inversely proportional to depth and, hence, the areal rate coefficient in Equation 12.4 is constant. The same inverse proportion is found for the Arcata, California, pilot data, in which six pairs of emergent FWS wetland cells were run at two depths and different hydraulic loadings (data from Gearheart *et al.*, 1983). Thus, for both ponds and wetlands, there is strong evidence that the areal rate coefficient ($k_A$) is constant, whereas the volumetric rate coefficient ($k_V$) decreases with increasing depth. In this book, the areal rate coefficient will be used and presumed constant over some modest depth range, such as 20–80 cm. However, FWS volumetric rate coefficients, when they are reported elsewhere, may be easily converted to an areal basis simply by dividing by the free water depth.

A far more serious question unique to pathogen removal is the internal pattern of the flow (number of tanks in series, $N$) to be assigned to the system for which $k$ is to be determined or used. For other measures of wetland water quality improvement, such as biochemical oxygen demand (BOD), total suspended solids (TSS), and nutrient removal, reductions are rarely greater than 90–95% (less than one $\log_{10}$ removal). For pathogens, reductions often reach 99.99% (two to three $\log_{10}$ removal) or more. This is precisely the region of performance in which reductions are extremely sensitive to the number of tanks-in-series ($N$TIS) value (see Chapter 6). Equation 12.4 has been graphed for the case of a negligibly small $C^*$ ($C^* \ll C_o$) in Figure 12.5.

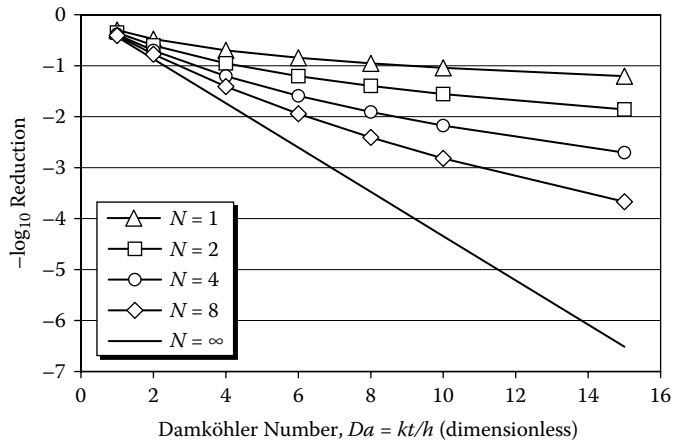

**FIGURE 12.5** Reductions according to a first-order model in the high removal range.

The Damköhler number ($Da = k_A\tau/h$) embodies the intrinsic rate of removal together with the detention time and depth. Independent of these factors, the wetland may have differing degrees of hydraulic efficiency (see Chapter 2), as indicated by different values of *N*. Figure 12.5 indicates that the number of $\log_{10}$ reductions increases steeply with number of tanks in series (*N*) at any given detention time (Damköhler number).

The underlying phenomenon is hydraulic short-circuiting. Small elements of flow can carry enough organisms to the outlet, without treatment, to jeopardize the high levels of removal that prevail for the remainder (majority) of the flow. Conversely, if a wetland exhibits performance of, say, two $\log_{10}$ reduction, the rate coefficient is extremely sensitive to whether the *N*TIS value is 4, 8, or ∞ (plug flow); the computed areal rate coefficient ($k_A$) changes by approximately 100% if $N = 4$ as opposed to $N = \infty$ (plug flow) (Figure 12.5).

Data from waste stabilization ponds provides confirmation of this phenomenon. Lloyd *et al*. (2003) studied fecal coliform removal in a sequence of pond modifications, each designed to improve the hydraulic efficiency. The levels of contamination were in the range of $10^4$–$10^6$ fecal coliforms per 100 mL, outlet to inlet; thus, in this instance, *C** is negligible. The results may be summarized as follows:

| | | |
|---|---|---|
| Open pond, aspect 4:1 | 90.26% | (1.01 $\log_{10}$) |
| Channelized, aspect 36:1 | 96.03% | (1.42 $\log_{10}$) |
| Channelized, aspect 36:1, wind break | 98.13% | (1.78 $\log_{10}$) |
| Batch reduction (plug-flow equivalent) | 99.7% | (2.6 $\log_{10}$) |

Although tracer tests were not performed to determine the number of tanks in series, it is clear that the increasing aspect ratio and decreasing wind mixing had very large effects on the performance of the pond. These results correspond nicely to the theoretical projections of Figure 12.5 for a Damköhler number of about 6.0. From these considerations, it may be concluded that the reduction of pathogens in FWS wetlands is critically dependent on the internal flow patterns.

## Longitudinal Profiles

Irrespective of the degree of hydraulic efficiency in a particular wetland, global first-order models forecast a decline in pathogens through the wetland, provided the incoming levels exceed the regrowth and reintroduction potentials. This theory corresponds to observations for a number of wetlands, such as the Byron Bay, Australia, FWS system (Figure 12.6). There is a drop of about two $\log_{10}$ over the first third of that system, followed by a plateau at levels of 300–2,000 fecal coliforms per 100 mL, depending upon the year in question. Avian use of the outlet portions of the system may account for the plateaus. For most FWS wetland systems, complete elimination of fecal coliforms has not been achieved, and therefore the inclusion of a *C** value in the first-order model is a necessity.

Because of residual indicator bacteria populations in all wetlands, bacteria removal efficiency is a function of the inflow bacteria population. Removal efficiency is typically high at high-inflow populations but declines to negative efficiencies when inflow populations are lower than the *in situ* bacteria production and addition rates. For instance, at the Titusville, Florida, wetland treatment system, inflow to the wetland contains essentially no indicator bacteria because of a high level of pretreatment and disinfection (less than 1 CFU/100 mL); however, the wetland outflow contains small numbers of fecal coliforms (63 CFU/100 mL) and fecal streptococci (170 CFU/100 mL), presumably because of wetland bird use (unpublished data from Titusville, Florida).

## Implications for Design

There are two important points to be kept in mind when extracting information from the literature for use in design: (1) literature die-off rates are often computed using the plug-flow equivalent of Equations 12.3 and 12.4, and (2) the use of that plug-flow formulation in design in an extrapolation mode is extremely dangerous, because it creates large overestimates of reductions.

Data from 28 FWS systems, totaling 47 wetland years, was used to estimate fecal coliform areal rate coefficients ($k_A$) for a presumed $C^* = 40$ CFU/100 mL. These systems were selected for having inlet fecal coliform concentrations of at least 1,000 CFU/100 mL, thus eliminating systems with low influent fecal coliform concentrations, whether due to pretreatment disinfection or other factors. The hydraulic parameter *N*, representing the number of tanks in series, was relaxed to the more general case of *P*, which accounts not only for the nonideal hydraulics but also treatment effects as well ($P < N$), as discussed in Chapter 6. Because the critically important *P*TIS values were not known, three different assumptions were made:

*P*TIS = ∞ (plug flow; known to be wrong, but in common use)
*P*TIS = 3 (a modest degree of departure from both plug flow and complete mixing)
*P*TIS = 1 (complete mixing)

The resulting annual areal rate coefficients were

| | | |
|---|---|---|
| *P*TIS = ∞ | $k_A \pm$ s.e. = 85 ± 17 m/yr | (median = 40 m/yr) |
| *P*TIS = 3 | $k_A \pm$ s.e. = 288 ± 73 m/yr | (median = 83 m/yr) |
| *P*TIS = 1 | $k_A \pm$ s.e. = 16,300 ± 9,500 m/yr | (median = 1,030 m/yr) |

It is seen that the presumed degree of nonideal flow has a very large effect on the calibrated areal rate coefficients, as has been theoretically explained previously. This wide disparity exists for each individual wetland as well as for the means and medians of the N = 28 dataset.

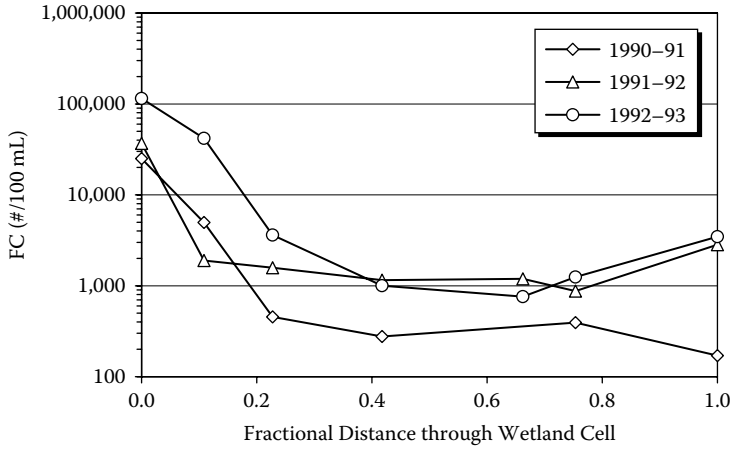

**FIGURE 12.6** Average annual longitudinal profiles of fecal coliforms in the Byron Bay, Australia, treatment wetlands. (Unpublished data from Byron Bay operations.)

The danger of extrapolation is seen in an example for which we assume $C^* = 0$ for simplicity. Suppose that the given wetland is producing 1.0 $\log_{10}$ reduction at a hydraulic loading rate of 10 cm/d and the wetland hydraulics can be characterized by $P$TIS = 3. The plug flow $k_A = 84$ m/yr (areal die-off coefficient) (Equation 12.5), and the 3TIS $k_A = 126$ m/yr (Equation 12.4). It is desired to improve performance by lowering the hydraulic loading rate to 2 cm/d. According to the plug flow model (Equation 12.5), performance should increase to 5.0 $\log_{10}$ reduction. But, according to the 3TIS model (Equation 12.4), performance would increase to only 2.49 $\log_{10}$ reduction. Thus, even though the plug flow rate coefficient is typically considered to be "conservative," it is in error by more than a factor of 300.

It is concluded that first-order modeling is not useful in design unless the hydraulic characterization of the wetland is taken into account.

Nonetheless, it is appropriate to explore the rates of reduction of pathogens in FWS systems, and here the indicator fecal coliforms is used to identify the intersystem variability. Table 12.3 shows the frequencies of reductions and areal $k$-values for a set of FWS wetlands that are in the mode of removal, i.e., they receive a load of organisms at or above the expected background, here taken to be 40 CFU/100 mL. For a presumed $P$TIS = 3, the median reduction is 1.54 $\log_{10}$, and the median $k = 83$ m/yr.

## Seasonal and Stochastic Effects

There are no pronounced seasonal or temperature effects for pathogen removal in the FWS treatment wetland datasets that are currently available. Computation of cosine trends in outlet concentrations typically produces a low amplitude, about 12% in $\log_{10}$, with the annual maximum in September (Table 12.4). Ten years' data from Estevan, Saskatchewan, showed an increase in fecal coliforms in the wetland (0.26 $\log_{10}$ increase), but a decrease in total coliforms (2.01 $\log_{10}$ reduction). However, the seasonal trend for both displays higher summer values (Figure 12.7).

### *Temperature Coefficients*

There are conflicting potential effects of temperature on pathogen reduction. Cold temperatures are inimical to

**TABLE 12.3**
**Annual Reduction of Fecal Coliforms in FWS Wetlands**

**Stipulations**

1. Annual averages are used in calculations.
2. For $k$-value calculations, the following $P$-$k$-$C^*$ parameters are selected:
   a. $C^* = 40$ #/100 mL
   b. $P = 3$ TIS
3. Ranges of variables:

| | HLR (cm/d) | $\log_{10}$ FC In (CFU/100 mL) | $\log_{10}$ FC Out (CFU/100 mL) |
|---|---|---|---|
| **Mean** | 3.8 | 5.21 | 3.28 |
| **Median** | 4.6 | 4.76 | 3.25 |
| **Max** | 24.3 | 6.89 | 5.43 |
| **Min** | 0.2 | 3.02 | 1.14 |

**Results (N = 47 wetland·years for 23 wetlands).**

| Percentile | $\log_{10}$ Reduction (CFU/100 mL) | Rate Constant (m/yr) |

*Note:* For all but Listowel 1, 2, and 5 and Richmond Open Water, there is evidence that near-plug-flow prevailed.

the survival of organisms that originate in warm-blooded organisms, and thus human pathogens usually do not survive well outside the body. Survival times in waters are typically 10–30 days (Crites and Tchobanoglous, 1998). On the other hand, the activity of predatory organisms, such as protozoa, is lessened at cold temperatures, although direct lethality is unlikely (Davies-Colley *et al*., 2005). Removal by adsorption is expected to be insensitive to temperature but slightly less effective under cold conditions. The very high temperature coefficients suggested for ponds and FWS wetlands ($\theta = 1.19$) (U.S. EPA, 2000a; Shilton and Mara, 2005) are unlikely to prevail in the subsurface environment and do not apply. A number of FWS wetlands have a median of $\theta = 0.963$ (Table 12.5).

For example, the reductions in fecal coliforms for Listowel Systems 4 and 5 show slight but opposite trends with temperature, with a low degree of variability explained (low $R^2$) (Figure 12.8). System 4 shows $\theta = 0.985$, whereas System 5 shows $\theta = 1.021$, where $\theta$ is the modified Arrhenius temperature coefficient. Part of these trends are due to flow changes

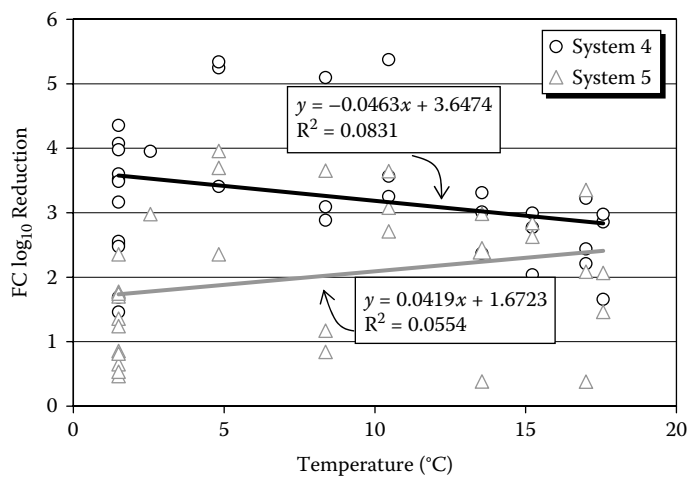

**FIGURE 12.8** Dependence of $\log_{10}$ reduction of fecal coliform for Listowel, Ontario, Systems 4 and 5. Three years of monthly data are represented. (Data from Herskowitz (1986) *Listowel Artificial Marsh Project Report*. Ontario Ministry of the Environment, Water Resources Branch: Toronto, Ontario.)

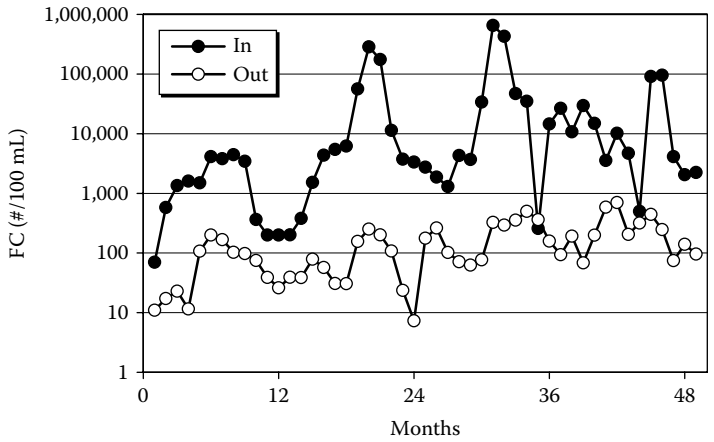

**FIGURE 12.9** Time series of monthly fecal coliforms entering and leaving the Imperial, California, treatment wetlands. (From unpublished data.)

from summer to winter, and thus the rate constants exhibit lesser temperature dependence ($\theta = 0.997$ and 1.002, respectively, Table 12.5).

Stochastic variability in the bacterial indicator organisms leaving FWS wetlands is very large. Fecal coliform counts are due to internal loading within the wetland as well as declines in populations entering with wastewater. For example, at the Imperial, California, wetland, the four-year time series of monthly incoming fecal coliforms varied over three orders of magnitude (factor of 1,000) and the wetland effluent fecal coliforms varied over two orders of magnitude (factor of 100) (Figure 12.9). Such time series may be expressed as probability density plots, such as those for Listowel Systems 4 and 5 (Figure 12.10). For these side-by-side wetlands, the variability of fecal coliform in the lagoon source water was much less than in the wetland effluents, which display a spread of more than three orders of magnitude. It is also noteworthy that the wetland of greater aspect ratio (System 4) shows a greater reduction.

Excursions around mean performance should be acknowledged in design and regulation. Trends in outlet pathogens can form the basis, or predictions from a first order or other model. Table 12.4 shows example trend fits for several FWS wetlands, together with the multipliers necessary to contain excursions of a given frequency of occurrence. For instance, the 95th percentile median $\log_{10}$ of concentration is 1.31 times higher than the trend. If the outlet trend value is 1,000 CFU/100 mL, then 1 out of 20 times, the outlet may reach $1{,}000^{1.31} = 8{,}511$ CFU/100 mL.

## Input–Output Relation for Fecal Coliforms

FWS treatment wetlands reduce high numbers of incoming fecal coliforms. Wetland data has been acquired for a number of systems, with examples listed in Table 12.6.

Input–output annual data for 256 wetland years is displayed in Figure 12.11. The scatter in these data is quite high

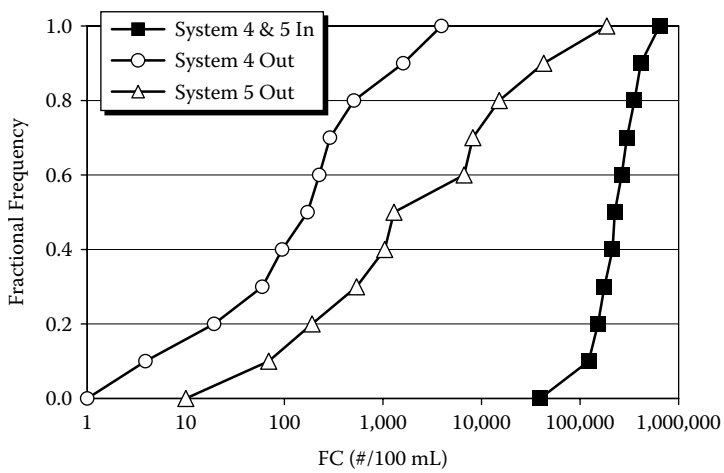

**FIGURE 12.10** Probability densities for monthly fecal coliforms entering and leaving Listowel, Ontario, Systems 4 and 5. System 4 had aspect ratio L:W = 84:1, whereas System 5 had aspect L:W = 5:1. (Data from Herskowitz (1986) *Listowel Artificial Marsh Project Report*. Ontario Ministry of the Environment, Water Resources Branch: Toronto, Ontario.)

and is reflective of two points discussed previously. First, there is a nonzero background for this indicator organism group, and that background is itself quite variable. Disinfected influents tend to emerge from an FWS wetland in the range 10–1,000 CFU/100 mL, with a median of 60 CFU/100 mL for those wetlands that receive a disinfected inflow. Second, when inlet concentrations are above about 1,000 CFU/100 mL, there is a $log_{10}$ reduction of about two, but results are widely variable from wetland to wetland. The addition of the hydraulic loading rate to the variables, in the form of a loading plot, does little or nothing to reduce the scatter.

Ponds are also effective in lowering fecal coliform, over a very wide range of inlet concentrations (Kadlec, 2005e). Over a range of nine orders of magnitude of inlet fecal coliform, an average reduction of just over one $log_{10}$ is achieved in ponds of varying size, loading, and configuration. Wetlands have typically been exposed to lesser inlet fecal coliform concentrations than ponds, also spanning seven orders of magnitude, but including the very low inlet values associated with disinfected source waters. For an inlet range of $10^4$–$10^6$ CFU per 100 mL, wetlands appear to be slightly superior in removal to ponds. But at lower inlet counts, wetland performance decreases to a condition of regrowth and reintroduction.

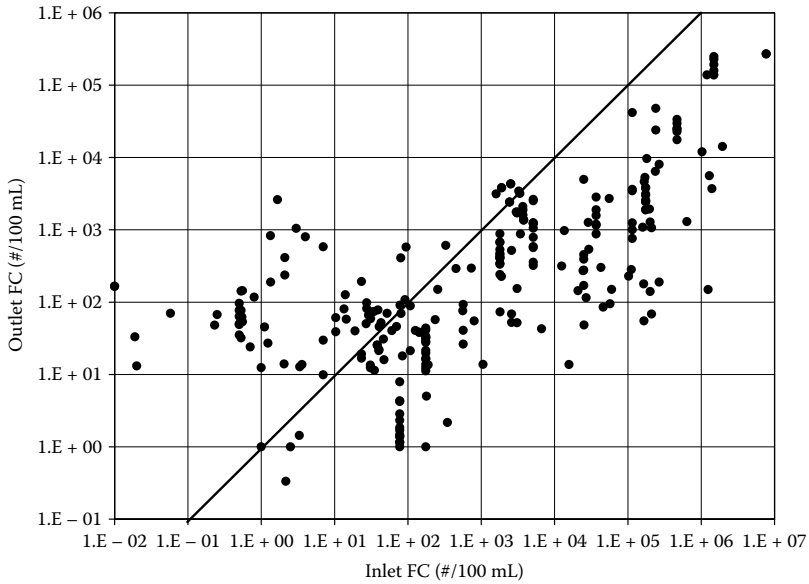

**FIGURE 12.11** Outlet fecal coliforms versus inlet fecal coliforms for FWS wetlands. There are 256 annual data points for 79 different wetlands.

## 12.4 REMOVAL OF OTHER INDICATOR BACTERIA IN FWS WETLANDS

### Total Coliforms

The coliform group has been used as the standard for assessing fecal contamination of waters throughout the twentieth century (Gerba, 2000). Although total coliforms have been widely used in older studies and monitoring, many of the organisms in this broad group are not limited to fecal sources. Accordingly, the subgroup of fecal coliforms has become the preferred indicator, which includes the genera *Escherichia* and *Klebsiella*. A simple lab test allows differentiation.

Here, it is noted that FWS treatment wetlands reduce high numbers of incoming total coliforms. Wetland data have been acquired for a number of systems, with examples listed in Table 12.7. As for fecal coliforms, wetlands reintroduce total coliforms to a disinfected influent, to a limited degree, as evidenced by the Orlando Easterly Wetland (OEW) data. For nondisinfected influents, there are reductions of one to two $\log_{10}$.

### Fecal Streptococcus

Fecal streptococcus belongs to the genera *Enterococcus* and *Streptococcus*. These are considered to have advantages over fecal coliforms as an indicator because (1) they rarely multiply in water, (2) are more resistant to environmental stress, and (3) generally persist longer in the environment (Gerba, 2000). A high ratio of fecal streptococci to fecal coliforms is taken as strong evidence that the source is of human origin.

Inflow and outflow densities of fecal streptococcus bacteria have been monitored at a number of pilot and full-scale wetland treatment systems. Table 12.8 summarizes these data for some of the wetland treatment systems receiving municipal wastewater, pretreated to differing extents. Data for disinfected influents again show reintroduction in treatment wetlands, with effluent numbers in the range 50–200 CFU per 100 mL. For nondisinfected influents, there are reductions of one to two $\log_{10}$.

### *Escherichia coli*

*Escherichia coli* is found in the intestinal tract of all warm-blooded animals and is usually considered harmless (Gerba, 2000). However, several strains are capable of causing gastroenteritis and include organisms that may cause hemorrhagic colitis, a dangerous disease, especially for the elderly. For this reason, *E. coli* has found favor in some instances as a replacement for fecal coliforms as an indicator organism.

*E. coli* has the ability to regrow or to be reintroduced in FWS wetlands. Considerable numbers were found in the wetland effluents at Tres Rios, Arizona, for a disinfected influent (Table 12.9). Conversely, large reductions may occur when the wetland influent has large numbers. Such reductions may be quite large for highly compartmentalized wetlands of high aspect ratio, for instance, the Brawley, California, wetlands.

### Miscellaneous Bacteria

*Clostridium perfringens* is exclusively of fecal origin. It is regarded as particularly resistant to pH and temperature stress and was therefore chosen for monitoring at the Listowel, Ontario, system (Herskowitz, 1986). *Salmonella* is a large group, all of which are pathogenic to humans. *Salmonella* causes typhoid and paratyphoid fevers, and is found in a large variety of both warm-blooded and cold-blooded animals. *Yersinia enterocolitica*, a bacterium that causes gastroenteritis, was found in large numbers in the Listowel lagoons. Because it survives well at cold temperatures, it was monitored in the Listowel project. *Pseudomonas aeruginosa* is associated with the disease *otitis externa*, or "swimmers ear" (Herskowitz, 1986). All these organisms, plus others, have been found to be reduced in FWS treatment wetlands (Table 12.10).

## 12.5 PARASITE AND VIRUS REMOVAL IN FWS WETLANDS

### Parasites

Parasites include protozoa and helminths. In the United States, the two protozoa of special interest are *Giardia lamblia* and *Cryptosporidium parvum*. The former is the most frequently identified intestinal parasite in the United States (Maier *et al.*, 2000). The latter was implicated in an outbreak in 1993 in Milwaukee, Wisconsin, in which over 400,000 people were infected. *Giardia* is of special interest in connection with wetlands because beavers and muskrats are believed to be reservoirs of infection. Worldwide, *Ascaris lumbricoides* is the most prevalent parasitic infection, with an estimated 22% of the world population affected (Maier *et al.*, 2000). Adult *Ascaris* are roundworms which inhabit the intestine, but they are ingested as eggs. Two other prevalent infectious worms are *Trichuris trichiuria* and *Taenia saginata*, and these are of special concern in warm climates.

FWS wetlands reduce the numbers of these parasitic organisms by reducing the number of eggs or cysts that survive in the aquatic environment (Table 12.11). One mechanism is presumably sedimentation of eggs, followed by eventual inactivation. Nelson (2003) reports egg numbers in pond sludges ranging from less than ten per dry gram in France, to thousands of *Ascaris* eggs per dry gram in Brazil. Inactivation may take more than a year. However, Stott *et al.* (2001) determined that oocysts of *Cryptosporidium parvum* were effectively ingested by protozoans, notably *Paramecium caudatum* and *Stylonychia mytilus*. Therefore, predation may also be a factor in the observed reductions.

### Viruses

The average viral content of domestic sewage in the United States is about 7,000 particles per liter (Gersberg and Gearheart, 1989). Because the potential infective dose of viruses can be so low (<10 particles), and viruses are generally hardier in natural environments than bacterial pathogens, there has been considerable concern about their fate in wetland and conventional treatment systems. However, because viruses are more costly and difficult to monitor analytically, they have not received as much study as bacterial indicator populations. Existing research indicates that wetlands are generally hostile environments for viruses (Table 12.12).

Scheuerman *et al.* (1989) found that bacteriophages and enteroviruses in a natural cypress wetland declined with distance from an outfall, indicating that wetland virus removals can be effective if residence time is adequate. In this test, bacteriophages were removed at a slower rate than bacterial indicators and enteroviruses. Enteroviruses declined at the fastest rate and were not observed to accumulate in downstream sediments. High removals of enteroviruses were also found at the Houghton Lake, Michigan, natural treatment wetland (unpublished data) and the Gainesville, Florida, natural treatment wetland (Wellings, 1977). Most recent research has focused on the reduction of bacteriophages in wetlands (Table 12.12), with reductions of greater than 90% at a number of geographically distinct sites.

### Wildlife Pathogens

Wildlife pathogens are also potentially associated with treatment wetlands as they are with natural wetlands. Avian

[a] BDL—Below detection limit.

cholera (caused by *Pasteurella multocida*) and avian botulism (caused by *Clostridium botulinum*) have been found in association with sewage lagoons and natural and treatment wetlands (Friend, 1985). Conditions that favor transmission are exposed mudflats together with stressed and overcrowded bird populations. The nematode *Eustronglydes ignotus* has been identified as a potential threat to wading birds that feed and nest near nutrient-rich sites. However, extensive research on the fish that are intermediate hosts have shown no potential vector in Florida wetlands treating agricultural runoff (SFWMD, 1997).

## 12.6 FECAL COLIFORM REMOVAL IN SSF WETLANDS

The most common indicator group is fecal coliforms; consequently, the performance database for SSF wetlands is largest for this indicator group. Global removals (input–output data), for example, in HSSF and VF wetlands, are shown in Table 12.13.

For a larger database of 130 wetlands or operating conditions, the median global removal was a 1.82 $log_{10}$ reduction in fecal coliforms. Generally, fecal coliform removal in HSSF

wetlands is enhanced under the following conditions:

- Longer nominal hydraulic residence time (τ) or lower hydraulic loading
- Finer bed materials (sand), but only to the extent that the fine bed media does not impair hydraulic performance
- Warmer water temperatures
- Shallower bed depths

### Effect of Vegetation

In general, the presence of plants in HSSF wetlands has a beneficial effect on pathogen reduction (Table 12.14). It is not clear whether this is due to the effects of the plants on system hydraulics or to other causes, such as the presence of antibiotic exudates in the rhizosphere (Vacca *et al.*, 2005). Further, a plant advantage is by no means a universal conclusion.

### Effect of Depth

The year-long studies of Barrett *et al.* (2001) provide a side-by-side comparison of 30- and 60-cm depths of gravel with mixed plantings (Table 12.15). Both beds were supplied with the same flow rate, thus creating equal hydraulic loadings, but doubled detention time in the deep bed. There was a very strong effect, with the deeper gravel bed performing much more poorly. The calculated volumetric rate constants were about five times lower in the deep bed for most organisms, except for *Clostridium perfringens*, which was only 40% lower in the deep bed. This difference was so large that calculated areal rate constants were also lower in the deep bed, by about a factor of three. It is not known if these differences arise from system hydraulics or from other causes.

### Effect of Media Size and Uniformity

The data of García *et al.* (2003b) help to understand the potential importance of media size and uniformity. Four equal-sized side-by-side gravel beds were operated with equal but varied nominal detention times. Each bed had a different media (Table 12.16), with three particle sizes and three uniformities. As detention time was increased, the removal increased. However, there was no log-linear decrease, indicating that hydraulics were far from plug flow. When the data were reanalyzed with the *P-k-C** model (with $C^* = 0$), excellent fits were obtained for $P = 2.6$ for fecal coliforms and $P = 2.2$ for somatic coliphage. An increase in rate constant with decreasing particle size is apparent. However, there is a greater increase with decreasing media uniformity.

### Background Concentrations

There is no reason to expect a background concentration for organisms that originate from warm-blooded animals, such as fecal coliforms, in SSF systems. The opportunity for organisms to reach the water within the bed from external sources is very limited. Nonetheless, the outdoor environment of the SSF wetland is not sterile, and various bacteria may be found in natural systems, absent any effect of wastewater.

It is possible to gain some insight about background concentrations in three ways: from data on sterile water feeds, from operations at extremely long detention times, and from the possibility of an extrapolation limit on effluent organism counts as inlet counts are lowered, across multiple systems. Thurston *et al.* (2001) pursued the former method and introduced well water into a *Typha–Scirpus* HSSF wetland. The outlet averaged TC = 130 #/100 mL and fecal coliform = 22

#/100 mL over an 18-month period of operation. Operating data from some HSSF wetlands indicate that pathogen decline may be to a nonzero background concentration ($C^*$). For instance, a HSSF wetland operated in Craven County, North Carolina, returned an effluent concentration of 62 CFU/100 mL, despite an extremely long nominal hydraulic retention time of 56 days (Myers, 1993). This is comparable to the (Thurston *et al.*, 2001) result. The Water Environment Research Foundation (WERF) database contains outlet fecal coliform data for a large number of HSSF wetlands. Out of 4,400 reported values, 15% are less than fecal coliform = 3 CFU/100 mL. On the intersystem plot of outlet fecal coliform versus inlet fecal coliform (Figure 12.12), there is no plateau at low inlet fecal coliform, but rather a steady decline in outlet fecal coliform. However, this intersystem data does not extend to very low inlet concentrations.

It appears that if there is a background fecal coliform concentration for HSSF systems, it is quite low, probably <10 per 100 mL. That level does not affect the performance of wetlands that receive $10^5$–$10^6$ per 100 mL. Accordingly, the analysis of data herein assigns $C^* = 0$.

The existing data sets for fecal coliform reductions in VF wetlands are much more limited, with the largest body of knowledge for VF wetlands designed on the pulse loading system, commonly used in Europe. Flow in these wetlands is a complex combination of saturated and unsaturated flow (see Chapter 2). As a result, factors such as the loading/resting frequency, hydraulic loading rate, dose interval, and bed media

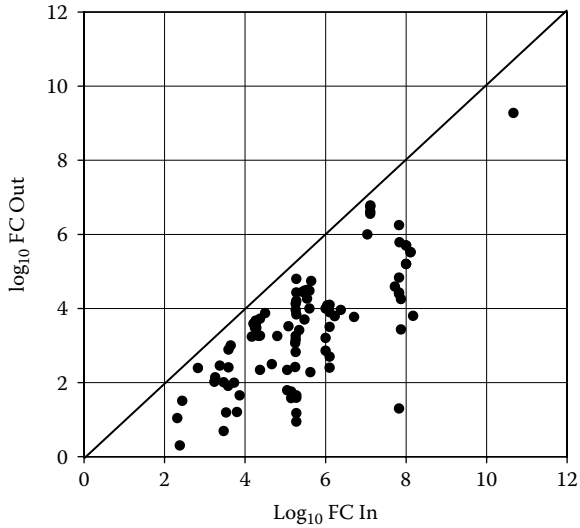

**FIGURE 12.12** Outlet fecal coliforms versus inlet fecal coliforms for HSSF wetlands. There are 97 data points for 88 different wetlands.

size all play an important role in the reduction of pathogens, including fecal coliforms. As a result of these interactions, it is difficult to generalize about the effectiveness of these systems in pathogen reductions. Table 12.13 lists example fecal coliform removals (input–output data).

For the six unsaturated downward flow systems listed in Table 12.13, the mean global removal was a 2.55 $\log_{10}$ reduction in fecal coliforms.

## First-Order Removal Models

### Longitudinal Profiles

Global first-order models forecast a decline in pathogens along the wetland flow path (provided the influent concentrations exceed the background concentrations for the system). This has been demonstrated for HSSF wetlands, as indicated in Figure 12.13.

As discussed previously for FWS wetlands, first-order models are traditionally used to account for pathogen inactivation, and such models are investigated here. There is adequate evidence that in the absence of artifacts of flow and mixing, exponential decays in the numbers of pathogenic organisms are to be expected in HSSF wetlands. For instance, Gersberg *et al.* (1987) studied inactivation of MS2 bacteriophage in dialysis bags located in the gravel matrix of a HSSF (bulrush) wetland at Santee, California. Log-linear decays were found, with over 3–5 $\log_{10}$ removal ranges (Figure 12.14). Although the study did not include the effect of gravel, it does indicate that water-phase inactivation is first order. The HSSF wetlands at Richmond, New South Wales, Australia, were tracer tested. When the data were analyzed, the gravel only and *Typha* in gravel wetlands were found to have *N*TIS = 25 and 21, respectively. These nearly plug flow systems may have resulted from the L:W = 25 used in their construction. The longitudinal profiles of fecal coliforms in these two wetlands are nearly log-linear (Figure 12.13).

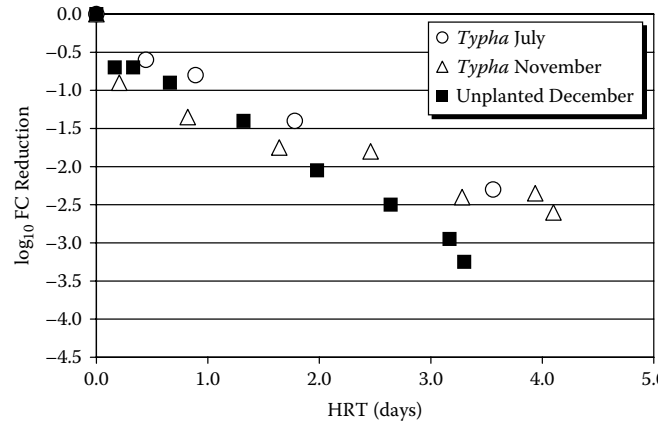

**FIGURE 12.13** Reduction of fecal coliforms at Richmond, New South Wales. Both wetlands were long and narrow (L:W = 25), and tracer test results indicated *N*TIS > 20. (Data from Bavor *et al.* (1988) *Treatment of secondary effluent*. Report to Sydney Water Board, Sydney, NSW, Australia.)

However, as noted in Chapters 2 and 6, flow in most HSSF systems is subject to greater nonplug flow effects. There is often enough nonideality to seriously affect removal behavior when reductions reach two or more $\log_{10}$ (99%).

Figure 12.5 is also valid for HSSF systems and demonstrates that exponential behavior is not to be expected even for fairly high *N*TIS values, e.g., *N*TIS = 8. García *et al.* (2003b) explored the effect of changing HRT for four HSSF wetlands for fecal coliform and somatic phage reduction. The expected deviation from exponential behavior can be found (see Figure 12.15).

In addition to the purely hydraulic effect of imperfect flow patterns, most pathogens are in fact mixtures of many species of organisms, and often occur in free form and in association with solids (TSS). Therefore, it is also expected that the mixture of organisms (e.g., fecal coliforms) will weather, as discussed in Chapter 6. The easier removals, which include

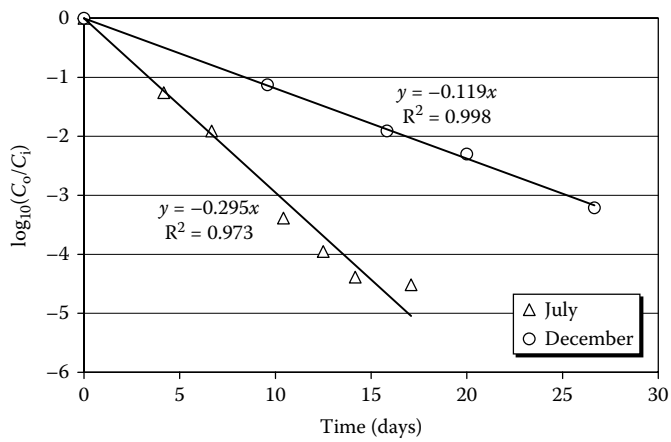

**FIGURE 12.14** The decay of bacteriophage MS2 in *in-situ* batch studies in the HSSF gravel bed environment at Santee, California. The values of $k_V$ are 0.27 and 0.68 $d^{-1}$ for December and July, respectively. (Data from Gersberg *et al.* (1989) In *Constructed Wetlands for Wastewater Treatment: Municipal, Industrial, and Agricultural.* Hammer (Ed.), Lewis Publishers, Chelsea, Michigan, pp. 431–445. Reprinted with permission.)

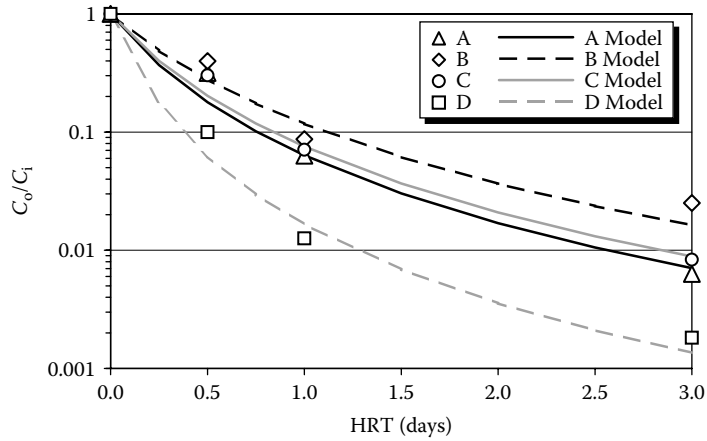

**FIGURE 12.15** *P*TIS model of the fecal coliform data from the four wetlands at Montcada i Reixac, Spain. The $R^2$ values range from 0.998 to 1.000. The *k*-values are 459, 312, 350, and 602 for A, B, C, and D, respectively, for *P*TIS = 2.6. The plug-flow model would be a straight line on this plot. (Data from García *et al.* (2003b) *Water Research* 37: 2645–2653.)

TSS pathogens, are likely to occur first, whereas die-off of specific organisms may occur later. The effect of weathering is the reduction of the *P*TIS value that is representative of pathogen removal.

Very different flow paths and conditions are typically present in HSSF and VF systems. HSSF wetlands use a saturated flow path, where the hydraulic residence time (τ) can be estimated (through nominal parameters) or measured (through tracer testing). In contrast, VF wetlands employ a variety of loading/resting schemes. In Europe, the most common mode of operation is a single-pass, pulse-loaded mode; in North America, recirculating systems with intermittent dosing are most common. The combined effect of these loading/resting modes is that movement of water through VF wetlands is a complex interaction of saturated and unsaturated flow mechanisms (see Chapter 2). As a result of these hydraulic differences, it is not possible to represent HSSF and VF pathogen removals using a common set of parameters.

## Rate Constants

The data from a number of HSSF wetlands has been analyzed to calculate first-order areal removal rate constants for use in the *P-k-C** model. Because tracer tests are typically unavailable for these wetlands, a value of $P = 6$ has been chosen. This is based on a median *N*TIS value of 8 (see Chapter 6), reduced to $P = 6$ to account for weathering phenomena. The value of $C^* = 0$ has been chosen. There is a wide range of *k*-values so calculated (see Tables 12.17–12.19). For fecal coliforms, the median $k = 103$ m/yr, corresponding to a $\log_{10}$ reduction of 1.82. For total coliforms, the median $k = 112$ m/yr, corresponding to a $\log_{10}$ reduction of 2.04. For various viruses, the median $k = 67$ m/yr, corresponding to a $\log_{10}$ reduction of 1.60. Importantly, the *k*-values are very sensitive to wetland hydraulics, and extrapolation to high removals is not acceptable for design purposes.

## Seasonal Trends

Some HSSF wetlands display seasonal effects for fecal coliform removal, with lower removal efficiencies during winter months at lower water temperatures. Data from Grand Lake,

**TABLE 12.17**
**Period of Record Reduction of Fecal Coliforms in HSSF Wetlands**

**Stipulations**

1. Period of record averages are used in calculations.
2. For *k*-value calculations, the following *P-k-C** parameters are selected:
   a. $C^* = 0.0$ #/100 mL
   b. $P = 6$ TIS
3. Ranges of variables:

| | HLR (cm/d) | $\log_{10}$ FC In (CFU/100 mL) | $\log_{10}$ FC Out (#/100 mL) |

Minnesota, show this pattern (Kadlec, 2004). Similar seasonal patterns (lower fecal coliform removal at lower water temperatures) have been observed for HSSF wetlands at Iselin, Pennsylvania (Watson *et al.*, 1987); Audlem, United Kingdom (Rivera *et al.*, 1995); and at NERCC, Minnesota (Axler *et al.*, 2001).

But there is no common theme for the variation of performance across the seasons. In some cases, there is a strong seasonal variation (Figure 12.16), whereas other HSSF wetlands display no such variation (Figure 12.17). The average amplitude of variation is 0.15 $\log_{10}$, and such trends account for only an average of 18% of the variability (Table 12.20).

### Temperature Coefficients

There are conflicting potential effects of temperature on pathogen reduction. Cold temperatures are inimical to the survival of organisms that originate in warm-blooded organisms, and thus human pathogens usually do not survive well outside the body. Survival times in waters are typically 10–30 days (Crites and Tchobanoglous, 1998). On the other hand, the activity of predatory organisms, such as protozoa, is lessened at cold temperatures, although direct lethality is unlikely (Davies-Colley *et al.*, 2005). Removal by adsorption is expected to be insensitive to temperature but slightly less effective under cold conditions. The very high temperature coefficients suggested for ponds and FWS wetlands ($\theta = 1.19$, Shilton and Mara, 2005; U.S. EPA, 2000a) are unlikely to prevail in the subsurface environment and do not apply.

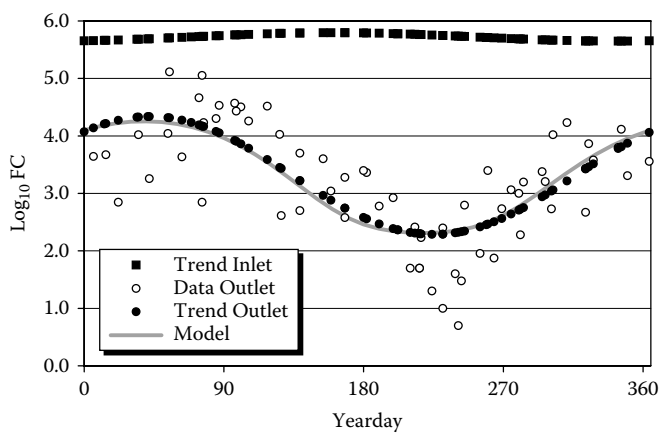

**FIGURE 12.16** Fecal coliform trends and model for the NERCC, Minnesota, HSSF wetland 1. The trends are cosine fits to the data. The model is the *P-k-C** with $P = \infty$, $k = 88$ m/yr, $C^* = 150$ per 100 mL, $\theta = 1.073$, $R^2 = 0.86$.

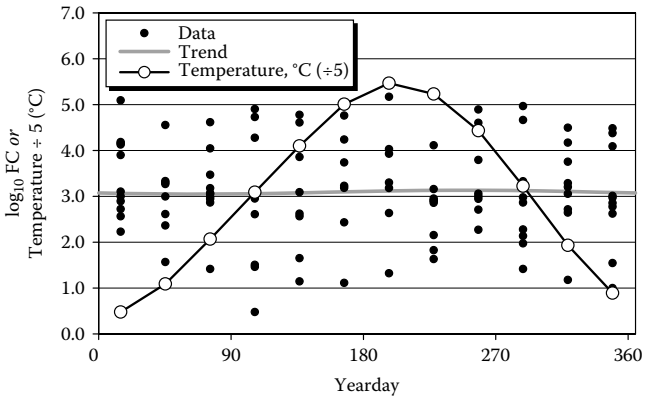

**FIGURE 12.17** Fecal coliform trend and data for the Tuckerman, Arkansas, HSSF wetland. The trend is a cosine fit to the data $R^2 = 0.001$. The 30-year normal mean monthly regional air temperature is also shown. (Data from WERF database (2006) *Small-Scale Constructed Wetland Treatment Systems Database (Project 01-CTS-5;* Final Report by Wallace and Knight, 2006). Compiled by J. Nivala and R. Clarke. Water Environment Research Foundation (WERF): Alexandria, Virginia.)

A number of HSSF wetlands have a median of $\theta = 1.002$ (Table 12.21). However, six systems display high values ranging from 1.043 to 1.073. The disparity in temperature effects is illustrated in Figures 12.16 and 12.17. There is no apparent relation that can explain the differences, because both high and low theta values occur across a variety of conditions.

### Variability

Stochastic variability in bacterial indicator organisms leaving HSSF wetlands is very large. Effluent fecal coliform concentrations are due to input loadings, decline of fecal coliform populations within the wetland, and potential reintroduction by wildlife. As a result, excursions around mean performance (Figures 12.16 and 12.17) should be expected and acknowledged in the design and regulation of HSSF wetland systems.

There is a very large degree of variation in organism numbers about seasonal trends, if any. Because of this, the $\log_{10}$ of the numerical counts is used to analyze variation. The $\log_{10}$ of the fecal coliform count at the 95% excursion level has a median of 1.55 times the trend value (Table 12.20). Suppose the trend outlet number density is 1,000 CFU/100 mL and thus the $\log_{10}$ FC = 3.00. At the 95% excursion level, the multiplier is 1.55 (Table 12.20), and the $\log_{10}$ FC = 4.65 to contain excursions at that frequency (one in twenty). Thus, the outlet number would be 44,668 CFU/100 mL, or over 40 times higher than the trend.

## 12.7 REMOVAL OF OTHER BACTERIA IN SSF WETLANDS

### Total Coliforms

The coliform group has been used as the standard for assessing fecal contamination of waters throughout the twentieth century (Gerba, 2000). However, many members of this broad group of organisms are not limited to fecal sources.

**TABLE 12.20**
**Annual Cyclic Trends and Trend Multipliers for the $\log_{10}$ of Concentration (CFU/100 mL) of Fecal Coliforms in the Effluent from HSSF Wetlands**

| System | Years | $\log_{10}$ Mean | $\log_{10}$ Amplitude | Yearday Maximum | $R^2$ | Excursion Frequency 50% | 80% | 95% | 99% |
|---|---|---|---|---|---|---|---|---|---|
| Hardin 1, Kentucky | 1 | 3.13 | 0.32 | 131 | 0.64 | 1.01 | 1.12 | 1.19 | 1.29 |
| Ola, Arkansas | 14 | 1.8 | 0.12 | 268 | 0.03 | 0.87 | 1.5 | 1.78 | 1.89 |
| Dierks, Arkansas | 12 | 2.24 | 0.09 | 237 | 0.01 | 0.72 | 1.79 | 1.92 | 1.98 |

| Gould, Arkansas | 14 | 2.92 | 0.02 | 319 | 0 | 0.99 | 1.33 | 1.46 | 1.55 |
| North Crossett, Arkansas | 14 | 2.34 | 0.04 | 178 | 0 | 1.11 | 1.65 | 1.78 | 1.88 |
| Gurndon, Arkansas | 14 | 1.88 | 0.12 | 204 | 0.04 | 0.93 | 1.32 | 1.55 | 1.74 |
| Grand Lake, Minnesota | 4 | 2.32 | 0.2 | 98 | 0.17 | 1.06 | 1.35 | 1.46 | 1.58 |
| North Yorkshire 1, England | 3 | 3.48 | 0.1 | 187 | 0.05 | 1.09 | 1.21 | 1.33 | 1.39 |
| Waipoua, New Zealand[a] | 4 | 2.53 | 0.09 | 183 | 0.06 | 1.07 | 1.22 | 1.25 | 1.36 |
| Benton 3, Kentucky | 1 | 1.88 | 0.37 | 174 | 0.3 | 1.02 | 1.26 | 1.39 | 1.46 |
| NERCC1, Minnesota | 4 | 3.31 | 0.31 | 43 | 0.47 | 1.05 | 1.17 | 1.27 | 1.32 |
| NERCC2, Minnesota | 4 | 3.45 | 0.23 | 72 | 0.39 | 1 | 1.21 | 1.25 | 1.31 |
| **Median** | **7.5** | **2.44** | **0.12** | **185** | **0.05** | **1.01** | **1.33** | **1.46** | **1.55** |
| **Mean** | **8.1** | **2.58** | **0.16** | **188** | **0.16** | **0.98** | **1.34** | **1.49** | **1.59** |

*Note:* Also shown are the multipliers that represent the frequency of excursions from the trend. For instance, the 95th percentile median $\log_{10}$ of concentration is 1.55 times higher than the trend. If the outlet trend value is 1,000 CFU per 100 mL, then one time out of twenty the outlet may reach $1{,}000^{1.55} = 44{,}700$ CFU per 100 mL. Trend multiplier is $(1 + \Psi)$; see Equation 6.61.

[a] Date adjusted 182 days.

Accordingly, fecal coliforms have become the preferred indicator, although total coliform reductions are widely reported in the literature. Examples of reduction of total coliforms in HSSF wetlands are reported in Table 12.22.

For a larger database of 54 HSSF wetlands/operating conditions, the mean global removal was a 2.04 $\log_{10}$ reduction in total coliforms. Removal mechanisms for total coliform bacteria are similar to those previously discussed for fecal coliforms. For nine studies of unsaturated downward VF systems, the mean global removal was a 2.02-log reduction in total coliforms (not shown).

### Miscellaneous Bacteria

A variety of other pathogenic bacteria have been assessed in SSF wetlands. These include *Escherichia coli*, *Clostridium perfringes*, Enterobacteriaceae, Enterococci, *Salmonella*, *Shigella*, *Yersinia,* and fecal streptococcus. The pathology of these organisms has been discussed for FWS wetlands.

Example data indicate that SSF wetlands are also effective in the reduction of these pathogenic organisms (Table 12.23).

Table 12.23 lists bacterial removals based on the period of record (POR) available from literature sources. For the 44 HSSF systems listed in Table 12.23, the mean global removal for these bacteria was a 2.21-log reduction. This is very similar to the reductions observed for fecal and total coliforms, presumably because the same removal mechanisms are operative. Broken down by species, these reductions are *Escherichia coli* (2.53-log), *Clostridium perfringes* (2.04-log), Enterobacteriaceae (1.59-log), Enterococci (1.40-log), *Salmonella* (2.47-log), *Shigella* (2.00-log), *Yersinia* (1.60-log), and fecal streptococci (2.43-log). It should be noted that the data in Table 12.23 do not represent a guarantee

of treatment performance, because the data on which the table is based is extremely limited.

Table 12.24 lists bacterial removals for 20 studies/operating periods in VF systems. The mean global removal for these bacteria was a 2.63-log reduction. This is very similar to the reductions observed for fecal and total coliforms, presumably because the same removal mechanisms are operative. Broken down by species, these reductions are: *Escherichia coli* (2.66-log), *Clostridium perfringes* (2.80-log), Enterococci (2.30-log), *Salmonella* (3.84-log), and fecal streptococci (2.10-log). It should be noted that data in Table 12.24, similar to Table 12.23, do not represent a guarantee of treatment performance, because the data on which the table is based is extremely limited.

## 12.8 PARASITE AND VIRUS REMOVAL IN SSF WETLANDS

### Parasites

Parasites include protozoa and helminthes. In the United States, two protozoa of special interest are *Giardia lamblia* and *Cryptosporidium parvum*. Worldwide, *Ascaris lumbricoides* is the most prevalent parasitic infection. The pathology of these organisms has already been discussed for FWS wetlands.

HSSF wetlands are effective in reducing the number of eggs or oocysts of these organisms (Table 12.25). This is presumably due to a combination of settling, filtration, interception, and predation. Removal percentages reported in the

**TABLE 12.23**

literature range from 79 to 100% for water-phase contamination (Thurston *et al*., 2001; Stott *et al*., 2003; Cirelli *et al*., 2006).

At the time of this writing, there is not sufficient data to assess the performance of VF wetland systems for parasite removal. Presumably, these systems (especially pulse-loaded designs that employ unsaturated flow) would remove parasite cysts or eggs effectively. This is based on the observation that VF systems typically remove bacteria and viruses (which have a much smaller particle size—see Figure 12.1) as effectively as HSSF wetlands.

### Viruses

Because the potential infective dose of viruses can be so low, and viruses are hardier in natural environments than bacterial pathogens, there is considerable concern about their fate and transport in wetland systems. However, because viruses are much more costly and difficult to monitor analytically, they are less studied in the literature than bacterial pathogens. Reduction of various viral organisms in HSSF wetlands is summarized in Table 12.26.

Data from the 32 systems listed in Table 12.26 indicate that the global reduction of viruses is on the order of 1.47-log. For different virus classifications, this is broken down as coliphage (2.52-log), somatic coliphage (1.14-log), F+ coliphage (0.41-log), MS-2 (1.78-log), and enterovirus (4.00-log). It should be noted that the data presented in Table 12.26 is limited to available research and does not imply a guarantee of treatment performance.

Compared to FWS or HSSF wetlands, considerably less is known about the fate and transport of viral organisms in VF wetlands. Barrett *et al*., (2001) indicate that pulse-loaded unsaturated flow VF wetlands can reduce viral organisms on the order of 2-log. This can be subdivided into somatic coliphage (2.70-log) and F+ coliphage (1.30-log). A similar study treating pond effluents by Torrens *et al*. (2007) also produced somatic coliphage (1.18-log) and F+ coliphage reductions (0.64-log).

## SUMMARY

Pathogenic organisms are a common component of domestic wastewater. Their populations are highly variable depending on the health of the human population contributing to the waste. Wetland treatment systems, especially those that have long residence times (greater than about ten days), provide some disinfection. The extent of removal is strongly dependent on the hydraulic efficiency of the wetland. Vegetated wetlands appear to be slightly more effective for pathogen removal than facultative ponds and other natural treatment systems that have less physical contact between pathogens and solid (biofilm) surfaces.

Because of the generally low density of actual wastewater pathogens and the difficulty associated with their enumeration, indicator organisms such as fecal coliforms, *E. coli*, and MS-2 bacteriophage are used to monitor the probable pathogenic activity of wastewater discharged to the environment. Empirical evidence is available that demonstrates that a significant die-off of indicator organisms and pathogenic species occurs in wetland treatment systems. It is also evident that wetlands, especially FWS systems, contain numerous animals that contribute base populations of these same indicator organisms to surface water quality. These naturally occurring indicator organisms must be recognized during regulatory permitting and review of data from wetland treatment systems.

Available information indicates that wetlands are at least as effective as other natural treatment technologies in reducing viral pathogen populations. In their review of the fate of pathogens in wetland treatment systems, Krishnan and Smith (1987) concluded that “while data exist to indicate the potential for public health problems arising from wetland discharges, no incidences of disease resulting directly from such discharges have been identified.” That conclusion appears to have withstood the test of time and remains true some 20 years later.

# 13 Organic Chemicals

Organic compounds are major constituents of biochemical oxygen demand (BOD) or chemical oxygen demand (COD) in municipal wastewater, as discussed in Chapter 8. However, there is an increasing number of treatment wetlands that target specific individual or groups of organic chemicals. These chemicals pose a new and somewhat more difficult set of problems because of their possible toxicity to plants and the limitations of aerobic and anaerobic degradation. The major routes for removal of hydrocarbons from wetland waters include: volatilization, photochemical oxidation, sedimentation, sorption, biological (microbial) degradation, and plant uptake. Three types of microbial processes can contribute: fermentation, aerobic respiration, and anaerobic respiration. The general principles and chemistry of processes affecting carbon compounds are discussed in Chapter 8; see Equations 8.10 through 8.18.

Wetlands manufacture and contain a wide spectrum of organic compounds. These compounds range from small molecules such as methane to humic acids of very high molecular weight. Many wetland soils are organic in nature and possess an affinity for introduced organics, via sorption and other binding mechanisms. Aliphatic hydrocarbons, both straight-chain and branched, are present as natural waxes. As a result, trace (background) amounts of some hydrocarbons are present in all wetlands, whether constructed or natural.

## 13.1 PETROLEUM HYDROCARBONS

There is considerable information on the use of treatment wetlands in the petroleum industry. Some of the general principles and available data have been summarized in a 1998 industry report (Knight *et al*., 1997; Knight *et al*., 1999). However, that compilation did not focus on specific hydrocarbon classes, such as BTEX and its constituent components (benzene, toluene, ethyl benzene, and xylenes). Two other hydrocarbon designations of interest include Gasoline Range Organics (GRO) and Diesel Range Organics (DRO). There is some overlap and ambiguity in these designations. Typically, GRO consists of hydrocarbons with 6–9 carbon atoms, while DRO contains 10–40 carbon atoms (Chapple *et al*., 2002). Total Petroleum Hydrocarbons (TPH) is a measure of the sum of paraffinic and aromatic constituents.

### BTEX

#### Biodegradation

Biodegradation of BTEX in a wetland environment is complicated by the existence of biofilms on submerged plant parts, plant litter, and gravel. Although small in terms of mass per unit volume, these biofilms are very active in biodegradation, and consequently serve as important sinks for organics. In this aspect, treatment wetlands resemble conventional attached-growth treatment processes.

Chang *et al*. (2001) established that all BTEX constituents degrade rapidly (half-lives of one to two days) when inoculated with a microbial consortium conditioned with toluene. Their study showed that benzene, toluene, and ethylbenzene were directly consumed as carbon sources, while xylene was removed by co-metabolism.

Moore *et al*. (2002) measured both aerobic and anaerobic biodegradation of BTEX in peat. Aerobic degradation was tracked via oxygen consumption and carbon dioxide production, and averaged 56 mg/kg·d. Anaerobic degradation was inferred from the consumption of other electron acceptors, including nitrate, sulfate, iron, manganese, and methane. About one third of the BTEX loss could have been attributed to anaerobic degradation.

#### Volatilization

BTEX constituents are volatile and may be easily lost from water, especially shallow water bodies, such as FWS wetlands. Lee *et al*. (2004a) have reported that first-order loss rate constants for BTEX constituents exhibit a fixed ratio to the loss rate constant for benzene, independent of the water-mixing regime (Table 13.1). Further, the presence of more than one BTEX compound, or of surfactants, had only minor effects on this ratio.

Of direct interest are the estimates, based on wetland data, of Keefe *et al*. (2004a) for an FWS wetland in Arizona. Values were determined of $K_w$ = 0.015 m/hr (130 m/yr) for toluene. This is a relatively high rate, compared to other pollutants treated in FWS wetlands.

Moore *et al*. (2002) evaluated volatilization losses from field vapor collection in a peatland contaminated with BTEX. Losses averaged 2,500 mg/m$^2$·d over all seasons. This high rate may have been in part due to the existence of a Light Non-Aqueous Phase Layer (LNAPL) in the peat.

#### Plant Uptake

Willows (*Salix babylonica*) were shown to materially contribute to the removal of benzene from water under hydroponic conditions (Corseuil and Moreno, 2001). Volatilization was effectively suppressed in the experiments, as demonstrated by control mesocosms. About 80% reduction in benzene was found with an HRT of one day. Corseuil and Moreno suggested that benzene was initially sorbed onto root biomass, followed by plant uptake and biological degradation.

**TABLE 13.1**
**Volatility of BTEX and Chlorinated Benzenes Compared to Benzene**

| Compound | Volatilization Ratio |
|---|---|
| Benzene | 1.000 |
| Toluene | 0.966 |
| Ethylbenzene | 0.922 |
| *m*-Xylene | 0.930 |
| 1,3 Dichlorobenzene | 0.882 |
| 1,3,5 Trichlorobenzene | 0.569 |
| 1,2,3,4-Tetrachlorobenzene | 0.530 |
| Pentachlorobenzene | 0.493 |

*Note:* The volatilization ratio is the ratio of first-order loss rate coefficients.

*Source:* Data from Lee *et al.* (2004a) *Water Research* 38(2): 365–374.

## Sorption

BTEX components are expected to partition strongly to organic wetland substrates, although a definitive wetland study is lacking. Wetland sediments typically have high organic content, and therefore sorption may be an important first step in overall removal. Benzene sorption onto peat was found to be strong, with a linear sorption coefficient of $K_{OC}$ = 5.6 L/kg (Moore *et al*., 2002), whereas binding to clay was much weaker, with $K_{OC}$ = 0.12 L/kg.

## Wetland System Studies

In all existing petrochemical plant applications, wetlands have been accompanied by pretreatment. However, other applications, such as those involving remediation, do not involve pretreatment. Hydrocarbon contamination of groundwater includes closed and operating sanitary landfills, army ammunition plants, and former oil refinery sites. These facilities were often the recipient of solvents and other organics, which in the course of time have contaminated nearby waters. Concentrations of petrochemicals in landfill leachate are typically lower than those associated with refineries and terminals.

### *Gulf Strachan, Rocky Mountain House, Alberta*

HSSF wetlands were tested for the ability to reduce hydrocarbons, notably BTEX and TPH (Moore *et al*., 2000a). The wetlands were planted with *Phragmites australis* and *Typha latifolia*. Reductions of 40–60% were achieved within 14 days of detention time with no aeration, while aeration produced 100% removal in the same detention time. Influent BTEX concentrations ranged from 4.5–12.1 mg/L, and influent flows ranged from 7–33 L/min.

At the same site, Moore *et al*. (2002) reported on the natural attenuation of BTEX in a natural peatland, which received both aqueous and nonaqueous phase hydrocarbons for more than 15 years. No BTEX was detected leaving the peatland. Companion studies elucidated some of the candidate removal mechanisms, including sorption, aerobic degradation, volatilization, and anaerobic degradation. Aerobic degradation, which was stimulated by air injection, was the dominant removal mechanism.

### *Former Oil Refinery—United Kingdom*

HSSF wetlands planted with *Phragmites* were tested for the ability to reduce hydrocarbons, notably DRO (Chapple *et al*., 2002). Reductions of 40–64% were achieved in less than one day's detention time. Gravel-based beds performed better ($k$ = 270 m/yr) than soil-based beds ($k$ = 137 m/yr) for DRO removal.

### *Mobil Oil AG Terminal at Bremen, Germany*

The information here is taken from Altman *et al*. (1989), which summarizes three years of research results at Bremen. Highly contaminated wastewater (COD up to 14,000 mg/L) was brought through an API separator, a parallel plate separator, and a percolating reactor to a two-train pilot wetland system patterned after the concepts of Seidel (1966; 1973) at the Max Planck Institute. Each train had five subsurface flow wetlands in series, each being 2.5 m wide, 4.0 m long, and 0.8 m deep. Beds 1 and 2 were vertical flow, with passive aeration to the underdrains. Beds 3, 4, and 5 were horizontal flow. Each bed was filled with a stratified media, from the bottom: 5 cm of 8/16 mm (pea) gravel, 20 cm of 36/72 mm stone, 25 cm of 8/16 mm gravel, 10 cm of sharp sand, and topped with 2 cm of organic soil. Water is intermittently dosed to the surface, where it spreads and infiltrates, ultimately reaching the (10 cm) under-drains in the second layer. The passive air is admitted to the first layer via perforated plastic pipe. Details of this type of system are given in Vymazal *et al*. (1998). The plants that proved best for Bremen were cattails (*Typha angustifolia*) and bulrushes (*Scirpus lacustris*).

Hydrocarbon removal performance of this system was primarily measured as total hydrocarbon, but BTEX and its constituents were also measured less frequently. The influent BTEX in August was 3.8 mg/L (1.5 mg/L benzene), and the outflow contained no detectable BTEX, with all constituents being below 0.01 mg/L. The flow of 5 $m^3$/d corresponded to about 5 cm/d hydraulic loading, or about five days' detention. Although these results are encouraging, they do not answer the question of how much of the five-bed system was needed to achieve a given reduction.

However, inferences about BTEX removal may be made from the removal of total hydrocarbon (TH). Data were taken at the outlet from each bed of the trains, and therefore a removal model may be calibrated. A first-order areal TH model yields $k$ = 66 m/yr, with no evidence of temperature dependence. This is consistent with the benzene removal rate coefficient, which cannot be less than 90 m/yr for the data in the preceding paragraph.

### *Williams Pipeline, Watertown, South Dakota*

An aerated HSSF wetland was operated to reduce BTEX from petroleum contact waters. Complete removal of

hydrocarbons was reported (Wallace, 2002), despite high influent concentrations ($CBOD_5$ > 16,000 mg/L, $NH_4$-N > 200 mg/L, and BTEX > 1 mg/L), but this facility operated at an extremely low hydraulic loading (1 mm/d), and consequently had no water discharge.

### *ESSO, Chilliwack, British Columbia*

A cardlock facility produced stormwaters contaminated by diesel fuel. FWS wetlands were found successfully reducing water-phase diesel range organics to permit levels (Nix, 1995). Removal rate constants were about 10 m/yr.

### *Marathon-Pitchfork, Wyoming Produced Water Project*

The Colorado School of Mines tested a combined pilot system for hydrocarbon removal (Caswell *et al*., 1992). Overland flow gravel beds (shallow) were loaded at 20–80 cm/d, and reduced benzene from 15 to 2 µg/L. Further removal in SSF wetlands reduced benzene to below detection.

### *Isanti-Chisago, Minnesota Leachate Treatment System*

The Isanti-Chisago Sanitary Landfill, an unlined municipal solid waste facility located near Cambridge, Minnesota, was closed in 1992 (Loer *et al*., 1999; Kadlec, 2003c). Leaching of soluble wastes had contaminated the surficial and increasingly deeper aquifers with toxic organic compounds and heavy metals. Extraction wells permit pumping of leachate to the top surface of the landfill mound, about eight meters above the surrounding landscape. Volatile Organic Compounds (VOCs), including BTEX, are largely removed by cascading the water down the side of the landfill into a sedimentation basin which serves to settle and store iron precipitates. The next component of the treatment train is a 0.6-ha FWS wetland. During five seasons of treatment, operating results indicated that the system efficiency ranges from 85–100% for VOCs and 98% for iron.

Only low levels of BTEX enter the system: (benzene 3.7 µg/L; toluene 0.6 µg/L; ethylbenzene 1.1 µg/L, xylene 1.8 µg/L). The cascade and settling basin do all the BTEX removal, although the FWS wetland does polish out any remaining traces of BTEX. Benzene, toluene, ethyl benzene, and xylenes are all individually below detection (0.1 µg/L) in the system outflow.

### *Saginaw Township, Michigan, Leachate Treatment System*

Saginaw Charter Township's Center Road Landfill was closed in the early 1980s (Kadlec, 2003c). Finger drains were installed in the seepage zones, which connect to a collection pipe. Leachate is then pumped to an aerator, which provides some ammonia and BTEX stripping. The water is then held in a sedimentation basin, to promote removal of solids. Water is discharged periodically to one of two intermittent sand/gravel filters, which provide filtration and nitrification. Underdrains then convey the water to two parallel free water surface wetlands. BTEX and its constituents were monitored for five years after startup. A mean total BTEX of 39 µg/L was removed, with only one detection in weekly samples (5.9 µg/L).

### *Phoenix, Arizona Wastewater Polishing*

A demonstration wetland project was studied for VOC removal (Keefe *et al*., 2004a). The wetland was a 1.4-ha free water surface system of depth about 60 cm. The detention time was 3.9 days. An 80% reduction of toluene from inlet to outlet was measured. Keefe *et al*. (2004a) attributed the reduction to volatilization, but concluded that theoretical predictions were only good for order-of-magnitude estimation.

### *Alcoa, Tennessee Groundwater Remediation*

A pilot wetland project was initiated and operated for a period of over one year, in a moderate north temperate continental climate. DRO and GRO were among the targeted substances (Gessner *et al*., 2005). GRO entered at monthly average values of 0.04–0.37 mg/L, and never exceeded the detection limit of 0.01 mg/L at the outlet of the FWS wetland. DRO entered at monthly average values of 0.29–1.08 mg/L, and exited at 0.11–0.44 mg/L. GRO removal rate constants could not have been less than 100 m/yr. In contrast, the DRO removal rate constants were 12 m/yr annual average. The first wetlands at the site were SSF wetlands, which were abandoned in favor of FWS because of continual operational difficulties.

### *Casper, Wyoming, Groundwater Remediation*

A pilot scale subsurface vertical flow wetland system was constructed at the former British Petroleum Refinery in Casper, Wyoming, in order to determine benzene, toluene, ethylbenzene, and xylene (BTEX) degradation rates in a cold-climate application (Ferro *et al*., 2002). The pilot system, consisting of four cells, each dosed at a nominal flow rate of 5.4 $m^3$/d, was operated between August and December 2002. The pilot tested the effects of wetland mulch and aeration on system performance. Areal rate constants ($k_A$) were calculated based on an assumed three tanks in series (3TIS). The presence of both wetland sod and aeration improved treatment performance. Mean $k_A$ values were 244 m/yr for cells without sod or aeration, and improved to 356 m/yr for cells with sod and aeration (Table 13.2).

Based on the results of the pilot system, a full-scale wetland system (capable of operating at 6,000 $m^3$/d) was started up in May 2003 (Wallace and Kadlec, 2005). The full-scale system achieved permit compliance within one week of start-up.

### *University of Edinburgh, Scotland*

Bench scale vertical flow wetlands were operated to demonstrate benzene removal (Eke and Scholz, 2006). The systems were operated in a fill-and-drain batch mode, cycling twice per week. Influent concentrations of 1,000 mg/L benzene were removed to 37–87 mg/L in the outdoor environment. The presence of wetland media (gravel), fertilizer, and warm temperatures were noted in improving treatment.

**TABLE 13.2**
**Casper, Wyoming, Mean Pilot System Areal Rate Constants $k_A$, in m/yr**

| | Aeration | | No Aeration | | Aeration |
|---|---|---|---|---|---|
| Compound | Wetland Mulch | No Mulch | Wetland Mulch | No Mulch | Full Scale |
| Benzene | 518 (237) | 456 (414) | 317 (273) | 226 (164) | 240 |
| BTEX | 356 (218) | 311 (136) | 257 (151) | 244 (151) | 350 |
| TPH | 1,058 (1,141) | 965 (722) | 725 (558) | 579 (506) | 325 |

*Note:* Based on 3TIS; standard deviation in parenthesis.

*Source:* Data from Wallace and Kadlec (2005) *Water Science and Technology* 51(9): 165–171.

### Alkanes

Omari *et al.* (2001) determined removal efficiencies in both vegetated and unvegetated horizontal-flow gravel beds for straight-chain alkanes of 10 to 26 carbon atoms. Removals were typically above 80% for a vegetated top-fed wetland mesocosm, and above 70% for a top-fed unvegetated mesocosm, in eight hours' detention. Removals were somewhat less for the lighter hydrocarbons, up to C15, but did not differ for the heavier alkanes. Omari *et al.* concluded that constructed wetlands planted with *Typha latifolia* were capable of treating oil-polluted water.

Similarly, Hoffman (2003) found no pronounced effects of chain length on alkane removals in willow mesocosms, over the range C10–C32. Willows enhanced the removal of TPH, with the effluent alkane concentrations in vegetated mesocosms about half of that in unvegetated mesocosms. Mechanisms of removal were not elucidated by these studies.

Salmon *et al.* (1998) evaluated removal of total hydrocarbons in FWS mesocosms in France. The bed was planted with *Typha latifolia,* and during the experiment, natural development of *Lemna minor* occurred. Constructed wetlands removed 90% of total hydrocarbons.

Descriptions of other petroleum industry treatment wetland projects may be found in Knight *et al.* (1997). These include the earliest such project at Mandan, North Dakota (Litchfield and Schatz, 1989; Litchfield, 1990; Litchfield, 1993), as well as well-studied projects such as that at Bulwer Island, Australia (Simi and Mitchell, 1999; Simi, 2000).

### Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) are fused ring aromatic compounds formed during the incomplete combustion of almost any organic material, and are ubiquitous in the environment (Figure 13.1). Some of them are considered as dangerous substances as a function of their toxic and mutagenic or carcinogenic potentialities. The presence of PAHs in contaminated soils and sediments may pose a risk to the environment and human health. PAHs are hydrophobic compounds, whose persistence within ecosystems is chiefly due to their low aqueous solubility. These materials are not volatile, and no loss to the atmosphere is anticipated under wetland conditions.

Creosote consists of a mixture of organic compounds, dominated by PAHs, many of which are individually designated as hazardous wastes. Wood may be treated with creosote to enhance its resistance to decomposition. For instance, railroad ties are typically treated with 128 kg/m$^3$. Many of the industrial sites that are or were used to treat ties are now

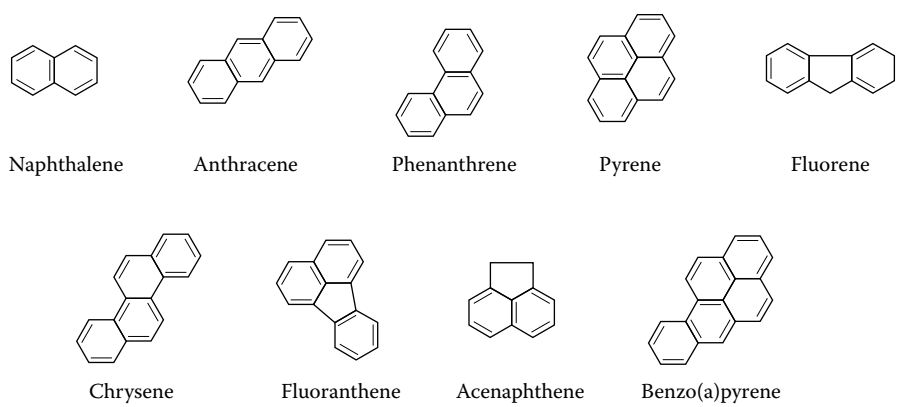

**FIGURE 13.1** Example polynuclear aromatic hydrocarbons.

classified as hazardous waste sites, due to spillage and the associated soil contamination. Conversely, there is little or no risk to aquatic and wetland environments from ties as they are normally placed (Brooks, 2000b), nor from bridge or dock pilings (Brooks, 2000a).

## Biodegradation

Aromatics follow a pattern, with polyaromatic hydrocarbons (PAHs) degrading more slowly than benzene; those with more than three rings may not support microbial growth (Zander, 1980). The aerobic microbial degradation of PAHs having two and three rings is well documented. A large number of bacteria that metabolize PAHs have been isolated (*Alcaligenes denitrificans*, *Rhodococcus* spp., *Pseudomonas* spp., *Mycobacterium* spp.; Giraud *et al*., 2001). A variety of bacteria can degrade certain PAHs completely to $CO_2$ and metabolic intermediates. As the number of fused rings increases, the degree of degradation decreases (Cookson, 1995, as referenced in Walsh, 1999). Degradation of PAHs by anaerobic organisms has not been very successful. However, some degradation has been achieved under denitrifying, sulfate reducing, and methanogenic conditions. Naphthalene and anthracene have been found to be slightly degraded anaerobically under denitrifying conditions (Walsh, 1999).

PAH-degrading bacteria were isolated from contaminated estuarine sediment and salt marsh rhizosphere by enrichment using naphthalene, phenanthrene, or biphenyl as the sole source of carbon and energy (Daane *et al*., 2001). Identification of the isolates assigned them to three main bacterial groups: gram-negative pseudomonads; gram-positive, non-spore-forming nocardioforms; and the gram-positive, spore-forming group, *Paenibacillus* (Table 13.3). This study indicated that the rhizosphere of salt marsh plants contains a diverse population of PAH-degrading bacteria, and the use of plant-associated microorganisms has the potential for bioremediation of contaminated sediments. Contaminated sediment was obtained from Newtown Creek in the New York Harbor, Brooklyn, New York. Chemical analysis showed the dredged sediment to contain 2 to 7 ppm of the PAHs naphthalene, anthracene, and phenanthrene. An induction period of 15 days was observed for pyrene, after which degradation was complete in 10 to 15 days. It should be noted that both the pure culture and microbial slurry experiments were performed under highly oxygenated conditions and that the limited diffusion of oxygen into organic-rich sediments has been found to restrict PAH biodegradation in the natural environment (DeLaune *et al*., 1981).

## Sorption

Peat soils adsorb PAH compounds quite effectively. These organics partition very strongly to carbonaceous soils (IT Corporation, 1997; Pardue and Shin, 2000), and are not readily desorbed (Pardue and Shin, 2000; Shin and Pardue, 2002). It is therefore expected that PAHs would be sorbed and stored in wetland peats. Partition coefficients in the range of $10^3$–$10^4$ L/kg were found for phenanthrene (Shin and Pardue, 2002).

## Plant Uptake

Polycyclic aromatic hydrocarbons are not taken up by wetland plants to any significant extent. Studies at Duluth, Minnesota, have shown very low concentrations in aboveground plant parts, and only trace amounts associated with roots (IT Corporation, 1997). PAHs were found in dogwood (*Cornus stolonifera*) and cattail (*Typha* spp.) shoots at the Duluth site. Willows (*Salix* spp.) and bulrushes (*Scirpus* spp.) have been reported to access tightly bound phenanthrene (Gomez-Hermosillo *et al*., 2000; Gomez and Pardue, 2002). Most of the PAH uptake was to the roots, and was associated

**TABLE 13.3**
**Abilities of Several Isolates to Utilize a Variety of PAHs**

| | % PAH Remaining | | | | |

*Source:* Data from Daane *et al*. (2001) *Applied and Environmental Microbiology* 67(6): 2683–2691.

with sorption. Because PAHs are not required for plant metabolism and growth, up take is dependent on concentrations and supplies to the pore water in the root zone.

### Wetland System Studies

Testing of wetlands for PAH removal has presented mixed results. Some tests show minimal removal, whereas others show excellent reductions. Anecdotal monitoring of a cypress swamp (forested peatland) receiving landfill leachate in Florida indicated no PAH removal after about 15 years (Schwartz *et al.*, 1999). However, other landfill leachate constructed wetland studies have shown no detectable PAHs in the effluent, including naphthalene at a Minnesota site; and naphthalene, fluorene, and phenanthrene at a Michigan site (Kadlec, 2003c). Boving (2002) found virtually no retention or removal of ten frequently detected PAHs in a stormwater system comprised of ponds and wetlands. Boving showed that heavier PAHs were present in urban freeway runoff at concentrations in excess of U.S. EPA benchmarks for chronic toxicity. In particular, benzo(*a*)pyrene was present at over 1.0 µg/L.

Subsurface flow constructed wetlands were used to treat coke plant wastewaters at Sollac, Fos sur Mer, France (Jardinier *et al.*, 2001). Removal of 45% was achieved in 11 days' detention. Jardinier *et al.* concluded that reedbeds were a valid method to remove PAHs.

In a German study, naphthalene was removed using hydroponic cultures of *Carex gracilis* and *Juncus effusus* and using sand-bed reactors planted with *Carex gracilis* and *Juncus effusus*, respectively, under batch and flow through conditions (Wand *et al.*, 2002). Concentrations of about 30 mg/L naphthalene were efficiently eliminated over periods of up to six months. Vegetated cultures were found to achieve a better removal rate than systems without vegetation. In the systems investigated, naphthalene was thought to be mainly degraded by bacteria in the rhizosphere.

The behavior of the three-ring PAH phenanthrene was investigated in a VF wetland system in Munich, Germany (Machate *et al.*, 1997), with overall removals of more than 99% at a detention time of 6.5 days. Intermediate degradation involved formation of 1-hydroxy-2-naphthoic acid as a bacterial metabolite, which subsequently was also removed in the wetland. Phenanthrene-degrading bacteria were enumerated, and found to be highest in the inlet zone of the system ($10^4$ per mL) in comparison to the outlet end (fewer than 10 per mL). Feed concentrations of 0.385 mg/L phenanthrene were reduced to less than 0.003 mg/L. The lava rock substrate had only a small partition coefficient, in the range 0.1 to 1.8 L/kg.

An experimental subsurface flow constructed wetland was developed in Curienne (Savoie-France), and operated with a feed of wastewater dosed with fluoranthene (Giraud *et al.*, 2001). Two beds were operated in series, with a total detention time of three days. The inlet fluoranthene concentration was set at 6,660 mg/L, and no PAHs were detected in the wetland outflows. A total of 40 fungal species (24 genera) were isolated and identified from samples (gravel and sediments) from the test wetland and a control wetland. Fluoranthene was degraded efficiently by 33 species whereas only two species were able to remove anthracene by over 70%.

Salmon *et al.* (1998) evaluated removal of total hydrocarbons in FWS mesocosms in France. The bed was planted with *Typha latifolia*, and during the experiment, natural development of *Lemna minor* occurred. Constructed wetlands removed 90% of total hydrocarbons.

## 13.2 CHLORINATED HYDROCARBONS

### Chlorinated Benzenes

Chlorobenzenes were and are used in the production of phenol, aniline, and DDT. Mono-, di-, and trichlorobenzenes are used as solvents (Grayson, 1985). Various benzene hexachloride isomers are used as broad-spectrum insecticides, including Lindane™. Mono-, di-, and trichlorobenzenes are resistant to photo-oxidation, and to both aerobic and anaerobic degradation in purely aquatic environments, with estimated half-lives of up to 6 to 24 months (Howard *et al.*, 1991). However, wetland environments are quite different, because of the close interactions with plants and soils. The major routes for removal of chlorobenzenes from wetland waters are: biological (microbial) degradation, sorption, volatilization, and plant uptake.

### Biodegradation

In general, chlorinated hydrocarbons may be dechlorinated under anaerobic conditions, and the responsible microbial consortia have been identified (van Eekert and Schraa, 2001). Reductive dechlorination of chlorobenzenes occurs via an anaerobic sequential pathway in wetland soils and sediments. Jackson and Pardue (2000) established that the dichlorobenzene (DCB) formed monochlorobenzene (MCB), which subsequently mineralized:

$$\mathrm{DCB} \rightarrow \mathrm{MCB} \rightarrow \mathrm{CO_2} + \mathrm{H_2O} + \mathrm{Cl^-} \qquad (13.1)$$

Their study showed that MCB produced reached half of the initial DCB concentration in 30 days, and was accompanied by the formation of methane. In separate experiments, Jackson and Pardue (2000) recovered 13% of $^{14}$C-MCB as $^{14}CO_2$ in a surface sediment modulated decomposition.

### Sorption

Chlorobenzenes sorb strongly to both organic and inorganic wetland substrates (Pardue *et al.*, 1993). Shin and Pardue (2000; 2002) showed that there are both reversible and irreversible portions of the overall sorption. For several sediment and soil samples, the reversible part ranged $1.88 \leq \log_{10}K_{OC} \leq 2.88$, while the irreversible part ranged $3.75 \leq \log_{10}K_{OC} \leq 5.55$. Thus, partitioning to organics is very strong, and dominated by irreversible binding.

Suspended particulate matter forms a mobile substrate for partitioned chlorobenzenes (Shugui *et al.*, 1994).

The FWS wetland biogeochemical cycle creates and processes very large quantities of total suspended solids (TSS), and thus can play an important role in organic chemical cycling and removal in these systems. The wetland environment is further complicated by the presence of large molecules of humic substances, which comprise a good share of dissolved organic carbon. Organic solutes can partition to these dissolved humic substances, thus creating two soluble forms with different chemical characteristics.

### Volatilization

The chlorobenzenes are volatile, and therefore may be easily lost from water, especially shallow water bodies, such as free water surface wetlands. Of direct interest are the estimates, based on wetland data, of Keefe *et al.* (2004a) for a FWS wetland in Arizona. Values were determined of $K_w = 0.011$ m/hr (100 m/yr) for chlorobenzene, and $K_w = 0.008$ m/hr (70 m/yr) for 1,4 dichlorobenzene. These are relatively high rates, compared to other pollutants treated in FWS wetlands.

### Plant Uptake

Plants are capable of taking up organic chemicals (Trapp and Matthies, 1995), and processing them in a number of ways. They may be carried through the plant into the atmosphere via the transpiration flux, metabolized, or accumulated in plant tissues. For example, Leppich *et al.* (2000) found up to 100 mg/kg of various chlorobenzenes in black willow (*Salix nigra*) bark, and up to 25 mg/kg dw in leaves. The willows were growing in a contaminated swamp site, with large concentrations of di-, tri-, penta-, and hexa-chlorobenzenes. Leppich *et al.* (2000) concluded that partitioning of these organics to the plants formed an important part of the site model.

### Overall Removal Coefficients

Despite the investigations detailed above, there is no reported treatment wetland that has specifically been designed to target chlorobenzenes. Therefore, results from several treatment technologies are examined here to gain some insight as to the anticipated rates of removal to be expected in wetlands.

#### *Wetlands*

Keefe *et al.* (2004a) calculated removal rate coefficients from a FWS dataset to be 135 m/yr for chlorobenzene, and 67 m/yr for 1,4 dichlorobenzene. The wetland was a 1.4-ha free water surface system of depth about two feet. The detention time was 3.9 days. These results correspond to a 67% reduction of 1,4 dichlorobenzene from inlet to outlet. Keefe *et al.* (2004a) attributed the reduction to volatilization, but concluded that theoretical predictions were only good for order-of-magnitude estimation.

Braeckevelt *et al.* (2006) studied monochlorobenzene reduction in a pilot-scale horizontal subsurface flow wetland constructed of local soil materials. Contaminated groundwater containing up to 22 mg/L of monocholorobenzene was added to the system at a hydraulic loading rate of 2.3 cm/d. Chorobenzene reductions of up to 77.1% were observed in the system. Monochlorobenzene reductions were highest in the upper soil layer, possibly due to volatilization, and decreased to 37.1% at the bottom of the wetland bed (0.5 m). Enrichment of $^{13}C$ and low dissolved oxygen concentrations suggest that reductive dehalogenation under anaerobic conditions was the dominant removal mechanism.

## Chlorinated Ethenes

Perchloroethylene (PCE) and trichloroethylene (TCE) are solvents that saw extensive use for metal cleaning and other applications in previous decades. At many locations, these materials found their way into groundwater, creating hazardous waste conditions, because of concern due to their carcinogenic properties. Wetlands provide environments for several mechanisms of removal of chlorinated aliphatic organics, including sorption, volatilization, reductive dechlorination, direct biological oxidation, co-metabolism, and plant uptake and metabolism (Pardue *et al.*, 1993; Parkin, 1999; Pardue *et al.*, 2000).

Kassenga (2002) conducted continuous vertical flow column and wetland microcosm studies to investigate the attenuation potential of chlorinated volatile organic compounds. Calibrated simulations indicated that removal of TCE in constructed wetland columns was controlled by biodegradation whereas both sorption and biodegradation were important natural wetland columns. Kassenga *et al.* (2003) evaluated the removal of *cis*-1,2-dichlorethene (*cis*-1,2-DCE) in upflow wetland mesocosms planted with *Scirpus americanus*. The results confirmed that biodegradation was occurring in the system, and sand, peat, and Bion soil mixture had greater degradation rate than the sand and peat mixture.

Lorah *et al.* (1997; 2002) observed complete removal of TCE and daughter products as contaminated water moved upward through peat to the surface. Reducing conditions were present in the peat, and both methanogenic and iron-reducing zones were identified. This important study provided the impetus to examine the future role of natural and constructed wetlands in the remediation of TCE.

A former TCE recycling plant is now the site of a city park in New Brighton, Minnesota. A TCE plume in a surficial aquifer discharges into the wetland of an adjacent lake (Bankston *et al.*, 2002). Transect studies showed TCE in monitoring wells just upgradient from the wetland, and to a lesser degree in the fringe of the wetland. The anaerobic degradation product of TCE, *cis*-1,2-DCE, was detected in the aquifer and the wetland. It was hypothesized that the indigenous cattail (*Typha latifolia*) assisted in phytoremediation. Accordingly, microcosm studies were performed to determine the fate of the removed TCE. The recovery of $^{14}C$ totaled 94.1%, of which 46.8% was volatilized, most likely as [$^{14}C$] TCE because it was added to the microcosms by surface application. Plant tissue contained 38.2% of the $^{14}C$; 5.3% was present as [$^{14}C$] $CO_2$, and 3.7% was recovered from the

**TABLE 13.4**

| | Annual | Winter | Spring | Summer | Autumn |
|---|---|---|---|---|---|
| HLR (cm/d) | 1.00 | 1.14 | 1.39 | 0.85 | 0.60 |
| T (°C) | 11.9 | 1.0 | 12.4 | 23.6 | 12.7 |
| TCE $C_i$ (μg/L) | 726 | 726 | 726 | 726 | 726 |
| TCE $C_o$ (μg/L) | 37 | 87 | 25 | 18 | 21 |
| cis-1,2-DCE $C_i$ (μg/L) | 472 | 472 | 472 | 472 | 472 |
| cis-1,2-DCE $C_o$ (μg/L) | 44 | 65 | 21 | 46 | 46 |
| VC $C_o$ (μg/L) | 5.8 | 5.4 | 1.6 | 8.5 | 7.6 |

*Note:* Inlet concentrations are average undiluted plume values.

soil and water. This data suggested that natural attenuation is a potential bioremediative strategy for TCE-contaminated wetlands.

Given that natural wetlands contribute to reduction of TCE, the next logical step is the reconstruction of former wetlands that are positioned in the flow path of a contamination plume. Richard *et al.* (2002; 2003) filled and planted a dredged channel that was conveying TCE from a contaminated site to a lake. In this case, an aquatic feature was converted to wetland to aid in treatment. This Minnesota project was completed in 2000.

In other cases, terrestrial landforms may be converted to constructed treatment wetlands to provide reductions in TCE. The Schilling Farm Project at Hillsdale, Michigan, intercepts a TCE plume for treatment in a constructed FWS wetland, built in a former corn field. The wetland system is made up of four treatment cells in parallel (see Figures 4.21 and 4.26). The two large central cells were sited to intercept the plume, and the two small flanking cells were added to ensure the full capture of that plume. Groundwater moves down a slight incline into a 4-m deep capture trench, designed to intercept approximately the top 2 m of the underground flow. This trench is filled with coarse rock to eliminate safety hazards and control rodent problems. The water flows upward and out across the FWS wetland cells, carrying TCE and DCE into the wetlands. During passage through the wetland, TCE undergoes reductive dechlorination to DCE and then to vinyl chloride (VC) in anoxic zones, and these are further degraded to carbon dioxide and water in aerobic zones. There is also volatilization of VC, and to a lesser extent DCE and TCE. Water is collected in rock-filled trenches, approximately 1 m deep, at the downstream end of all four cells. These four outflows are metered, and merged to form a single project outflow for compliance monitoring. Additionally, another independent rock-filled trench is positioned across the entire downstream end of the four cells, which is drained via perforated pipe into the compliance outflow. The purpose of this trench is to capture waters that may pass totally underneath the treatment wetland.

Control of this wetland system is solely by means of setting water levels in each of the four cells, by use of the weir settings in the outlet structures. It is totally passive, with no pumps, and runs year-round in a cold climate. Therefore, water level control must compensate for ice formation. The correct operating strategy is the subject of ongoing investigations. Herbivory and short-circuiting were created by muskrats (*Ondatra zibethicus*), necessitating removal of both the animals and their habitat, by filling trenches with large rock, and by fencing the wetland.

Table 13.4 shows the performance results for the system for 88 of the 95 months of operation, October 1998 through September 2005. Figure 13.2 shows performance for October 2003 through September 2005, respectively. The first seven months were a dormant period for vegetation planted in autumn 1998, which remained sparse for that period. Effluent standards for TCE (limit 150 μg/L) were met in 84 of 88 months after startup. Exceedances for VC (limit 13 μg/L) tend to occur in late summer, when wetland surface flow contributes little to the outflow.

In summary, these projects all utilize the characteristics of wetlands to reduce TCE. Research work continues at the time of this writing at Wright–Patterson Air Force Base in Ohio (Entingh, 2002; Blalock, 2003). The addition of recycle in 2007 has eliminated VC from the outflow.

## 13.3 ORGANIC CHEMICALS

### Explosives

It has been estimated that approximately 100 military bases and explosives manufacturing facilities have soil and/or groundwater contaminated with munitions (Medina *et al.*, 2000). Studies have shown that plants are capable of transforming 2,4,6-trinitrotoluene (TNT) without microbial contribution, but very little accumulation of TNT has been found in plant material. Therefore, plant-enhanced degradation, or phytoremediation, of TNT by aquatic macrophytes has been proposed as a promising groundwater treatment process.

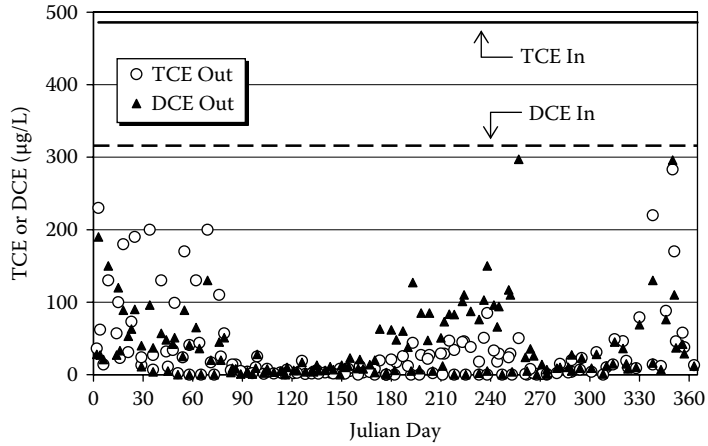

**FIGURE 13.2** Annual pattern of treatment of TCE and DCE in the Schilling Farm wetland system. The inlet concentrations have been adjusted for dilution with clean groundwater entering the flank cells. Winter conditions provide lesser treatment. There is a second period of lesser treatment in late summer and autumn, which is occasioned by very low surface flows and dominance of underground flows.

TNT is a reactive molecule that biotransforms readily under both aerobic and anaerobic conditions to give aminodinitrotoluenes (Brannon and Myers, 1997; Hawari *et al*., 2000; Xiang, 2001; Esteve-Nunez *et al*., 2001). The resulting amines biotransform to give several other products, including azo, azoxy, acetyl, and phenolic derivatives, leaving the aromatic ring intact. Little or no mineralization is encountered during bacterial or wetland treatment. The nonaromatic cyclic nitramine explosives hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) and octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX) lack the electronic stability enjoyed by TNT or its transformed products. Therefore, an enzymatic change on one of the N-$NO_2$ or C-H bonds of the cyclic nitramine could lead to a ring cleavage, and subsequent mineralization.

Medina *et al*. (2000) performed a series of batch-scale experiments to assess the engineering kinetics of phytodegradation of TNT under a variety of operational conditions. Parrotfeather (*Myriophyllum aquaticum*) was hydroponically grown in laboratory microcosms. TNT was degraded according to a near-first order model in vegetated microcosms, but not in unvegetated systems (Figure 13.3). Measurements at varying plant densities indicated that rate constants increased with increasing plant abundance. Removal rate constants also increased with increasing temperature from 2 to 34°C, leveled off between 34 and 43°C, and at 54°C, no activity was found. This pattern is also found for enzyme kinetics, in which rates increase until the enzyme denatures. Plants appeared healthy up to 34°C, but wilted at 43°C. Plants incubated at 54°C were dead by the end of the experiment. The modified Arrhenius temperature coefficient was 1.093 for water temperatures between 2 and 30°C. Hughes *et al*. (1997) found that Eurasian water milfoil (*Myriophyllum spicatum*) degraded TNT to aminonitrotoluenes, whereas unvegetated controls did not.

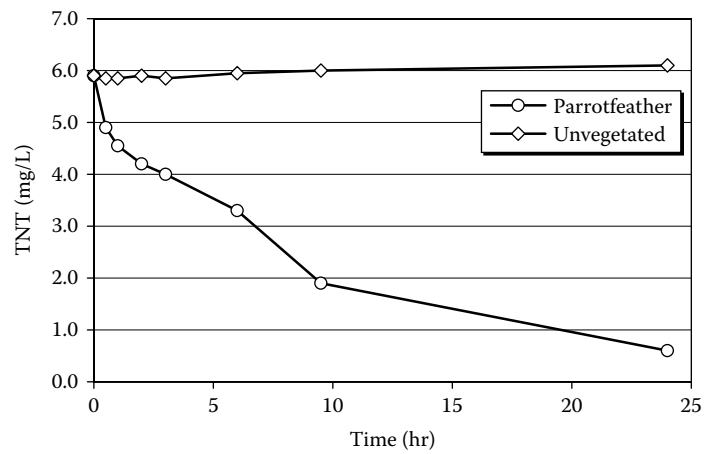

**FIGURE 13.3** Disappearance of TNT in batch microcosms. The vegetated system points represent the mean of five replicates. The half-life of TNT was about seven hours. (Data from Medina *et al*. (2000) *Water Research* 34(10): 2713–2722.)

**TABLE 13.5**
**Batch Kinetics of TNT Reduction for Several Submersed Species with Data Including Two Different Plant Densities**

| Scientific Name | Common Name | $k_A$ (m/yr) |

*Source:* Data from Best *et al.* (1997a) *Screening aquatic and wetland plant species for phytoremediation of explosives-contaminated groundwater from the Iowa Army Ammunition Plant.* Technical Report EL-97-2, U.S. Army Corps of Engineers Waterways Experiment Station: Vicksburg, Mississippi.

Zoh and Horne (2000) also performed a series of batch-scale experiments. Utilizing straw, cattail, and bulrush litter in water, they found no degradation without litter, and first-order behavior in the presence of litter. Sorption and $^{14}C$ studies indicated that removal was due to initial sorption followed by degradation to aminonitrotoluenes. Volumetric rate coefficients ($k_V$) translate to areal rates ($k_A$) on the order of 25 m/yr for TNT, regardless of litter type. A modified Arrhenius temperature coefficient ($\theta$) of 1.17 fit the observed difference in rates at 10 and 20°C.

The ability of ten species of submerged aquatic to phytoremediate explosives-contaminated groundwater was investigated by Best *et al.* (1997a). Phase I of this project provided for laboratory-scale plant screenings to evaluate locally adapted aquatic and wetland species for their differential ability to diminish levels of TNT and RDX. These were evaluated under hydroponic batch conditions. Analysis of the data according to a batch first-order areal model shows remarkable similarity among species (Table 13.5).

Best *et al.* (Best *et al.*, 1999a,b) reported that per unit of mass, uptake of TNT was higher in submerged (*Elodea canadensis, Potamogeton pectinatus, Heteranthera dubia, Myriophyllum aquaticum*) rather than emergent species (*Acorus calamus, Phalaris arundinacea, Scirpus cyperinus*) and biotransformation of TNT had occurred in all plant treatments after a seven-day incubation in 1.6 to 3.4 mg/L TN. TNT declined less with substrates, and least in controls without plants. Mineralization to $CO_2$ was very low, and evolution into C-volatile organics negligible. RDX disappeared less rapidly than TNT from groundwater.

Cattails (*Typha angustifolia*) in FWS mesocosms were used to test treatment of mono-, di-, and trinitrotoluene mixtures at the Volunteer Army Ammunition Plant, Tennessee (Best *et al.*, 2000; 2001). Rate coefficients (Table 13.6) ranged from 16 to 45 m/yr. The potential contribution of photodegradation was determined by shielding nonplanted mesocosms from UV in sunlight. Radiation accounted for 30% of TNT, 60% of DNT, and 10% of NT removal in the absence of plants.

**TABLE 13.6**
**Continuous-Flow Kinetics of Nitrotoluenes Reduction for *Typha angustifolia* Mesocosms**

| Contaminant | Inlet (mg/L) | Outlet (mg/L) | Percent Removal (season) | Areal Rate Constant (m/yr) |
|---|---|---|---|---|
| Trinitrotoluene | 2.73 | 0.30 | 79% | 31 |
| 2,4-dinitrotoluene | 16.66 | 6.00 | 58% | 16 |
| 2,6-dinitrotoluene | 5.17 | 1.40 | 61% | 17 |
| 2 nitrotoluene | 42.64 | 2.20 | — | 45 |

Means and Hinchee (Eds.), Wetlands and Remediation: An International Conference; Battelle Press: Columbus, Ohio, pp. 365–374; and Best *et al.* (2001) *Water Science and Technology* 44(11–12): 515–521.

*Note:* Season refers to June through October.

However, planted mesocosms had higher removal rates than unshielded unplanted systems (Best *et al*., 2001).

The U.S. Army Corps of Engineers constructed treatment wetlands with the purpose of containing and treating residual TNT (2,4,6-trinitrotoluene) and RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine) contamination at the Iowa Army Ammunition Plant (Thompson *et al*., 2003). Screening studies established the relative capabilities of various plants to reduce explosives found at the site (Best *et al*., 1997a,b). Demonstration studies were then conducted to establish vegetative uptake, fate, and toxicity of TNT and RDX. Results from two years of testing indicated that TNT concentrations were undetectable in surface water or plant tissues. Concentrations of RDX in wetland surface waters were below the U.S. EPA human health advisory level of 2 µg/L and were undetectable in plant tissues during the summer months.

Based upon these results, and other wetland design considerations, testing then proceeded to pilot scale. Behrends *et al*. (1997) reported that a FWS wetland system of two cells, each 9.4 × 24 meters, performed poorly for TNT and RDX removal at Milan, Tennessee. This was attributed to an inability to maintain the vegetation, parrotfeather (*Myriophyllum aquaticum*), in the face of tadpole herbivory and hailstorms. In contrast, a two-cell SSF system (473 $m^2$ total) performed well for TNT, RDX, and HDX. Cold weather limited the gravel-based system's ability to reduce the total nitrobodies below the 50 ppb demonstration goal (Sikora *et al*., 1997).

Analysis indicated that the full-scale system could be economically resized to overcome the winter performance deficit by increasing the retention time from 10–14.5 days (ESTCP, 1999).

Xiang (2001) tested VF wetland mesocosms, in series, the first two planted with *Typha* spp., and the last three with *Scirpus lacustris*. Virtually all of the TNT was removed in the first two cells, at a combined detention time of 2.4 days. In radiolabelled experiments, less than 0.1% of the radioactivity added to the system as TNT was present in the metabolically produced $^{14}CO_2$. Consequently, mineralization was not an important pathway. Small amounts of mono- and dinitrotoluenes were detected, indicating some utilization of a pathway that removed $NO_2$ groups. Sorption experiments showed negligible binding to the media. Planted cascades removed 80% of the TNT, while unplanted removed only 23%. It was noted that photodegradation might have contributed to the removals in the planted tank. Only small amounts of TNT and aminodinitrotoluene were found in plants in the first tank, about 1.0 mg/kg of TNT in shoots, and 0.25 mg/kg (dry weight unless otherwise noted) in roots. Slightly greater amounts of aminodinitrotoluene were found, 1.8 mg/kg in stems and 0.8 mg/kg in roots. Xiang (2001) found enhanced removal with the addition of a carbon source (molasses or sucrose).

## De-icing Compounds

The waste generated by aircraft de-icing operations represents a threat to the environment arising from the high biological oxygen demand of commonly used propylene and ethylene glycols (Castro *et al*., 2004). Other candidates for de-icing include urea, which can also pose a pollution threat to nearby receiving waters (Thoren *et al*., 2003). In temperate climates, pollutant loadings are seasonal, and generally occur from November to April.

Both glycol and urea are biodegradable. Microbial metabolism of glycol within a wetland system utilizes the material as it would other forms of $BOD_5$ (see Chapters 8 and 13). Degradation of urea follows patterns established for other species of nitrogenous compounds (see Chapter 9). However, pollutant loads occur at cold temperatures, which minimize some biological processes, notably those for nitrogen reduction. The threat of bird–aircraft strikes indicates the use of SSF wetlands in many cases.

The applicability of treatment wetlands for reducing the concentration of ethylene glycol is being tested or implemented at several airports, including Pearson Airport in Toronto, Edmonton International Airport in Alberta, Heathrow Airport in London, and Westover Air Reserve Base in Massachusetts. Constructed wetlands are also in use for nitrogen de-icer control at Kalmar Airport, southeast Sweden. Pilot wetland testing has occurred at the Airborne Express airport in Wilmington, Ohio (Naval Facilities Engineering Service Center and Wetland Solutions, Inc., 2004b); Zurich, Switzerland (Richter *et al*., 2004); and Schonefeld Airport in Berlin, Germany (Abydoz Environmental, Inc., 2005).

In 2000, the Greater Toronto Airports Authority (GTAA) constructed the first full-scale vertical flow treatment wetland in Canada for reduction of ethylene glycol in stormwater (Flindall *et al*., 2001). The facility consists of a two-cell treatment wetland preceded by a sedimentation forebay. The wetland facility collects water discharged from a drainage area of approximately 382 hectares, comprised of terminal aprons, taxiways, and runways where aircraft receive glycol de-icing compounds. The facility provides 24 to 48 hours of retention to attenuate storm flows and provide removal of suspended sediment. Cell 1 of the wetland is a 0.42-ha VF system, and Cell 2 is a 1.38-ha FWS system, and is primarily intended for storage of runoff rather than treatment. Both treatment cells were planted with *Phragmites australis*. A key component of the facility is the sediment forebay, which provides temporary storage of flows entering the facility. The forebay allows removal of some of the sediment load in the runoff, which is necessary to prevent blockage of the vertical flow reed bed. Additionally, forebay storage allows intermittent dosing of the vertical flow reed bed, which is an important design feature of the vertical flow system.

Urea (chemical formula: $NH_2$-CO-$NH_2$) is used as a de-icing agent at Kalmar Airport, southeast Sweden (Thoren *et al*., 2003). To reduce stream transport of nitrogen from airport, agricultural, and other diffuse sources to the Baltic Sea, a FWS wetland system was constructed in 1996. The 18-ha wetland consists of four ponds (1.5 m deep), which are dominated (75%) by the submerged plant *Elodea canadensis*, separated by shallower water (0.5 m deep) dominated by common reed (*Phragmites australis*). The theoretical water retention times for the wetland are 5.3 and 2.4 days during

average and high water discharges, respectively. Annual wetland retention of TN varied in the range of 6 to 36% during 1998 to 2001. During airport de-icing, January through March 2001, 660 kg urea-N out of 2,600 kg applied urea-N reached the wetland, and approximately 40% of the incoming urea-N was eliminated in the wetland system at air temperatures around 0°C.

The Edmonton Airport in Canada has a subsurface wetlands treatment facility to treat stormwater contaminated with ethylene and propylene glycol from the de-icing activities that occur at the airport (Higgins and Maclean, 2002; Edmonton Airports, 2003). The HSSF facility is comprised of six trains of two cells each. The 4.5-ha wetlands started operating in 2001. Cells are vegetated with cattails (*Typha* spp.), with the exception of one cell being planted with reed canary grass (*Phalaris arundinacea*). The new system integrates the stormwater collection system serving the apron area by channeling the fluids into a 300,000 cubic meter detention facility, prior to the wetlands. Treated water flows out of the area to surface receiving waters. The cost to construct the wetlands was CDN $2 million.

A 0.24-ha HSSF wetland system was installed at the Westover Air Reserve Base in Chicopee, Massachusetts to demonstrate the treatment of stormwaters from on-site de-icing operations (Karrh *et al.*, 2002; ESTCP, 2004; Naval Facilities Engineering Service Center and Wetland Solutions Inc., 2004a). The apparent hydraulic residence time in the bed was estimated at 1.3 to 1.9 days. Event mean flow through the wetland was 278 $m^3$/d for an average hydraulic loading rate of 11.4 cm/d. Peak inflow BOD concentrations ranged from 974 to 15,098 mg/L during ten de-icing events in 2002, and these were reduced by more than 50% in 5 of the 10 events. Event flow-weighted mean concentrations for BOD were 1,183 and 937 mg/L at the wetland inflow and outflow for an estimated mass reduction of 21%. Overall averages for the season are given in Table 13.7. The estimated mass removal rate was 286 kg/ha·d. The system was overloaded by a factor of four due to extreme conditions during the winter of testing.

London's Heathrow airport began pilot testing of wetlands for glycol removal in 1994 (Chong *et al.*, 1999; Revitt *et al.*, 2001). Surface and subsurface flow systems and floating rafts were operated, with detention times of less than one day. Modest reductions (approximately 30%) of various glycols were achieved (Worrall *et al.*, 2002). Subsequently, a 1.2-ha floating raft wetland and a 2.08-ha HSSF were built, and planted with *Phragmites*. The design detention times were both just over one day (Revitt *et al.*, 2001; Richter *et al.*, 2003). Evaluation of performance is in progress, with a five-year data acquisition period (Richter *et al.*, 2003; Richter *et al.*, 2004). The system responds to pulse events by delaying and reducing the incoming COD peak (Figure 13.4).

The Buffalo–Niagara International Airport (BNIA) has studied the use of aerated vertical flow wetlands for glycol removal. A pilot-scale system was constructed to determine necessary design parameters (Higgins *et al.*, 2006a). A volumetric rate coefficient of $k_v = 3.3\ d^{-1}$ was observed for reduction of glycol-produced COD. This rate coefficient was developed based on a hydraulic flow model of two tanks in series (2TIS) and an operating temperature of 4°C.

## Phenols

Phenol is a compound of considerable industrial importance and a frequent pollutant in industrial effluents. It also has been studied for over four decades in the wetland treatment context. Early work at the Max Planck Institute in Krefeld, Germany, focused on SSF microcosms with bulrushes (*Schoenoplectus* (*Scirpus*) *lacustris*) and resulted in a series of publications on removals and effects on plant physiology (for example, Seidel, 1966). That data showed degradation rates of 5 to 20 g/$m^3$·d, and in some instances, an induction period of one to three days

**TABLE 13.7**
**Summary of Results from the 2002–2003 De-icing Season at Westover Air Reserve Base**

| Constituent | Inlet | Outlet | Percent Reduction |
|---|---|---|---|
| BOD (mg/L) | 2,226 | 2,094 | 6% |
| COD (mg/L) | 1,883 | 1,335 | 29% |
| MeBT (mg/L) | 0.68 | 0.72 | –6% |
| DO (%) | 52.2 | 47.7 | –9% |
| pH (S.U.) | 7.58 | 9.54 | — |
| Redox (mV) | 391 | 172 | –56% |
| Turbidity (NTU) | 5.22 | 4.61 | 12% |

*Note:* MeBT is methyl-1H-benzotriazole, an additive to the de-icing fluid.

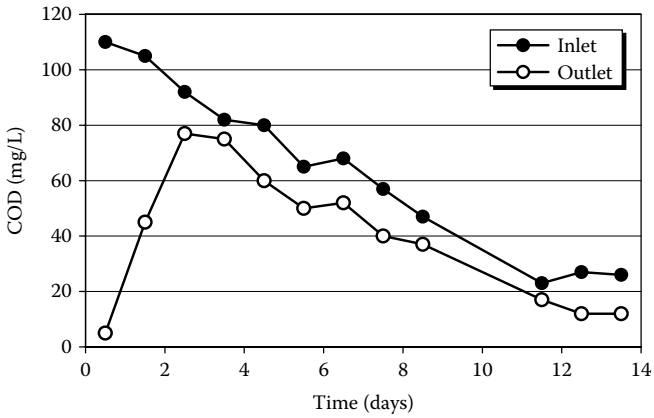

**FIGURE 13.4** Time series of COD into and out of the Heathrow reedbeds. (Data from Richter *et al.* (2004) *Treatment performance of Heathrow constructed wetlands*. Liénard and Burnett (Eds.). Proceedings of the 9th International Conference on Wetland Systems for Water Pollution Control, 26–30 September 2004; Association Scientifique et Technique pour l'Eau et l'Environnement (ASTEE), Cemagref, and IWA: Avignon, France, pp. 125–132.)

before reduction commenced. The Seidel data may be modeled by a zero-order reaction. The zero-order rate constant for the Krefeld data was $k_0 = 81 \pm 18$ mg/d in summer, and 34 ± 10 mg/d in winter. The corresponding modified Arrhenius temperature coefficient is $\theta = 1.083$.

Wolverton and McDonald (1981) evaluated removal of phenol in experimental mesocosms filled with 16 cm of 2.5–7.5 cm diameter railroad rocks covered with 5 cm deep of 0.25–1.3 cm diameter pea gravel. The mesocosms were planted with *Phragmites australis* and *Typha latifolia*. After 24 hr the concentration of phenol dropped down from 104 to 7 mg/L in *Phragmites* unit whereas in *Typha* unit the phenol concentration dropped down from 101 to 17 mg/L during this time. After 48 hours the respective phenol concentrations were 4 and 7 mg/L. Phenol concentration in unplanted control unit dropped from 100 to 40 and 28 mg/L after 24 and 48 hours, respectively.

Microcosm research on FWS wetlands with cattails produced similar results (Kadlec and Srinivasan, 1995). The average value of the zero-order rate constant was 76 ± 33 mg/d (loss = 0.55 g/m$^2$·d) for vegetated microcosms, and 108 ± 26 mg/d (loss = 0.78 g/m$^2$·d) for unvegetated microcosms. The sizes of these microcosms were comparable to those at Krefeld. There was little selective loss of phenol from microcosms containing only water and the phenol dose. This study showed no effect of water depth, but a slight effect of soil type, with more organic content promoting phenol removal. There were higher evaporative losses in summer, with phenol being lost with water at the bulk water concentration. There was not significant evaporative concentration or selective stripping of phenol.

Polprasert *et al.* (1994; 1996) operated both FWS microcosms and a FWS pilot wetland in Bangkok, Thailand, for phenol reduction at high strength. Nearly complete removal of phenol was measured for loading rates up to 300 kg/ha·d. Some phenol was volatilized; some was found in the roots of the cattails. Removal followed a first-order model, with rate constants on the order of 100 m/yr. About one third of the removal was reported due to volatilization, and the remaining two thirds due to biodegradation, plant uptake, and sorption.

Abira *et al.* (2005) studied duplicate pilot scale subsurface flow wetlands for phenol reduction, with two cells each of unvegetated gravel, *Cyperus papyrus, Phragmites mauritanius,* and *Typha domingensis*. Removals in the 15-month study ranged from 50–75%, with higher reductions for ten days detention compared to five days. Unvegetated cells performed nearly as well as vegetated cells. The paper mill wastewater had high COD (300–600 mg/L), but only about 1 to 3 mg/L of phenol.

The Jinling Petrochemical Company, Beijing, China, reported reductions in several parameters, including phenol, in water hyacinth wetlands (Tang and Lu, 1993). Two wetlands, 25 m × 150 m × 1 m deep, received wastewater at detention times ranging from 2 to 12 days. One channel was 80% covered by *Eichhornia crassipes*, the other was unvegetated. The calculated rate constants for phenol removal were 150 m/yr for the vegetated system, and 76 m/yr for the unvegetated system.

Dong and Lin (1994a) report data and models for a research facility polishing secondarily treated petrochemical wastewater in six wetlands and six ponds comprising a 1.5-ha test unit at Yanshan Petroleum, in Niukouyu, China. This research facility tested a variety of plants and soil substrates over the seasons. Phenol was reduced by 28–37%, with higher values in warm months. Dong and Lin (1994b) then described a full-scale facility, built in 1990, consisting of 50 ha of wetlands and ponds treating 100,000 m$^3$/d. Average inflow and outflow phenol concentrations were 27 mg/L and 10 mg/L, respectively, with a mean removal efficiency of 63%. The full-scale facility had a phenol rate constant removal rate coefficient of 100 m/yr.

The treatment system at Amoco Mandan, North Dakota, is comprised of an API separator, lagoon, and a series-parallel set of FWS wetlands. Approximately 5,700 m$^3$/d of process water is directed to an API separator for primary treatment, and then passed through the oxidation lagoon for secondary treatment. Process wastewater and stormwater are then directed through an 0.8-km earthen canal to 6 of the 11 cascading ponds (16.6 ha) before eventual discharge from Dam 4 to the river. The remaining five ponds (19.1 ha) are reserved for wildlife. (Litchfield and Schatz, 1989; Litchfield, 1990; Litchfield, 1993). Removal of phenol amounted to 94% with an average outflow concentration of 5 mg/L.

Microcosms and pilot scales display removal rates that are greater than those observed in some full-scale field situations. For instance, the Mandan, North Dakota, wetlands do not reduce phenols to zero, as they should, because of a detention time on the order of months (Litchfield and Schatz, 1989; Litchfield, 1990; Litchfield, 1993). Further, the loss rates for the Jinling project are also much smaller than would be predicted from the microcosm data (Tang and Lu, 1993).

Both of these systems receive phenol at concentrations much lower, by a factor of more than 100, than the lab studies. It is clear that microcosms are not adequate for determination of design parameters for phenol. For instance, the areal mixing efficiency of the wetland may be an important determinant of trace amounts of phenol in the effluents from pilot and full-scale wetlands.

The Listowel studies included the monitoring of phenols in five wetlands for four years (Herskowitz, 1986). These substances were present in the aeration cell and in the lagoon that provided the wetland influent, at concentrations on the order of 10 µg/L. Winter levels were higher than summer, and the wetlands did not provide removal at these low concentration levels.

### Surfactants

Linear alkylbenzene sulfonate (LAS) is a widely used synthetic surfactant for domestic detergents. This group of substances is amenable to phytoremediation using both terrestrial and wetland plants (Schwitzguebel *et al.*, 2001). Wetland plant detritus is an important source of carbon and energy and offers a large surface area for sorption of dissolved organics. To examine the biodegradation of surfactants by detrital microorganisms, Federle and Ventullo (1990) obtained submerged oak leaves from a laundromat wastewater pond, which were incubated in water amended with $^{14}$C-labeled LAS. Sorption and evolution of $^{14}CO_2$ were followed with time. LAS that was sorbed to the detritus was mineralized without a lag, with a half-life of 12.6 days. This study showed that detritus represents a significant site of surfactant removal in detritus-rich systems.

Barber *et al.* (2001) performed synoptic sampling of several existing treatment wetlands, including analysis for LAS (Table 13.8). Results were mixed, with removal occurring in some, but not all, systems.

Adsorption and degradation were found to both be operative in the wetland and in companion laboratory research (Inaba, 1992). LAS was effectively reduced in a FWS *Typha–Phragmites* wetland. The 474-m$^2$ system treated gray water from a 100-inhabitant community. The calculated plug flow volumetric removal coefficients ($k_V$) for the removal of these surfactants were in the range of 30 to 80 m/yr, depending upon chain length and isomeric form, with greater removal rates for the longer chain lengths. Seasonal dependence was strong, with a temperature factor of $\theta = 1.087 \pm 0.005$ averaged over all forms of the detergent. The inlet concentration totaled about 5 mg/L, and was reduced by over 90% in summer and over 40% in winter at an average hydraulic loading of approximately 5 cm/d. The surfactant partitioned strongly to wetland TSS, with a partition coefficient of 30 L/kg for chain length 11, isomer 5. Values for other forms of the surfactant were higher, ranging up to 520 L/kg for chain length 13, isomer 2. Sorption was not diminished at cold temperatures. Therefore, the sorption capacity and TSS trapping efficiency of the wetland partially offset the diminished degradation during winter.

LAS was investigated in SSF pilot subsurface flow constructed wetlands comprised of eight beds of 55 m$^2$ with different aspect ratios, two water depths and two medium sizes (Huang *et al.*, 2004). The *Phragmites* wetlands treated urban wastewater. Under the most favorable conditions, LAS was biodegraded up to 71%. Shallower water depth (27 cm) was considerably more efficient than deeper (47 cm) for LAS removal. Water temperature has a significant positive effect on the LAS reduction. Biodegradation of LAS was found to occur under both sulfate- and nitrate-reducing conditions. C13 LAS homologues were generally removed in higher extent than the shorter alkyl chain counterparts, thus reinforcing the findings of Inaba (1992).

Del Bubba *et al.* (2000) used a pilot HSSF system planted with *Phragmites australis* to study LAS removal in Florence, Italy. With HLR of 3.7 cm/d the inflow LAS concentrations in unfiltered samples of 278 mg/L and 18.8 mg/L were reduced to 0.18 mg/L and 0.06 mg/L. This resulted in respective removal efficiencies of 99.9% and 99.7%. The authors also pointed out that the biodegradation of LAS homologues increased with increasing carbon atom number: C14 > C13 > C12 > C11.

Kantawanichkul and Wara-Aswapati (2005) reported that LAS inflow concentration of 40 mg/L was reduced by 89% in an experimental HSSF constructed wetland planted with *Typha angustifolia* in Thailand. The highest LAS removal

**TABLE 13.8**
**Results of Synoptic Sampling of Linear Alkylbenzene Sulfonate (LAS) at Several Treatment Wetland Sites**

| Site | Wetland Type | Source Water | Area (ha) | $\tau_n$ (days) | $C_i$ (µg/L) | $C_o$ (µg/L) |
|---|---|---|---|---|---|---|
| Hemet | FWS | Municipal | 10 | 14 | 6.2 | 4.0 |
| Arcata treatment | FWS | Lagoon | 6 | 1 | 0.9 | < 0.1 |
| Arcata enhancement | FWS | Wetland | 12 | 20 | <0.1 | 1.9 |
| Halsey | HSSF | Pulp mill | 0.13 | 2–10 | 10.0 | 11.2 |
| Halsey | FWS | Pulp mill | 0.13 | 2–10 | 10.0 | 3.4 |
| Halsey | FWS | Pulp mill | 0.13 | 2–10 | 10.0 | 7.9 |
| Corvallis | FWS | Dairy | 0.02 | 7 | 92.6 | 1.9 |

was achieved at HLR 15 cm/d while at HLR of 10 cm/d and 20 cm/d the respective removals amounted to 87% and 77%.

Billore *et al.* (2002) operated a 300-$m^2$ SSF wetland, vegetated with *Phragmites karka*, and studied LAS reduction over a 12-month period. Three days' nominal detention provided 43, 61, 76, and 88% reduction of C10, C11, C12, and C13 LAS, respectively, again reinforcing the findings of Inaba (1992).

LAS was monitored for one year at three SSF *Phragmites* reedbed sites in the United Kingdom (Thomas *et al.*, 2003). Hydraulic loadings were 133 cm/d at Brynsiencyn, 14.5 cm/d at Clutton, and 77 cm/d at Rosset; and had average reductions of 57% at Clutton and 55% at the other two sites. The longer alkyl chain homologues were removed to a greater extent.

### Miscellaneous Hydrocarbons

The estrogenic hormones 17-estradiol (E2) and 17-ethinyl estradiol (EE2) have been detected in municipal wastewater effluent and surface waters at concentrations sufficient to cause feminization of male fish (Gray and Sedlak, 2004). These hormones were added to an engineered treatment wetland, and 36% of E2 and 41% of EE2 were removed in 3.5 days' nominal retention time. The observed attenuation was attributed to sorption, followed by biotransformation. Sorption was indicated by the retardation of the hormones relative to a conservative (lithium) tracer. Biotransformation was indicated by elevated concentrations of the E2 metabolite, estrone.

A full-scale FWS treatment wetland has been in operation since 1995 at Quimigal S.A. in Estarreja, Portugal, for reducing organics in the effluent from a sulfanilic acid plant (Haberl *et al.*, 2003) (Figure 13.5).

This wastewater contains nitrobenzene, aniline, and sulfanilic acid. Four vertical flow wetland beds totaling one hectare are operated at a hydraulic loading rate of 2.4 cm/d. Removals were 6 g/$m^2$·d (99%) for aniline, 2 g/$m^2$·d (98%) for nitrobenzene, and 4 g/$m^2$·d (99%) for aniline. *Phragmites* has survived well in this industrial wastewater (Figure 13.5).

*Lemna minor* batch mesocosms displayed half-lives of one to three days for a variety of chlorinated phenols (Tront, 2004; Tront *et al.*, 2004). Rapid sorption (less than five minutes) was observed, followed by first-order removal. There was no clear pattern associated with chemical structure. The microcosm research at Krefeld, Germany, found a surprisingly large amount of pentachlorophenol was absorbed in wetland systems (Seidel, 1976). This result was somewhat unexpected, as pentachlorophenol is used as a wood preservative and does not biodegrade readily.

Polar organics are also degraded in constructed wetlands. Oil sands tailings water contains toxic constituents naphthenic and naphthoic acids (Wood *et al.*, 1995). Cattail mesocosms were used to examine the removal of naphthoic acid in a Kadlec and Srinivasan (1995) project. A lag time was observed before removal started, as observed in the Krefeld experiments with phenol (Seidel, 1976). However, that lag phase was followed by a steady but slow decline of this hydrophilic hydrocarbon. The zero-order rate constant is smaller than for phenol, $k_0 = 0.044$ g/$m^2$·d.

Three polar organic solvents, acetone, tetrahydrofuran (THF), and 1-butanol, were tested in experimental microcosm subsurface constructed vegetated with *Juncus effusus*, *Carex lurida*, *Iris pseudacorus*, *Pondeteria cordata*, and unplanted controls (Grove and Stein, 2005). Ninety percent removal of 1-butanol typically took less than three days, acetone required from 5 to 14, and THF required at least ten days, but was frequently not achieved in 14 days. Removal was typically better in planted replicates, and was slower in winter. Herrera-Melian *et al.* (2004) found essentially complete removal of methanol and formaldehyde in planted and unplanted gravel mesocosms in less than one day. Small SSF wetlands were examined for potential use in reduction of benzoic acid (Zachritz *et al.*, 1996). Planted (*Schoenoplectus* (*Scirpus*) *validus*) and unplanted rock bed mesocosms were fed 5 to 50 mg/L benzoic acid at hydraulic loading rates of 4.9 and 9.6 cm/d. Removals were 30 to 96% in single- and double-tank systems.

Phthalate acid esters (PAEs) are important at many industrial products, and occupy 80–85% of the global plasticizer market (Eljertsson *et al.*, 1997). Studies have shown that PAE contamination in waters, sediments, soils, and biota (Staple *et al.*, 1997) may be toxic to mammals, and aquatic organisms (Adams *et al.*, 1995; Foster *et al.*, 2000; Patyna and Cooper, 2000). In addition, the high bioaccumulation rate and mutagenic action posed a potential threat to human health (Zhou *et al.*, 2005b). Di-*n*-butyl phthalate (DBP) is the most frequently identified PAE in diverse environmnetal symplex, and it has been listed as a priority polutant by the U.S. EPA.

Zhou *et al.* (2005b) evaluated the fate of di-*n*-butyl phthalate in a downflow/upflow constructed wetland in China. The results indicated that on the tenth day, 35% of the DBP in the surface soil and 62% of the DBP in the subsurface soil remained. After 30 days, 95.7% DBP was degraded in the surface soil and 64.2% DBP was degraded in the subsurface soil. The degradation fit a first-order model and the kinetic equations gave rate constants for surface and subsurface soils of 0.50 and 0.17 $d^{-1}$ and the half-life of DBP in the respective soils was 1.4 and 4.0 days.

## 13.4 PESTICIDES

The list of pesticides is very long, and therefore wetland fate and transport studies lag far behind their introduction and use. A distinction may be drawn between the persistent chemicals used prior to the 1950s and the more degradable substances used since that time. Possible retention factors are adsorption to soil particles and organic matter, sedimentation of particles, photodegradation, plant uptake, and biodegradation. The U.S. Department of Agriculture, Agricultural Research Service publishes a compendium of chemical and physical properties of 334 widely used pesticides. Information included in the database focuses on 16 of the most important properties that affect pesticide transport and degradation characteristics (U.S. Department of Agriculture, 2001).

**FIGURE 13.5** Reed bed treating sulfanilic acid at Quimigal S.A. in Estarreja, Portugal.

Many of the "old" pesticides, such as DDT, are very persistent in the environment. These substances partition strongly to particulate matter. It is doubtful that wetlands can provide any very effective mechanism for degradation, but wetlands can act as a trap for the particulates that carry most of the load. Very little data is available for this class of compounds, but Winter (as referenced in Gilges, 1991) reports some success treating PCBs and Lindane™ in SSF systems.

Studies at the Des Plaines, Illinois, treatment wetlands indicated the presence of some of the old "hard" pesticides. The river and wetland sediment samples all contained quantifiable levels of PCBs and some of them also had one or more of the chlorinated pesticides or metabolites DDT, DDE, and dieldrin. All identified species were found in the low micrograms-per-kilogram (parts per billion) range. PCBs were present at the 20–25 µg/kg level in river-borne sediments throughout most of the year, and were found in the sediments of wetland EW3 at less than 10 µg/kg. DDT, together with its decomposition product DDE, were present at approximately 2 µg/kg. Wetland cell EW3 sediments contained similar low levels of DDT and DDE. Dieldrin ranged from 0.1 to 3.0 µg/kg in river sediments and 0.5 µg/kg in wetland sediments.

Modern pesticides degrade more readily, and wetlands have been found to generally reduce levels of many of these compounds. Some of these may also volatilize (Suntio *et al*., 1988). However, the many types of wetlands and modes of operation (continuous flow, event flow, batch) compound with a very long list of pesticides to create very numerous combinations. Examples of studies that partially define treatment expectations are shown in Table 13.9. Perhaps the most commonly used agricultural herbicide is atrazine, and it has therefore been the subject of many treatment wetland studies.

### Atrazine

Atrazine (2-chloro-4-(ethylamino)-6-(isopropylamino)-s-triazine) is a triazine herbicide used to control broadleaf weeds in corn, sorghum, sugarcane, turfgrass, fruits, and vegetables (Kao *et al*., 2001b). Agricultural practices produce runoff with atrazine at concentrations which sometimes peak in excess of the federal drinking water standard (Alvord and Kadlec, 1995; Anderson *et al*., 2002). The atrazine–wetland interaction is very complex, including removal from the area by convection in the water, loss of chemical identity by hydrolysis to hydroxytriazine and dealkylation, and sorption on wetland sediments and litter. Atrazine degrades to trihydroxytriazine in ultraviolet light (Hequet *et al*., 2001), but this process is not rapid in natural waters (Konstantinou *et al*., 2001). Degradation half-lives in various natural waters range from 26 to 65 days (Table 13.10). In the absence of light, aqueous degradation rates are much slower, half-lives greater than 1,000 days, even with added carbon sources (Chung *et al*., 1996; Ghosh and Philip, 2003).

The studies of Seybold *et al.* (2001) illustrate that wetland soils and water, by themselves, are not efficient reducers of atrazine. Soil samples for the study were collected from a tidal freshwater wetland site along the James River in Prince George County, Virginia. The soil was a Levy silt loam with an organic matter content of 14.1%. The half-life was 38 days for atrazine in the anaerobic sediments, and 86 days in the overlying water. Metabolites detected in the aqueous phase above the soil were hydroxyatrazine, deethylatrazine, and deisopropylatrazine. The hydroxyatrazine accumulated in the sediments, and was resistant to further degradation.

Anderson *et al.* (2002) studied the mineralization of atrazine in sediments from a constructed wetland in central Ohio. Atrazine mineralization potential was measured by $^{14}CO_2$ evolution from [U-ring-14C]-atrazine in biometers. The constructed wetland showed 70 to 80% mineralization of atrazine within one month (Figure 13.6). The highest levels of mineralization were localized to the top 5 cm of the wetland sediment.

Weaver *et al.* (2004) pointed out that atrazine dissipated in saturated and flooded soils with a half-time of approximately 23 days, but only 10% of atrazine was mineralized to $CO_2$. The major route of atrazine dissipation was incorporation of atrazine residues into methanol-nonextractable (soil-bound) components, with minimal extractable metabolite accumulation. A mixed-mode extractant (potassium phosphate:aceto-nitrile) recovered greater amounts of $^{14}C$-residues from atrazine-treated soils, suggesting that hydrolysis of atrazine to hydroxylated metabolites was a major component of the bound residues.

Atrazine transport, sorption, and identity loss were studied at the Des Plaines River constructed wetland site, and in accompanying laboratory work. Sorption was effective for soils and sediments, but the more organic materials, such as litter, showed a stronger affinity for atrazine than the mineral base soils of the wetland cells at Des Plaines, Illinois (Alvord and Kadlec, 1995; 1996). Atrazine was found to degrade on those sediments according to a first-order rate law, with a half-life of 40 to 90 days. However, degradation was faster on cattail litter, precluding a rate measurement. The estimated half-life on cattail detritus was on the order of five days.

*Source:* Data from Konstantinou *et al.* (2001) *Journal of Environmental Quality* 30(1): 121–130.

Outflows from the Des Plaines wetland cells contained reduced amounts of atrazine compared to the river water inputs. During 1991, atrazine peaked in the river due to two rain events. Only about 25% of the incoming atrazine was removed in wetland cell EW3, but 95% was removed in wetland cell EW4, due to longer detention time. Either time averaged or dynamic models, both embodying a nonideal mixing model, fit the data for wetland EW3 (Figure 13.7). A removal rate coefficient ($k$) of approximately 14 m/yr calibrated the models to the data.

McKinlay and Kasperek (1999) tested two-stage, recirculating VF mesocosms. Clubrush (*Schoenoplectus* (*Scirpus*) *lacustris*), cattails (*Typha latifolia*), iris (*Iris pseudocorus*), and *Phragmites australis* provided complete removal of atrazine, as did sterile unplanted systems, but rates were slower in the sterile systems. These results confirm those of Stearman *et al.* (2004) for a SSF system treating simazine, another triazine herbicide (Table 13.11). There were not large differences among plant species. Acclimatization was observed in serial dosing, with later atrazine doses removed at higher rates. The fastest removals showed a half-life of about five days.

Moore *et al.* (2000b) dosed atrazine into 0.1-ha FWS demonstration wetlands at Oxford, Mississippi (Rodgers and Dunn, 1992). Between one third and two thirds of the atrazine was removed, with observed half-lives of 16 to 48 days. Atrazine was not detected in plant or sediment samples.

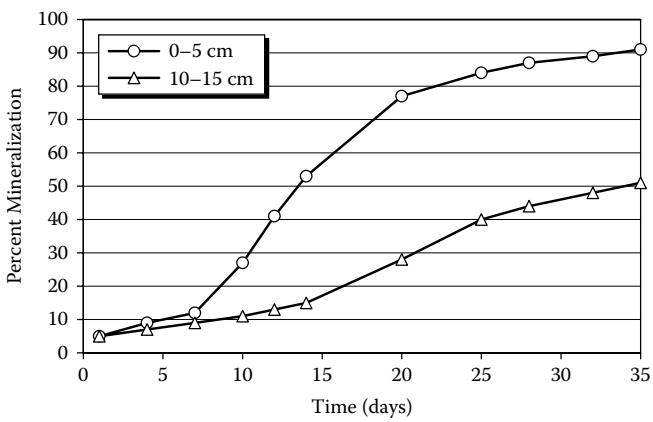

**FIGURE 13.6** The mineralization of atrazine to $CO_2$ in treatment wetland sediments. (Data from Anderson *et al.* (2002) *Water Research* 36(19): 4785–4794.)

Detenbeck *et al.* (1996) performed comprehensive studies on FWS wetlands, for the purpose of determining ecological effects of atrazine on receiving wetlands. Experiments were carried out in the downstream wetland portions of four of the eight outdoor experimental wetland/stream mesocosms located at the U.S. EPA Ecological Research Station in Monticello, Minnesota. Dominant emergent plants consist of cattail (*Typha* spp.), reed canary grass (*Phalaris arundinacea*), and wild rice (*Zizania aquatica*). Dominant submersed vegetation consists of waterweed (*Elodea canadensis*), pondweed (*Potamogeton* spp.), and coontail (*Ceratophyllum demersum*), and floating-leaved vegetation dominated by duckweed (*Lemna minor*). Half-lives of 8 to 14 days were found. Sorption measurements gave isotherms for sediments that agreed with those found by Alvord and Kadlec (1995), but sorption alone predicted half-lives of 36 days. Therefore, other mechanisms were involved in the overall reductions. Ecosystem effects included repression of periphyton, and early senescence of the wild rice.

Runes *et al.* (2001) evaluated the microbial degradation of atrazine in sediments taken from a constructed wetland treating irrigation runoff from a container nursery near Portland, Oregon. To stimulate atrazine-degrading ability in wetland sediments, dried shoot material from cattail was incorporated, and sediment soil was bioaugmented with an atrazine spill-site soil known to contain atrazine-mineralizing microbial populations. The population density of atrazine-degrading microorganisms in unbioaugmented sediment was increased from about $10^2$/g to $10^4$/g by bioaugmentation (1:100 w/w) and increased by another 60-fold ($6 \times 10^5$/g) after incubation with 10 μg/g of atrazine. A high population of atrazine degraders (approximately $10^6$/g) and enhanced rates of atrazine mineralization also developed in bioaugmented sediment after incubation in flooded mesocosms planted with *Typha latifolia* and supplemented with atrazine (3.2 mg/L, 1 μg/g sediment). In the absence of atrazine, neither the population of atrazine degraders nor the atrazine mineralizing potential of bioaugmented sediment increased, regardless of the presence or absence of cattails.

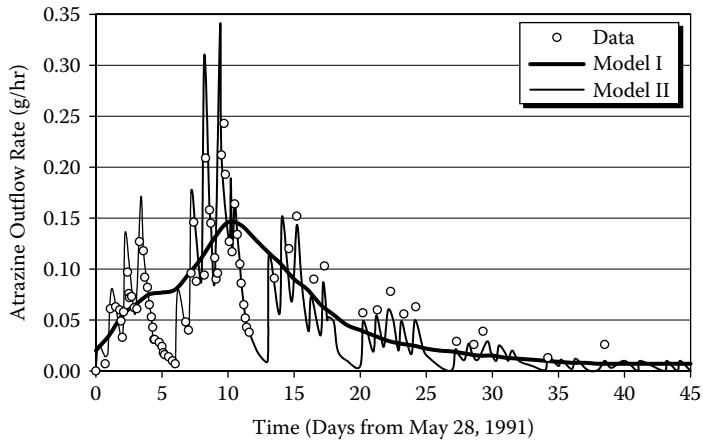

**FIGURE 13.7** Des Plaines wetland EW3 atrazine mass outflow as a function of time. Model I is a steady-flow, tracer-based RTD calculation. Model II is a dynamic simulation which fits the hourly changes in flows of water and atrazine. Both models use the same postulated first-order homogeneous reaction rate constant ($k$ = 14.4 m/yr). (Data from Alvord and Kadlec (1996) *Ecological Modelling* 90(1): 97–107.)

Runes *et al.* (2003) then conducted field experiments in a constructed wetland consisting of five sequential cells, each approximately 3 m × 40 m filled with a silt loam, and planted with *Typha latifolia* at greater than 75% coverage. Water came from a container nursery facility, and was delivered episodically, and dosed with atrazine. Flow events were ranked by intensity (low: less than 250 L/min; medium: 250 to 500 L/min; high: greater than 500 L/min) and frequency of the events (low: fewer than 6 events per week, medium: 6 to 9 events per week, high: greater than 9 events per week). Atrazine treatment efficiency at the outlet of the constructed wetland during a seven-day period ranged from 76 to 82% in 1998 (experiments 1 through 3) and 83 to 84% in 1999 (Table 13.12), but zero treatment was found in one monitoring period. For all experiments, deethylatrazine and deisopropylatrazine accounted for 13 to 21% of the initial application. Hydroxyatrazine was rarely detected in the water.

## 13.5 CYANIDE

Cyanide has an active cycle in nature, where it is present in green plants as part of the methionine cycle (ethylene production), and is therefore prevalent in autumn foliage and ripening fruit (Neuhauser and Swallow, 2005). If not handled properly, black and bing cherries (*Prunus serotina* and *Prunus avium*) and cassava can cause toxicity in humans. There are clear risks associated with cyanide release into the environment because of toxicity. The most toxic species are the free cyanides (HCN and $CN^-$), which are infrequent in uncontaminated soils and groundwater. Iron cyanide is less toxic, and often predominates in environmental samples. The U.S. Environmental Protection Agency and various state agencies regulate cyanide in groundwater and surface water differently. Agencies either choose to regulate the total or the free cyanide form. Because of the potential for photolytic production of free cyanide from iron cyanide, regulatory agencies may consider total cyanide to be indirectly toxic. U.S. EPA criteria for free cyanide include a drinking water standard of 200 µg/L, a freshwater acute criterion of 22 µg/L, and a freshwater chronic criterion of 5.2 µg/L.

Cyanide compounds are classified into those that are readily converted into hydrogen cyanide under acidic conditions, or into CN under basic conditions, and those that are strongly complexed. This Weak Acid-Dissociable cyanide (WAD) is distinguished from strong complexes formed with iron and cadmium, as examples. Total cyanide is the sum of both forms (Kavanaugh *et al.*, 2003).

Cyanide is a pollutant of concern in several situations. Gold mine wastewaters may contain cyanide as the result of the extraction process. Manufactured gas plants historically left residues rich in cyanide and other constituents, which may subsequently leach to natural water bodies. Aluminum processing produces spent pot liners, which, when landfilled, cause similar leaching of cyanide.

| High | Medium | 90 | 69 | 76 |
| Medium | High | 99 | 94 | 80 |
| High | High | 27 | 76 | 83 |
| Low | Low | 55 | 48 | 84 |

*Source:* Data from Runes *et al.* (2003) *Water Research* 37: 539–550.

Both aerobic and anaerobic microorganisms are able to destroy cyanide (Hinchee *et al.*, 1995; Goncalves *et al.*, 1998; Alexander, 1999). Further, plants such as willows are able to ingest cyanide, and metabolically degrade it (Larsen *et al.*, 2004). As a consequence, a natural treatment system that provides maximum opportunity for contact between cyanide-contaminated water and plants and microbes would have strong promise for removal and degradation of cyanide. Treatment wetlands are leading candidates to accomplish these goals.

The processing of cyanide in wetlands is known to involve microbial degradation, volatilization, plant uptake, and complexation with iron (Young, 2003). Additionally, iron cyanide decomposes photolytically to free cyanide (Kim *et al.*, 1998). The aerobic and nutrient-rich environment promotes the growth of the microbial population capable of uptake, conversion, sorption, and/or precipitation of thiocyanate, cyanide, ammonia, nitrate, sulfate, and metals. The microbial removal involves production of ammonia (Goncalves *et al.*, 1998; Akcil, 2003):

$$M(CN)_2 + 4H_2O + O_2 \rightarrow M^{2+} + 2HCO_3^- + 2NH_3 \quad (13.2)$$

$$SCN^- + 3H_2O + 2O_2 \rightarrow SO_4^{2-} + NH_4^+ + HCO_3^- + H^+ \quad (13.3)$$

where $M$ represents a metal species.

Various *Pseudomonas* species are responsible for oxidation of cyanide and thiocyanate. Some of the organisms known to oxidize cyanide include species of the genera *Actinomyces*, *Alcaligenes, Arthrobacter, Bacillus, Micrococcus, Neisseria, Paracoccus*, *Pseudomonas*, and *Thiobacillus* (Akcil and Mudder, 2003).

However, plant uptake is also potentially active (Ebbs *et al.*, 2003; Larsen *et al.*, 2004; Samiotakis and Ebbs, 2004; Larsen *et al.*, 2005). Larsen *et al.* (2005) found Michaelis-Menten kinetics with half-lives of less than a day (batch, with leaves or roots). Samiotakis and Ebbs (2004) tracked the transport and metabolism of two cyanide compounds, potassium cyanide and potassium ferrocyanide, by willow (*Salix eriocephala*), using a hydroponic system that preserved cyanide speciation and solubility. The cyanide compounds were labeled with $^{15}N$ to quantify transport. These analyses revealed that while little free cyanide was detected in the aerial tissues of plants exposed to either of these two cyanide compounds, significant enrichments in $^{15}N$ were observed, suggesting transport and subsequent metabolism of free cyanide as well as ferrocyanide. Yu *et al.* (2005) found temperature to be a factor for uptake by willow (*Salix babylonica*), from which Arrhenius factors of about 1.07 may be calculated. Disappearance rates in solution, using detached leaves, were characterized by half-lives of about eight hours.

These encouraging process studies have led to several treatment wetland projects targeting cyanide reduction. Garcia (2003) found more than 90% reduction in wetland mesocosms (*Typha*). Alvarez *et al.* (2006a; 2006b) experimented with wetland-based passive systems at laboratory and field scale at the site of a gold mine in northern Spain. The pilot-scale system was comprised of aeration cascades and aerobic and anaerobic cells. Results suggest that this technology is able to treat wastewaters with about 25% reduction for dissolved cyanide for nominal detention of six days. The waste strengths in this study were quite high, with total cyanide of about 200 mg/L and dissolved cyanide of 75 mg/L. The removal of WAD cyanide was 99%, from 15 mg/L to 0.14 mg/L. Vegetated cells (*Typha latifolia*) performed only marginally better than gravel control cells.

A large-scale trial was conducted at the Rustler's Roost mine near Darwin, Australia. A 3.2-ha site was configured as ponds and wetlands, covered with peat, and planted with *Typha orientalis* (Halford, 1999). A light hydraulic loading (<1 cm/d) was applied during the dry season of 1996 (July–September). The incoming water had total cyanide of about 2,000 µg/L, and the system discharge was 40–400 µg/L. Weak acid dissociable cyanide (WAD) was reduced from about 900 to 200 µg/L.

Wetland remediation of groundwaters contaminated with cyanide from landfills associated with the aluminum industry has been shown to be effective (Gessner *et al.*, 2005). A pilot project at Alcoa, Tennessee, consisted of two lined FWS cells operated in series. Softstem bulrushes (*Schoenoplectus* (*Scirpus*) *tabernaemontani*) were planted in Cell 1 (around 5 m × 15 m), and cattails (*Typha latifolia*) were planted in Cell

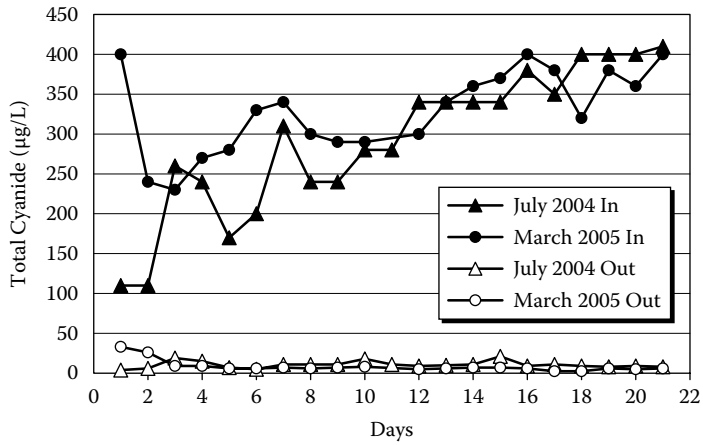

**FIGURE 13.8** Input–output data for two intensive sampling periods for total cyanide at the Duck Spring FWS treatment wetland at Alcoa, Tennessee. (Unpublished data from Alcoa Aluminum.)

2 (around 7 m × 12 m). Inflow concentrations typically ranged from 0.03 mg/L to 0.05 mg/L, while all outflow concentrations except one were below the lowest reporting level (LRL) of 0.01 mg/L. Total cyanide showed a statistically significant ($p < 0.00005$, N = 25) decrease in mean concentration (88%) between the treatment wetland inflow and outflow. By the time water reaches the midpoint of the treatment wetland, total cyanide average concentrations are at, or below, the LRL. A second pilot project was operated during 2004–2006, also in Alcoa, Tennessee. This 2,300-$m^2$ system was one lined FWS cell that received about 300 µg/L of total cyanide at 130 $m^3$/d, resulting in a nominal detention time of about three days. This system achieved well over 90% reduction in total cyanide (Figure 13.8).

The early successes of wetland treatment have caused optimism for continued application of wetlands to reduce cyanide. The PIRAMID summary research report stated that "the safe, passive destruction of residual cyanide leaching from gold mine tailings has been achieved using compost-based wetland-type passive systems" (PIRAMID Consortium, 2003b). This report goes on to suggest that WAD removal in such systems can be expected to average around 10.6 mg/$m^3$·d, which equates to an area-adjusted removal rate of 4.2 g/$m^2$·d for a substrate 0.5 m in depth. However, this recommendation is ten times higher than the results of Alvarez *et al.* (2006b), who found 0.49 g/$m^2$·d for WAD cyanide.

## SUMMARY

Wastewaters containing a wide variety of hydrocarbon constituents are presently being treated in wetland systems, and performance has been generally good. Rate constants are typically high, especially for volatile materials. The surfactant work has collectively shown that individual compounds may behave quite differently, depending upon isomeric form and upon small changes in molecular weight. This is somewhat daunting, because it means pre-project investigations for specialty chemicals are a necessity; rate constants may not be inferred from data on related compounds. The available data on phenol show that microcosms are only qualitative predictors of the performance of full-scale wetland systems. This means that pilot-scale tests are a necessity for generating design data.

However, there is some removal of nearly every organic compound tested in wetland treatment systems, whether full scale, pilot scale, or microcosm. This includes organics from very important generators: pesticides, petroleum and petrochemicals, food wastes, and remediation. In each of these categories, there are multiple studies that have initiated the design database. Current knowledge shows great promise for wetlands technology for organics control, especially in situations where passive systems can be fit into the landscape and accumulated organics will not pose a threat to wetlands biota.

# 14 Event-Driven Wetlands

The treatment of stormwaters of various origins is of growing concern as attempts to rectify point-source pollution reach maturity. Runoff from urban, agricultural, and industrial sources comprises a sizeable fraction of the total pollution load to receiving waters in many locations. Often, these sources are relatively dilute compared to primary or secondary domestic sewage but, nevertheless, they may negatively impact receiving waters.

Urban stormwater wetlands were first surveyed by Strecker *et al.* (1992), who documented the performance of 25 natural and constructed wetlands treating runoff. The implementation of the technology and the knowledge base continued to build, resulting in a compilation of data from 76 wetlands worldwide by Wong *et al.* (1999), and from 49 wetlands in the United States by Carleton *et al.* (2001). In North America, these are all FWS systems, and that is the predominant wetland type elsewhere as well. A typical configuration consists of a sedimentation basin as a forebay, followed by some combination of marshes and deeper pools. Design guidelines have now been promulgated by a number of sources (for example: Schueler, 1992; Breen and Lawrence, 1998; Wong *et al.*, 1999; LEC, 2000; Center for Watershed Protection, 2001).

Agricultural stormwater occurs as runoff from crops and pastures. Early work on constructed wetlands for row crop runoff control was centered in the state of Maine (Higgins *et al.*, 1993) (Wengrzynek and Terrell, 1990; U.S. Department of Agriculture, 1991). Runoff from sugarcane is being treated in the huge FWS wetlands (>16,000 ha) called stormwater treatment areas (STAs) of South Florida (Goforth, 2001). However, there has also been significant application of constructed wetlands at a more modest scale for vegetable farming (Rushton and Bahk, 2001). Nonetheless, effective control of runoff may require consideration of the entire watershed (Crumpton, 2000). More recently, attention has been on controlling pasture runoff (Tanner *et al.*, 2003).

Industrial stormwaters have received less attention than urban and agricultural sources. These typically will contain contaminants specific to the industry in question. For instance, rain runoff from a fertilizer plant site will potentially contain high levels of nutrients, whereas rain runoff from a petroleum facility will carry hydrocarbons. For instance, in South Africa, a number of reed bed wetlands were established to treat waters generated from truck washing operations at oil industry depots (Wood, 1993). An HSSF wetland treated runoff from a 0.8-ha vehicle yard in Surprise, Arizona, with 54–92% removal of oil and grease (Wass and Fox, 1993).

Although rainfall runoff is the source of water for many event-driven wetlands, there are other situations in which a treatment wetland is subjected to episodic flows. These include wetland systems that treat stormwater, urban or agricultural runoff, combined sewer overflows, and treatment systems that are operated in batch mode. Whatever the source, wetlands that receive pulsed flows utilize the suite of wetland removal mechanisms in different ways than their continuous-flow counterparts.

## 14.1 SOURCE CHARACTERIZATION

### Incoming Flows

The amount of water to be expected from a given watershed is variable and is keyed to rainfall in the contributing basin. The land uses and soils in the contributing basin are an important modifier of the runoff and infiltration. The antecedent dryness in the basin is also a contributing factor. Detailed methods of estimating runoff are available, for instance, the SCS (U.S. Soil Conservation Service) method (McCuen, 1982), which has been summarized by Novotny (1995). There are also numerous computer models that account for very detailed features of the contributing watershed and produce both the quality and quantity of the runoff to be treated. The focus here is the treatment wetland, and it will be presumed that the incoming flows will be characterized to the appropriate level of detail.

For purposes of rough estimation, the rational formula may be used to estimate peak flow, $Q_P$ (ASCE, 2006):

$$Q_P = C_R \cdot I \cdot A_b \tag{14.1}$$

where

$A_b$ = watershed area, $m^2$
$C_R$ = runoff coefficient, dimensionless
$Q_P$ = peak runoff flow, $m^3/h$
$I$ = average rainfall intensity, m/h

The values of $C_R$ are a function of land use and storm intensity, as well as the climatological region. An example of the range of $C_R$ for an arid region is shown in Table 14.1. To illustrate the regional effect, consider that agricultural land in Arizona is rated at $C_R = 0.1–0.2$ for high return-frequency events, whereas the value for agricultural land in South Florida is $C_R \approx 0.5$. Water is used consumptively in arid regions, whereas the high water table and rainfall in a wet region leads to more runoff. Modifications to this simplest formula have been presented on a site-specific basis (see, for example, Brezonik and Stadelmann, 2002; ASCE, 2006).

For modeling purposes, the time series of water flows entering the treatment wetland inlet hydrograph is sometimes needed. This time series is driven by the pattern of rainfall associated with a particular event (represented by a *hyetograph*), together with the collection and transfer characteristics of the basin. In some instances, such transfer is solely by gravity, but in some cases pumps may be used. Usually, the inlet hydrograph contains both a rising and falling limb, although the rising limb is normally quite steep (for an example, see Figure 14.1).

In some instances, the events are separated by interevent periods of no inflow to the treatment wetland. These periods are important because the wetland will act as a batch reactor during much of these no-inflow durations. A typical sequence is (1) wetland filling with no outflow, (2) flow through with both inflow and outflow, (3) draining with no inflow, and (4) finally, a batch-holding mode with neither inflow nor outflow. The rates and duration of these inflows and outflows are in part controlled by structures. The volume of water in the wetland is also in part controlled by structures, but evapotranspiration may be an important component during interevent periods. The durations of no-flow periods are very much a function of the climatological region in which the system is located. For instance, in Florida, during the rainy season, the most frequent periods are measured in hours (4–20 hours, Wanielista and Yousef, 1991). In contrast, the dry season of central north island New Zealand has periods of months with no rain, and interevent periods can be several months (Tanner *et al*., 2005b).

Many stormwater wetlands are fed by pumps. These may range in size from small sump pumps for small localized urban systems to the huge pumps that send water to the Florida stormwater treatment areas (a.k.a. STAs, or treatment wetlands). Those Florida inflow and outflow pumps are among the largest in the world, up to three stories tall, with capacities up to 10,000,000 $m^3$/d (Figure 14.2). A key feature of pumped systems is intermittent feed to the treatment wetland, usually at fixed but incremental rates, corresponding to the number of pumps that are operated, for periods of time dictated by conditions in the contributing watershed.

There is typically a hydraulic limitation to the event size that may be treated in a given wetland. It is generally not feasible to size a wetland to treat the 100-year return frequency storm because of cost and footprint considerations and because of the need for maintenance water for the (large) wetland under normal conditions. Consequently, part of the design decision process is the determination of the maximum design storm to be treated. Even if the system is sized to treat

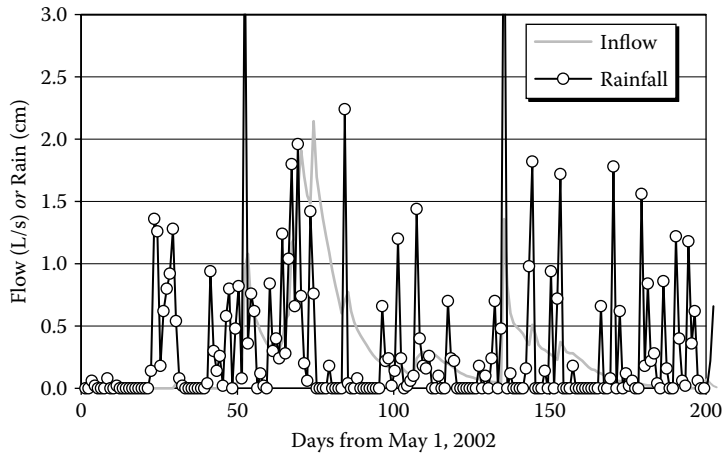

**FIGURE 14.1** Time series of flows entering a treatment wetland from an improved pasture in Toenepi, New Zealand. Several rain events occurred during this winter wet season, as indicated by the repeated spikes in inflow. The runoff coefficients were 0.23–0.30 and were the result of tile drains. (Adapted from Tanner *et al*. (2005b) *Agriculture, Ecosystems and Environment* 105(1–2): 145–162.)

a modest-sized storm flow, there remains the possibility that dry conditions might persist in some years to the point that the integrity of the wetland ecosystem is jeopardized. If such detrimental dryout conditions are expected, then a source of irrigation water for ecosystem maintenance should be identified.

### Incoming Concentrations and Loads

Concentrations of most parameters in stormwater are time dependent, as are the flows. Stormwater concentrations and loads are episodic due to periods of dryfall and deposition, followed by the first flush of runoff after rain, followed by exponential decreases in runoff constituent concentrations as storages rinse from the landscape, and finally, dry conditions and deposition until the next storm event. The time series of concentrations in the inflow to the wetland is called the *chemograph*. An example chemograph for an agricultural runoff wetland, targeting nitrogen reduction, is shown in Figure 14.3.

In some watersheds, the chemograph is not synchronized with the hydrograph, but instead provides higher concentrations early in the inflow event. This phenomenon is termed *first-flush* behavior, referring to the surge of pollutants contained in the first water to leave the contributing basin. For instance, Wanielista and Yousef (1991) report that, in Florida, the first 25 mm of runoff from urban systems typically carries 90% of the pollution. However, for the large agricultural

**FIGURE 14.2** The outflow pump station from STA1E (Stormwater Treatment Area 1 East) of the Everglades Protection Project. The capacity of this pump station is 9,740,000 $m^3$/d, and it serves to drain a 2,700-ha FWS wetland.

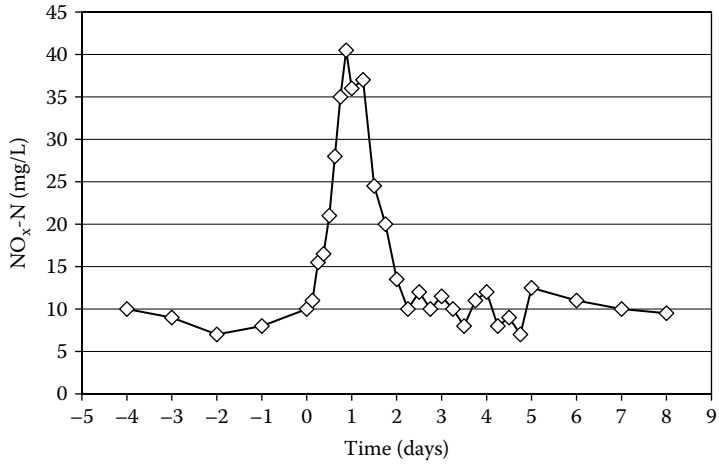

**FIGURE 14.3** The time series of nitrate nitrogen arriving at an agricultural runoff treatment wetland in McDowell County, North Carolina. The rain event started at time zero and drove runoff that entered the wetland by stream flow. (Adapted from Kao and Wu (2001) *Water Science and Technology* 45(3): 169–174.)

watershed of South Florida, there is no such first-flush effect. Despite the site-specific nature of the chemograph, there is no reliable database documenting dynamic time series of concentrations in any given watershed. Of necessity, average concentrations of some sort must be used, of which the flow-weighted concentration is most useful. This may be evaluated on a long-term basis or as an event mean concentration for the inlet water:

$$C_e = \frac{\int QCdt}{\int Qdt} \tag{14.2}$$

where

$C$ = instantaneous concentration, mg/L
$C_e$ = event mean concentration, mg/L
$Q$ = instantaneous flow, $m^3/h$
$t$ = time, h

and where integration is over the period of one event. The numerator is the mass of pollutant entering or leaving during the event. As described in Chapter 6, the performance of the wetland may be described in terms of the loads applied to and emanating from the system.

Tables 14.2 and 14.3 provide long-term mean concentrations for constituents in urban stormwater. The averages are flow-weighted to provide realistic estimates of the total constituent load that escapes during multiple storm events. Instantaneous concentrations may rise considerably higher than these averages. Pollutant concentrations and loads generally range from low levels from undeveloped and park lands to low-density residential and commercial, to agricultural, to higher-density residential and commercial, and finally to high-density commercial, industrial, and agricultural land uses. Mean concentrations per event for $BOD_5$ vary from below detection for undeveloped lands to 20 mg/L for high-density urban areas. Total suspended solids concentrations vary from about 10 mg/L for undeveloped areas up to 150 mg/L for high-density urban areas. Typical concentrations for other stormwater pollutants are also summarized in Tables 14.2 and 14.3.

The mass loading rates represent normalized pollutant loads that are somewhat independent of local rainfall amounts. Because pollutant loads per area per time are relatively constant between similar land use areas, variable local rainfall washes these loads off the land in a few large events or over many smaller events. Urban pollutant loads increase with the imperviousness of the watershed. Although 20 to 40% of the material on street surfaces is organic, it does not biodegrade easily because it comes from leaf and wood litter, rubber, and road-surface material (Novotny, 1992). The high metal content of highway solids comes from vehicle emission. Novotny (1992) reported that the average total nitrogen load from urban lands is 5 kg/ha·yr (1 to 38.5 kg/ha·yr), and the total phosphorus load averages 1 kg/ha·yr (0.5 to 6.25 kg/ha·yr).

Constructed wetlands are being increasingly used to treat runoff from intensive animal operations (CH2M Hill and Payne Engineering, 1997; Tanner *et al.*, 2003) and from crops (U.S. Department of Agriculture, 1991; Crumpton, 2000). Concentrations and loads from agricultural land uses vary considerably. Flows and loads are typically highest from areas with high animal densities or high fertilization rates. Runoff pollutant concentrations from animal feedlots can be extremely high unless runoff is collected and treated. Pollutants from feedlot runoff typically include high levels of organic and inorganic solids and associated nutrients. Nutrient concentrations and loads from row crops and pastures depend on fertilization practices and type of soil.

There exist many computer models for the amounts of contaminants that may be expected in runoff from different

landscapes. Novotny (1995) summarized the characteristics of six models for urban watersheds, and seven for agricultural watersheds, and the number has grown since that time. A large part of the design of event-driven treatment wetlands is the determination of the flows and loads to be treated.

## Hydrology of Pulsed and Seasonal Systems

Event-driven wetlands are dynamic in all respects, and the principal underlying hydraulics exhibit variable water depths and flows. The behavior is strongly conditioned by the nature

**TABLE 14.3**
**Typical Concentration Data for Pollutants in Urban Stormwater**

| Constituent | Units | Urban Runoff | Source |
|---|---|---|---|
| TSS | mg/L | 54.5 | Smullen and Cave (1998) |
| TP | mg/L | 0.26 | Smullen and Cave (1998) |
| TN | mg/L | 2.00 | Smullen and Cave (1998) |
| Cu | µg/L | 11.1 | Smullen and Cave (1998) |
| Pb | µg/L | 50.7 | Smullen and Cave (1998) |
| Zn | µg/L | 129 | Smullen and Cave (1998) |
| Fecal coliforms | 1,000 CFU/mL | 1.5 | Schueler (1999) |

of inflow and outflow structures that may be designed to improve detention and treatment (Somes and Wong, 1997). The most general situation may have several complicating factors, but here a simple and common case is explored for purposes of illustration. It will be presumed that the wetland is relatively small and consequently behaves as a level-pool system, with no gradients in stage. Stormwater wetlands experience event flows and concentrations, followed by periods of batch operation. It is then necessary to account for the dynamics of water storage within the wetland.

The dynamic, level-pool water mass balance for the wetland for unsteady state inflows and meteorology is

$$\frac{d(Ah)}{dt} = Q_i - Q_o + A(P - ET - I) \tag{14.3}$$

where

$A$ = wetland wetted area, $m^2$
$Q_i$ = inflow, $m^3/d$
$Q_o$ = outflow, $m^3/d$
$P$ = rainfall, m/d
$ET$ = evapotranspiration, m/d
$h$ = water depth, m
$I$ = infiltration, m/d
$t$ = time, d

The stage is often controlled by an outlet structure, here supposed to be a rectangular weir. Thus the outflow-stage relation would be given by the Francis formula (French, 1985):

$$Q_o = \beta(h_{ow})^{\alpha} \tag{14.4}$$

where

$h_{ow}$ = height over the weir, m ($h_{ow} = H - H_w$)
$H$ = wetland stage, m
$H_w$ = elevation of weir, m
$Q_o$ = outflow, $m^3/d$
$\alpha$ = calibration exponent, dimensionless
$\beta$ = calibration constant, $(m^3/d)/m^{\alpha}$

It is noted that the wetted area is not constant but changes with stage according to the bathymetry of the wetland, represented by the stage–area–volume relationship (see Chapter 2). Further, the wetland catches rainfall over an area typically greater than the wetted area but loses water to *ET* from just the wetted area. Infiltration further contributes to water losses and may be a significant fraction of the output from the wetland, as in the case of the Hidden River wetland in Tampa, Florida (Carr and Rushton, 1995).

An example of this analysis is illustrated in Figure 14.4. For illustration, a wetland of 2,500 $m^2$ is subjected to a 5-cm rain event and the associated runoff from the contributing basin. The presumed conditions and wetland design are shown in Table 14.4. The wetland does not have a level bottom; rather, there is a presumed quadratic stage–volume relation, which implies that the wetted area increases linearly with stage. The hypothetical sequence of events is as follows:

- The wetland starting condition is partially full, with the water level 10 cm below the outlet weir.
- A steady rain begins at time zero and persists for one day.
- Runoff from the watershed begins after $t$ = 0.5 days and persists for 1.5 days.
- The wetland loses some water to *ET* (1.0 cm/d), and some to infiltration (1.0 cm/d).
- For the first half day ($t$ = 0–0.5 days), the wetland fills due to direct collection of rain.
- At $t$ = 0.65 days, the wetland has filled to the top of the outflow weir, and outflow commences.
- For the next half day ($t$ = 0.5–1.0 day), the wetland fills because of direct rain and incoming runoff.
- For the next day ($t$ = 1.0–2.0 days), the wetland fills because of incoming runoff.
- During $t$ = 2.0–3.1 days, there is no inflow, and the wetland is draining over the outflow weir. At $t$ = 3.1 days, the level has decreased to the top of the weir, and outflow stops.
- After time $t$ = 3.1 days, the wetland loses water to *ET* and infiltration, and the level continues a slow drop.

**TABLE 14.4**
**Parameters for a Hypothetical Stormwater Wetland Event Scenario**

| | |
|---|---|
| **Basin** | |
| Area = | 120,000 $m^2$ |
| Runoff coefficient = | 0.5 |
| **Wetland** | |
| WWAR = | 2 % |
| Nominal maximum depth = | 1.00 m |

| Wetland volume full = | 1,250 $m^3$ |
| Stage area: $A = aH$, $a$ = | 2,500 $m^2/m$ |
| Weir height = | 0.90 m |
| Weir coefficient = | 31,623 $(m^3/d)/(m^{1.5})$ |
| *ET* rate = | 1.00 cm/d |
| Infiltration rate = | 1.00 cm/d |
| Rain catchment = | 3,000 $m^2$ |
| **Rainfall** | |
| Period = | 1.00 d |
| Rain rate = | 5.00 cm/d |
| Basin catch = | 6,000 $m^3$ |
| Inflow start = | 0.50 d |
| Inflow end = | 2.00 d |
| Inflow rate = | 2,000 $m^3/d$ |
| Runoff = | 3,000 $m^3$ |
| Storm/wetland volume ratio = | 2.40 |

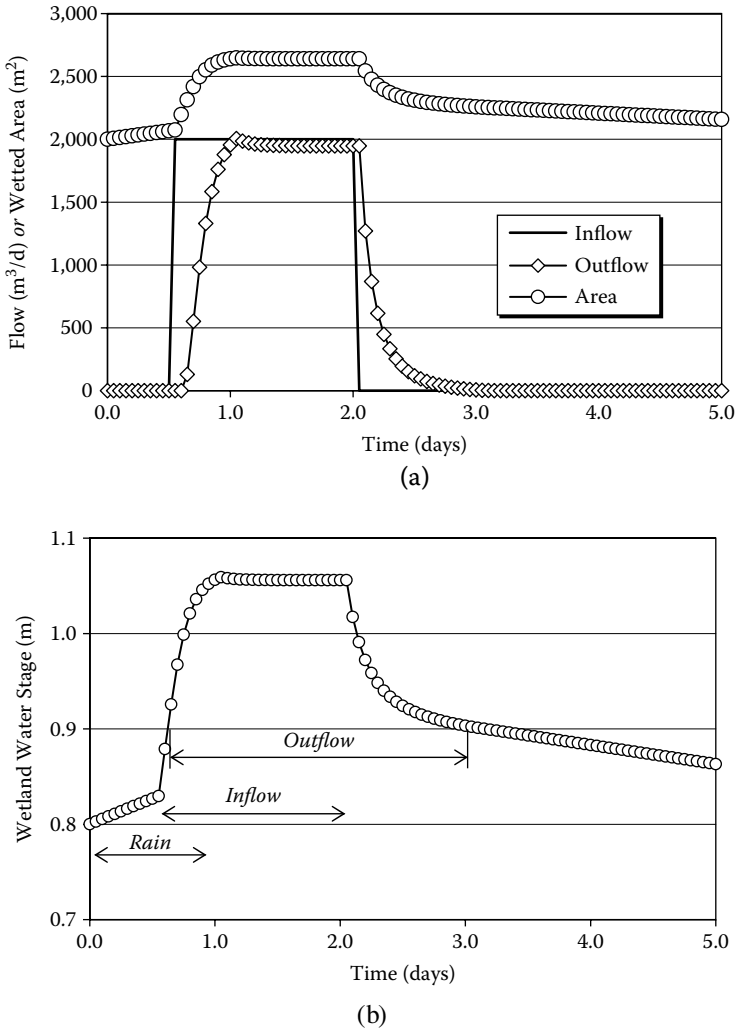

**FIGURE 14.4** Response of a hypothetical stormwater wetland to a one-day steady rain. Runoff into the wetland begins after half a day. The wetland fills, and outflow persists for just over three day. Infiltration and *ET* deplete the water after the event. See Table 14.4 for parameters.

Because of the assumed bathymetry, the wetted area first grows and then shrinks through this course of events.

This simple model has been found to fit event wetland data quite well (Kadlec, 1994; Hey *et al.*, 1994; Kadlec, 2001a). However, there are several different inlet and outlet structures that may be used, and the level-pool model must be modified accordingly for other situations.

## Flow and Capture

Event-driven wetlands operate with periods of flow through and periods of water-holding or batch processing. Any water that does not escape the wetland during a particular event will be held until the next event, and possibly longer. Therefore, it is subject to the water quality improvement functions of the wetland for not only the event duration but also the interevent period. Conversely, water that enters and leaves the wetland during the event is subject to treatment only during the (possibly brief) period of detention during the event. Therefore, at the first level of consideration, it would seem desirable to contain the entire volume of water associated with an event within the wetland. This requirement is often referred back to the contributing watershed in terms of the rain amount and runoff coefficient that generated the storm volume. The wetland may be sized to nominally contain the runoff volume associated with a rain event of specified amount or return frequency.

One limit on performance is the expulsion of water that resides in the wetland at the time of event initiation. This water is at a background concentration if the events are widely spaced. In this example, the time for background to be reached was on the order of two or three days. The length of time for the wetland water surcharge to dissipate, and thus for stage to reach the weir elevation, was also of the order of two or three days. If the events are more closely spaced, then the resident antecedent water will not be at background but rather will exhibit a concentration representing only partial treatment of the previous event. A second limit on performance is the

ultimate removal that would be associated with a continuous water input at the event average flow rate. This is likely to be a relatively low percentage reduction because of the high flow in the event.

A complicating factor in analysis is that wetlands are not hydraulically simple and do not operate on a basis of plug-flow displacement. Therefore, the fraction of incoming water that remains in the system for a particular event is not determined merely from displacement. Depending on the configuration of the wetland, some of the very first water that enters the wetland may find its way to the exit far in advance of nominal retention time during the event. This is partly due to preferential flow paths, and partly due to the positioning of water-level control structures.

If it is assumed that the wetland behaves hydraulically as several mixed tanks in series, it is reasonable to use the known detention time distribution to compute how much of the incoming water is still in the wetland after a period of flow of known magnitude. Figure 14.5 shows the results as a function of the nominal number of wetland volumes of water that have passed through the system. If the flow were plug flow, then the retention is 100% until the nominal detention time is reached, after which the new event water begins to exit. For less ideal flow conditions, the amount of the new event water that is held is less.

The presumption of Figure 14.5 is that all of the wetland water is involved in flow. That can be far from true because of wetland design factors (see Appendix B). For instance, if there is a point inlet to the system, and a point outlet aligned directly opposite, then the incoming pulse of water can travel directly to the outlet, never reaching zones to the side of the most direct flow path. That renders the corner areas essentially out of the flow path and reduces the volumetric efficiency quite markedly (Agunwamba, 2006). Walker (1998) investigated this situation using computational fluid mechanics (simulations) of unvegetated FWS basins. He determined that aspect ratio (L:W) was the major determinant of such shortcircuiting and calculated a retention-displacement chart (Figure 14.6).

For individual, separated inflow events, the concept of retained volume provides a strong correlating factor for performance. If the event is small, it is wholly contained and held until the next displacing flow. Treatment proceeds in the batch mode for the interevent duration. If the event is large, then it is processed by flow through at the detention time of the event flow. Because such flows are typically large, the wetland will have a short detention time, which results in decreased treatment performance. Therefore, mass reductions decrease (exponentially) as the number of nominal displacements caused by the event increases.

The storage and treatment potential for individual events may ultimately be linked to the sequence of events that are likely to occur over a long period of record. The three required probability distributions are for the event duration, the event intensity, and the interevent duration (Wong and Somes, 1995). To further complicate matters, when the wetland basin is "full," water will be diverted away (bypassed). Thus, a wetland that drains quickly, i.e., one with short detention time, will be in a position to detain more water upon refilling than a wetland that drains slowly. Wong and Geiger (1997) examined the runoff patterns for Melbourne, Australia, and concluded that the hydrologic effectiveness (the percentage of runoff that is exposed to treatment) was inversely proportional to the wetland detention time.

These factors all point to the existence of a set of performance determinants that go beyond those for continuous-flow treatment wetland systems. Batch interevent rate coefficients and background concentrations are important. The internal flow patterns are also important as determinants of the concentration and timing of the flushed antecedent water. The dynamics of water flow and storage of the wetland are important because they determine the volumetric constraints on performance.

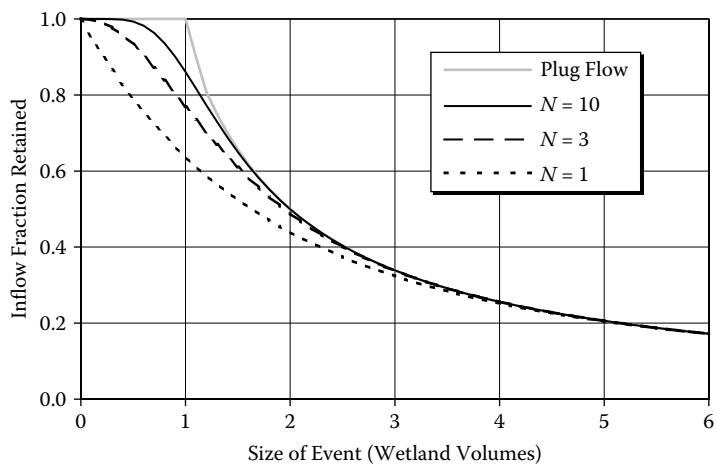

**FIGURE 14.5** Fraction of the inflow retained for a range of numbers of tanks in series for event volumes of different nominal displacements.

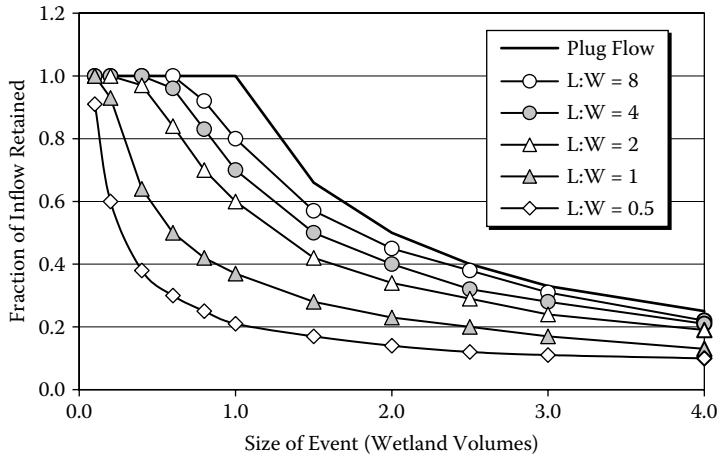

**FIGURE 14.6** Fraction of an inflow event contained in a wetland as a function of the event volume and the aspect ratio (L:W). (From Walker (1998) *Ecological Engineering* 10(3): 247–262. Reprinted with permission.)

Ultimately, the computed description of performance will either be expressed as long-term mass removal or by dynamic modeling that produces time series of outflow and effluent concentrations in response to the inlet time series. Most of the stormwater wetland literature reports mass removals over some period of record. However, there are now first-generation dynamic models for some applications. For instance, there is a flow and phosphorus model for application in south Florida called the Dynamic Model for Stormwater Treatment Areas (DMSTA) (Walker and Kadlec, 2005).

## 14.2 TECHNOLOGY STATUS

Data reporting falls into two general categories: event time-series analyses, and summaries of removal efficiencies. Two concepts are needed to organize these bodies of information: event mean concentrations and mass balancing. Because the concentration pulses and flow pulses are often out of sync, the event mean concentration (EMC) is used:

$$EMC = \frac{\Sigma(VC)}{\Sigma V} \tag{14.5}$$

where

$C$ = concentration in a water parcel, g/m$^3$ = mg/L

$V$ = water volume in the parcel, m$^3$

In effect, the EMC is the mass average concentration over the course of an event and may be calculated for both inlet and outlet flows of various types for the wetland. If only the directed inflow and outflow are considered, the EMC reduction is defined as

$$\text{Concentration Reduction} = \frac{(EMC_i - EMC_o)}{EMC_i} \tag{14.6}$$

The outflow from the wetland corresponding to a given inflow event may total less than the inflow due to infiltration and evapotranspiration. The mass load reduction for a given pollutant is

$$\text{Load Reduction} = \frac{(V_i EMC_i - V_o EMC_o)}{V_i EMC_i} \tag{14.7}$$

### Urban Stormwater

Runoff from roofs, lawns, parking lots, and other urban landscape features often contains several classes of pollutants (see Table 14.2). There will be small amounts of nitrogen and phosphorus and biochemical oxygen demand (BOD), but possibly relatively greater amounts of total suspended solids (TSS), metals, and perhaps pesticides. An important subset of urban runoff control is focused on highway runoff (Shutes *et al.*, 2001; Bulc and Sajn Slak, 2003; Pontier *et al.*, 2003). However, the greater number of systems are used to treat rainwater runoff from more generalized urban areas. Here the focus is upon gravity-driven constructed systems, as opposed to pumped or natural systems. Such systems are often quite small, serving small catchments (Figure 14.7).

In this section, attention is on gravity-fed, constructed systems treating urban stormwater. Pumped systems have been included in other summaries, such as Carleton *et al.* (2001) and Wong *et al.* (1999), but many of these do not reflect the random and episodic nature of wetlands receiving rain-driven events and are omitted here, as are natural wetland systems. A sampling of TSS performance is given in Table 14.5, in which it is clear that there is a wide spectrum of performances for all common constituents, with median removals far from 100%.

Removal percentages are insufficient for design purposes, and hence it is necessary to find relationships between system characteristics and performance measures. Carleton *et al.* (2001) concluded that long-term pollutant removals could be described in terms of the same kinds of first-order, steady-flow design equations currently employed for wastewater treatment wetlands. They present rate coefficients that

**FIGURE 14.7 (A color version of this figure follows page 550)** An urban stormwater wetland in the city of Blue Mountains, Australia.

are intended to be used in a procedure such as that described by Wong and Geiger (1997) and Wong *et al*. (2006). As discussed in Chapter 6, that method has inherent drawbacks, and calibrations for event-driven systems provide only central tendencies. Additionally, rate coefficients derived from single events may not be adequate for a time series of meteorologically driven flows.

Data sets analyzed by Strecker *et al.* (1992) and extended by Carleton *et al.* (2001) include about half natural wetland systems that receive stormwater. Strecker *et al.* (1992) in fact found that natural wetlands performed somewhat better than constructed wetlands, but the use of natural wetlands is not encouraged because of real and perceived negative impacts (U.S. EPA, 1993e). The median areal rate coefficients reported

*Note:* All are FWS except for Slovenia, which is HSSF.

by Carleton *et al.* (2001) for FWS constructed gravity-fed systems (N = 9) are

- Total Phosphorus: 8.3 m/yr
- Ammonia: 5.0 m/yr
- Nitrate: 6.7 m/yr

These are very low compared to the *k*-values reported for continuous-flow systems in the preceding chapters. Individual events are afforded much better treatment.

Carleton *et al.* (2001) also suggest that wetland-to-watershed area ratio (WWAR) may be used as a predictor of performance. Their regression equations are developed for small data sets, including natural wetland systems, and have low correlation coefficients ($R^2 \approx 0.15$–$0.45$). Within the range $0 < WWAR < 0.1$, the data scatter was particularly large. Regressions of the data in Table 14.5 are unsatisfactory; in general, the fractions remaining increase slightly with WWAR.

Duncan (1998; as referenced and reported by Wong *et al.*, 1999) suggested the use of regression equations for purposes of sizing. Relations are based on analysis of subsets of 76 stormwater wetland systems, presumably including pumped systems, inclusive of those in the United States and complemented by systems in Australia. The proposed empirically derived relations are

$$\text{TSS Percent Remaining} = 78q^{0.33}C_i^{-0.49} \quad R^2 = 0.80 \qquad (14.8)$$

$$\text{TP Percent Remaining} = 12q^{0.44} \quad R^2 = 0.71 \qquad (14.9)$$

$$\text{TN Percent Remaining} = 14q^{0.43} \quad R^2 = 0.78 \qquad (14.10)$$

where

$C_i$ = inlet concentration, g/m$^3$
$q$ = hydraulic loading rate, m/yr

The range of loading rate data for this regression is approximately $2 < q < 200$ m/yr, and the percents remaining ranged from 10 to 100%; about 30 systems were involved in each regression.

### Agricultural Stormwater

The acquisition of knowledge about wetland treatment of agricultural runoff has often been spurred by regional water quality problems as well as by the slow growth of experiences on small-scale systems. Nutrients from agriculture have been implicated in eutrophication of marine environments (nitrogen) and freshwater (phosphorus) environments. Agricultural runoff is episodic by nature, and there is an extensive literature on predicting the amounts of water and particulate matter that leaves the fields. However, fertilization practices dictate the availability of nutrients to be washed off the fields, and hence the patterns of loading are different from those in urban or industrial settings. Non-point source (NPS) pollution from agriculture may occur when nutrients are applied at rates greater than crops can utilize or when timing of nutrient applications occurs in close proximity to heavy rains (Stone *et al.*, 2003).

A fraction of the fertilizers applied to fields is unavoidably lost to runoff and shallow groundwater. Tile drainage systems collect subsurface waters and vent them to receiving streams, where their nitrogen content, together with phosphorus, may cause problems. Wetlands are being used at various points in the agricultural landscape, corresponding to drainage areas ranging from individual fields (U.S. Department of Agriculture, 1991; Tanner *et al.*, 2003), to small-order streams (Stone *et al.*, 2003), to large regional landscape units of thousands of hectares (Reilly *et al.*, 2000). Some of these receive pumped water at relatively constant rates, and these have been included under the discussion of continuous flow (but possibly variable flow) wetlands. Those that receive water as a result of meteorological events are considered here.

### Target: Nitrogen

Nitrogen compounds are among the principal pollutants of concern in fresh and marine waters because of their role in eutrophication, their effect on the oxygen content of receiving waters, and their potential toxicity to aquatic invertebrate and vertebrate species. For example, the nitrogen content of the streams and rivers of the midwestern United States is of particular importance at this point in history because of hypoxia in the Gulf of Mexico, together with the associated ecological and economic consequences (Diaz and Solow, 1999). Both point and nonpoint sources contribute to the nitrogen content of waters within the Mississippi River drainage basin. About 60% of the waterborne total nitrogen is in the form of nitrate (Goolsby and Battaglin, 2000).

The source of the nitrogen is about two thirds from agriculture and one third from other sources, including urban runoff, atmospheric deposition, and point sources. The result is a surface-water nitrate concentration, in the upper portions of the basin, of about 4 mgN/L.

Federal and state officials have agreed on an action plan that includes a component intended to promote restoration and enhancement of natural systems for nitrogen retention and denitrification (U.S. EPA, 2001a). The premier natural system that has the capability to effectively remove nitrate from surface water is the free water surface wetland, based simply on its ability to place contaminated water in intimate contact with the biogeochemical cycle that removes nitrogen. More than half of the presettlement wetlands in the upper Mississippi River basin have been lost to drainage (Dahl, 1990). It is therefore synergistic to restore wetlands that are positioned to effectively function for nitrate reduction. Considerable attention has therefore been devoted to constructed and restored wetlands for nitrogen control in the midwestern United States (Kovacic *et al.*, 2000; Hey, 2002; Mitsch *et al.*, 2005; Hey *et al.*, 2005; Kadlec, 2005b). Similarly, the Chesapeake Bay in the eastern United States is impacted by agricultural runoff from farms in Maryland (Whigham *et al.*, 1999; Jordan *et al.*, 1999). Studies on seven constructed

(restored) wetlands demonstrated that nutrients could be removed from field runoff. Wetland systems have also been implemented for runoff control from other row crops, such as potatoes (Wengrzynek and Terrell, 1990; U.S. Department of Agriculture, 1991; Higgins *et al.*, 1993).

The problem of excessive nitrogen runoff has also been identified as detrimental to the Baltic Sea. The role of wetlands in southern Sweden has been thoroughly explored. Data were acquired on eight constructed wetlands and used to extrapolate the effects of 40 wetlands of total area 92 ha on the runoff from a 22,400-ha catchment (Arheimer and Wittgren, 1994; 2002). In Finland, retention performance of constructed wetlands has been studied at four agricultural study sites (Puustinen and Koskiaho, 2003). In Norway, field studies at five sites were conducted over several years, focusing on nutrients and sediments (Braskerud *et al.*, 2000; Braskerud, 2001b; 2002a; 2002b; 2003).

Rural settings often contain pastures, which form a source of nutrients and TSS to the drainage waters. FWS wetlands are a convenient method of intercepting some of the nutrient loads, and have been implemented in Australia (Raisin *et al.*, 1997) and New Zealand (Tanner *et al.*, 2003; Tanner *et al.*, 2005b). Typical on-farm systems are not large (Figure 14.8).

### Target: Phosphorus

Although phosphorus has also been studied in the various small-scale studies discussed previously, much of the research on agricultural phosphorus removal in treatment wetlands has originated from the Everglades protection projects of South Florida. The receiving Everglades ecosystem is conditioned by very low total phosphorus, in the range of 6–12 μg/L. Even modest amounts of field runoff phosphorus pose a threat to that ecosystem (Davis, 1994). Tests were performed on dozens of mesocosm tanks, thirty 0.2-ha test cells, and four 2-ha field scale wetlands. In parallel, a 1,500-ha, five-cell wetland, the Everglades Nutrient Removal Project (ENRP) was operated as a research device. These FWS systems variously contained emergent vegetation, submerged plants, or algae, and testing was conducted over the period 1994–2005. A summary of results is given by Walker and Kadlec (2005). Details of ENRP results were presented in a special issue of *Ecological Engineering* (Vol. 27, Issue 4, 2006). Although these studies were directed toward the design of pumped event-driven systems, the trials were in general conducted at conditions of steady flow. Plans to study event operation were abandoned because the full-scale wetlands were placed in operation and became the study platforms.

There are presently six Stormwater Treatment Areas (STAs) in operation, aggregating over 16,500 ha and treating an annual average flow of $4.4 \times 10^6$ m$^3$/d (annual average HLR = 2.7 cm/d). These FWS wetlands have been in operation for periods of two to eight years and receive episodic deliveries of pumped inflows, occasioned by the flat topography of South Florida. An example of the flows and total phosphorus concentrations over the life of STA6 is shown in Figure 14.9. Summaries of performance may be found in annual reports (e.g., SFWMD, 2006).

### Industrial Stormwater

The stormwater runoff flows and quality from "industrial" facilities cannot be generalized because those facilities are quite different in the chemicals that find their way into runoff. A broad definition of industrial is taken here, excluding urban and agricultural runoff. This category includes inorganic sources of nitrogen, such as nitrates and ammonia from fertilizer manufacturing plants (TCI, 2005), and urea from airport de-icing (Thoren *et al.*, 2004).

The Simplot engineered FWS wetland (TCI, 2005) was designed to intercept, retain, and treat previously uncontrolled, meteorologically driven, nitrogen-contaminated groundwater forced to the surface in wet weather conditions and otherwise

**FIGURE 14.8** A constructed FWS wetland system treating tile drainage from a pasture in Toenepi, New Zealand. Wetlands are incised to capture tile drainage by gravity.

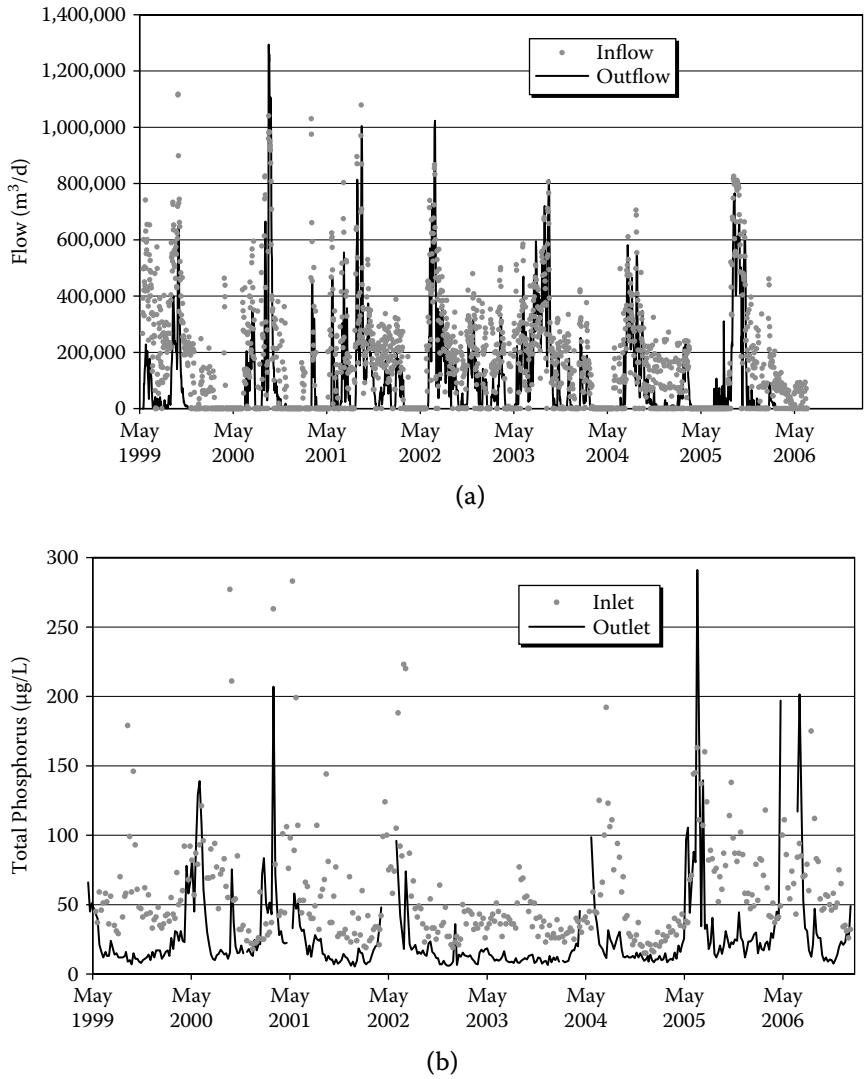

**FIGURE 14.9** Flows (a) and TP concentrations (b) entering and leaving STA6 in Florida. The average inflow rate was 161,000 $m^3$/d; the average outflow was 103,000 $m^3$/d. The arithmetic mean inlet TP concentration was 58 µg/L, and 25.2 µg/L at the outlet.

contributing nutrients to the Assiniboine River. A 4-cell, 22-ha constructed wetland was implemented in Autumn 2003, near Brandon, Manitoba. Approximately 100,000 $m^3$ of nutrient-rich water entered the wetland in 2004, over the April-through-November operating period, corresponding to an annualized HLR of 0.19 cm/d (0.28 cm/d instantaneous). Flows varied by a factor of ten, depending upon rainfall. Inlet concentrations were 400 mg/L total nitrogen (TN) and 165 mg/L ammonia nitrogen, and were reduced by 39% for total nitrogen and 82% for ammonia. The system was zero discharge in 2004, losing 460 mm of water. This corresponds to design net *ET* of 500 mm in a typical eight-month operating period.

The 18-ha FWS Kalmar Dämme wetland was built near Kalmar Airport in southeast Sweden (Thoren *et al*., 2004). Urea was used as the runway de-icing agent, and annually contributed about 41 metric tons of total nitrogen to receiving waters during 1998–2001. Airport runoff joined agricultural runoff from a 48-$km^2$ catchment. The wetland removed 17% of the TN load from all sources, but removal of urea was estimated to be 38%, based on source allocation. Winter removals were much lower than summer.

These two examples serve to illustrate the applicability of constructed wetlands to controlling nitrogen from sources other than municipal and animal wastewaters, or urban and agricultural runoff. Both represent high nitrogen loadings, which were treated to a good degree.

## Batch Systems

Not all event flows are caused by meteorology: the introduction of water to a treatment wetland may be caused solely by a human decision. That is the case with batch-operated systems, in which water is added episodically and drained episodically. If this sequence occurs on a rapid cycle, then there is no significant period of batch holding, as would be the case for alternative of reciprocating wetlands

(Behrends *et al.*, 2001). However, if the holding time is long, then the mode would be termed sequential batch operation. The water may be simply held without flow during the batch time, or it may be continuously recycled (Sikora *et al.*, 1995a). Therefore, like the interevent period of storm-driven wetlands, batch operation is an option for treatment wetlands. The operational advantage is that water may be held until a specific water quality objective is met. The disadvantage is that some form of storage is necessary if the batch mode is to be used to treat continuous flows.

Although it is often assumed that time in a batch system is equivalent to transit time in a continuous-flow system, this is a perilous assumption for wetlands. There are several reasons why these are not equivalent.

- *Hydraulics.* Continuous-flow systems display a distribution of detention times, with different elements of water spending different lengths of time in the flowing wetland. In a batch system that is filled and drained very quickly, every element of water spends exactly the same time in the ecosystem. The result is that the batch system in effect reflects a circumstance strongly akin to plug flow. Consequently, only the distribution of reaction rate coefficients attributable to mixtures will affect the apparent rate of disappearance of a lumped pollutant category (see Chapter 2).
- *Sorption.* In continuous-flow systems, the substrate is exposed to a relatively constant water phase contaminant concentration, which causes the sorption capacity to be equilibrated and plays no further role. In a batch system, the sorbed pollutants may be used up by microbial and vegetative processes, along with the water-phase materials. Therefore, at the end of a batch, which is also the beginning of the next, the sorption sites may be empty and capable of immediate removal of pollutants to sorption storage. This phenomenon was reported by Sikora *et al.* (1995a).
- *Vegetation.* The environment for vegetation is different in the batch mode, with diffusion and transpiration flows providing the transfer of dissolved substances, such as oxygen and nutrients. In the flow mode, advective processes are present and may dominate. Stein *et al.* (2003) conducted microcosm studies on batch-loaded planted gravel bed systems and compared them to accompanying flow through systems. There were differences attributable to plants, including more pronounced seasonal effects and larger differences among plant species in the batch mode. The result was superior nitrogen and phosphorus removal in the batch mode in all seasons and from all conditions studied.
- *Microbes.* Microbial populations respond to their environment and evolve accordingly over a period of time. In a flow through system, there are gradients in water quality from inlet to outlet. Over the course of time, microbial populations adapt to different conditions near the inlet and outlet. Therefore, the water "sees" different types of microbes during its travel through a flowing system, which are the result of a stable growth–death balance at each location. In contrast, the microbes in a batch system undergo a transient in their population and relative abundance, i.e., they are in a growth phase.

Despite these differences in site characteristics, there is typically a near-exponential decline with time of pollutant concentrations in batch wetlands, often with a residual concentration. This is seen at the microcosm level (e.g., Gale *et al.*, 1993; Van Oostrom and Russell, 1994), the mesocosm level (e.g., Burgoon, 1993), and at field scale (Lakhsman, 1981; Sikora *et al.*, 1995a; Kadlec, 2001a). Declines in contaminant concentration are well described by the *k-C** model using the exponential decay because of the lack of detention time distribution (DTD) effects (Figure 14.10). However, the rate coefficients in batch systems may differ considerably from those determined under flow through conditions. For instance, Burgoon (1993) found a factor of two difference, with higher rate coefficients for CBOD for batch operation. Kadlec (2001a) also found higher values for phosphorus *k*-values for batch operation.

Experiences on full-scale batch systems are limited. Studies were conducted on three batch systems at Humboldt, Saskatchewan, in which lagoon waters were treated in wetlands utilizing a fill-hold-drain strategy (Lakhsman, 1982). In general, BOD was reduced from 90 mg/L to below 20 mg/L in four days, total Kjeldahl nitrogen (TKN) from 20 to below 3 mg/L in 20 days, and phosphorus from 12 to below 3 mg/L in 20 days. Given an operating depth of 0.3 m,

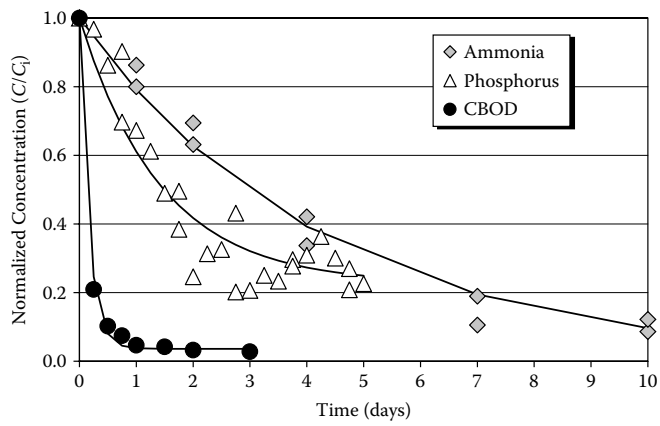

**FIGURE 14.10** Decline of pollutant concentrations in batch systems. Ammonia data is from FWS microcosms of Gale *et al.* (1993). Phosphorus data is from an FWS field-scale wetland of Kadlec (2001a). CBOD data is from SSF mesocosms of Burgoon (1993). All fit lines are for the *k-C** model using an exponential decay.

the equivalent hydraulic loading to reduce BOD was about 7 cm/d, but reduction of nutrients needed about 1.5 cm/d.

The Oak Hammock, Manitoba, headquarters and visitor center of Ducks Unlimited, Canada, near Winnipeg, utilizes a lagoon batch wetland system to treat domestic wastewaters (Pries, 1994). Waste enters unvegetated lagoon one, which functions as a facultative pond. It then travels to a second lagoon with partial vegetative cover of cattails, and finally to a FWS cattail wetland and then to receiving waters (also a marsh). About once per month, the water is drained from the third cell and it is refilled from cell two, which is in turn is filled from cell one. The system stores water during the winter. The discharge from the three-cell system averages 20 CFU/100 mL fecal coliforms, 0.37 mg/L total phosphorus, 1.3 mg/L TKN, and 0.2 mg/L oxidized nitrogen. The system is very lightly loaded, with the summer discharge totaling about 1 m/yr on less than 1 ha.

There is no large-enough database from which to forecast the behavior of batch systems. Ultimately, it would be desirable to be able to compare the long-term average performance of sequential batch operation to that of continuous flow.

### Combined Sewer Overflow (CSO)

In many communities in Europe and North America, there is but one sewer collecting domestic wastewater and storm flows. Wastewater treatment facilities are usually designed to treat flows up to but not including the storm flow. During large rain events, the excess is bypassed, which is termed a combined sewer overflow (CSO). One of the options for treating these event overflows is use of treatment wetlands. Several types of wetlands have been constructed for this purpose, and they are all event driven.

An FWS system to treat CSO was implemented at Houten-Oost, Netherlands, in 1984 (Lageveen and Waardenburg, 1985; van Oorschot, 1990). The CSOs are directed to a series/parallel network of FWS wetlands containing bulrushes (*Scirpus lacustris*) and common reeds (*Phragmites australis;* Figure 14.11). The wetlands comprise 1.5 ha and operate at a depth of about 0.5 m. Discharge from the wetlands is pumped to a cascade aerator and then to a canal. A brief monitoring study during the summer of 1987 provided data on two overflow events, both completely contained within the wetlands. Water quality improved rapidly during storage in the wetlands.

Severn Trent Water built many HSSF CSO systems in the mid-1990s in the United Kingdom. All were based upon dry-weather treatment in rotating biological contactors (RBCs), which bypassed flows above about six times the dry weather flow (Green and Martin, 1996). The bypassed water was treated in reed beds. In general, these systems provide significant improvement to the CSO waters (Figure 14.12). Twelve of these systems were surveyed in 2003–2004 and found to be producing effluent concentrations well below the regulatory levels (Rousseau *et al.*, 2005a). Varying degrees of sludge accumulation, weed growth, surface blinding, and unequal flow distribution were found, but these seemed to have only minor effects on treatment performance.

**FIGURE 14.11** The CSO treatment wetland at Houten-Oost, Netherlands.

A vertical flow design is in use for several stormwater and CSO systems in the state of Hessia in Germany (Frechen *et al.*, 2004; Uhl and Dittmer, 2005; Dittmer *et al.*, 2005). These are underdrained, planted basins that fill with about 1 m of water, which is then drained through about 1 m of sand or soil. The drainage from these retention soil filters (RSF) is controlled at 0.09–2.7 $m^3/d$ per $m^2$ of filter area. Design is for 30–40 m/yr total hydraulic load. The performance at Fulda, Germany, over a 23-event, two-year period was more than 90% removal of chemical oxygen demand (COD), BOD, TSS, and ammonia, and 70–90% of phosphorus.

## 14.3 TSS IN EVENT-DRIVEN WETLANDS

Event-driven treatment wetlands utilize the same suite of TSS processes as continuous-flow systems, but there are important differences in the mode of operation. In contrast to continuous-flow wetlands, there is a greater need to account for the flow and chemical dynamics. Often, the source-water TSS is unknown. Performance data acquisition is difficult because flows occur during storm conditions, and close-interval sampling is needed to define the course of a single event. Internal to the wetland, processes operate on a flow-and-stop time sequence. The moderately stable gradients established by steady flows may no longer be present. The between-event periods are close to batch operation. Small events may not completely displace the antecedent water in

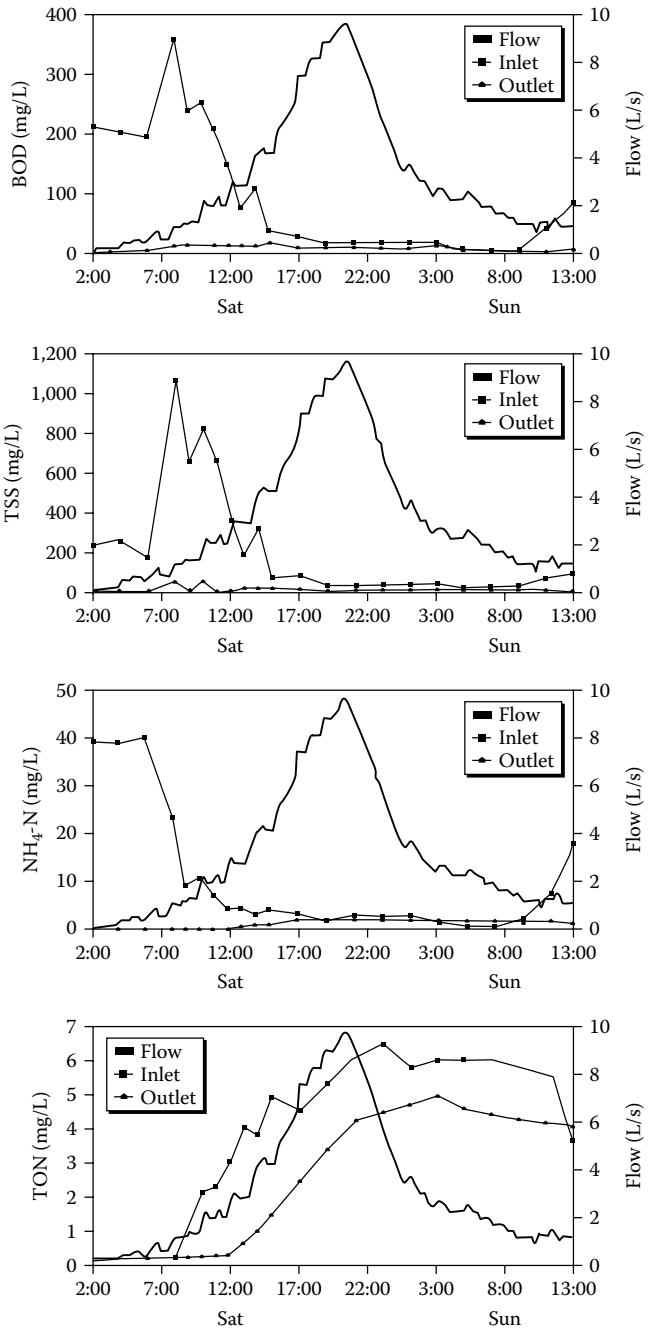

**FIGURE 14.12** Flow and concentrations in a CSO reed bed at Lighthorne Heath, Warwickshire, United Kingdom, in a November 1993 storm event. (From Green and Martin (1996) *Water Environment Research* 68(6): 1054–1060. Reprinted with permission.)

the wetland, but large events may replace it many times over. The flow velocities accompanying an event may be large and may cause resuspension.

## Dynamic Responses

The dynamics of both water and solids influence the performance of event-driven wetlands. If the event period is long compared to the detention time of the wetland under the event flow, then the first part of the event completely flushes the antecedent water, and the outflow concentration ramps up to the level dictated by the sustained event flow (Figure 14.13). After the cessation of event flow, the wetland outflows and outlet concentrations ramp back down to nonflow conditions. The majority of the treatment occurs during the period of high flow, and the expulsion of the highly treated antecedent water contributes little to overall performance during the event.

In contrast, if the event period is short compared to the detention time of the wetland under the event flow, then the event does not completely flush the (highly treated) antecedent water. Ramp-up of the exported solids load starts to occur but stops far short of a new steady state determined by the inflow (Figure 14.14). Ramp-down of the mass export is primarily due to the lower flows; TSS remained elevated in the immediate after-event period.

Data acquisition for individual events involves close-interval sampling, with numerous samples required to define an individual response. Consequently, studies akin to those at Des Plaines are few in number. It is easier and less costly to use flow-proportional autosampling, but the result is then restricted to the EMC for the event.

A second aspect of event wetland dynamics is the variability from event to event during the course of time. Defining such patterns is also a data-intensive effort, which has been accomplished in only a few instances (e.g., Carr and Rushton, 1995). Those researchers examined the water quality from a system for 83 storm events over a period of 30 months (Figure 14.15). The inflows to the Hidden River urban stormwater wetland followed the pattern of the wet and dry seasons for this Florida site, and it functioned with zero discharge in the dry months. Incoming TSS concentrations were quite variable during the year, but the outflow displayed spikes primarily during the dry season, under no-outflow conditions.

## Intersystem Performance

As for continuous-flow systems, there is a sizeable database of stormwater wetland performance. In the United States, this database originated with the work of Strecker *et al.* (1992) and Schueler (1992), and grew through continued efforts of Godrej *et al.* (1999). Table 14.5 shows that there is no clear trend for constructed urban stormwater wetlands with the WWAR if the ratio is greater than 1%. The median reduction is about 70%. In contrast, agricultural runoff does not display any trend at all with loading or WWAR (Table 14.6). That is because field runoff contains soil particles from the fields that can contain a large fraction of large and heavy mineral particles, which settle readily. Median reduction is 57%, but that is also achieved by very small wetlands treating tilled field runoff.

In contrast to continuous-flow system data, event systems have much greater variability in design. Loadings are extremely variable, as are the geometries and arrangements of deep pools, shallow marsh zones, and interconnecting channels.

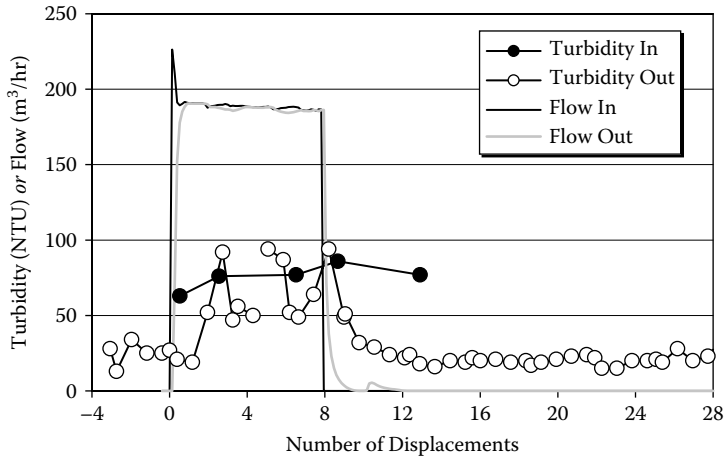

**FIGURE 14.13** Change in effluent turbidity for a 2.5-day pumping event for Des Plaines wetland C1. The nominal detention time for this pumping rate was 0.32 days. (From unpublished data.)

Therefore, the intrasystem database gives an impression of what has been accomplished, rather than what might be accomplished by "optimal" designs. Percent mass removals are high in many cases, with 60% of the U.S. data for stormwater wetlands of both kinds showing greater than 60% removal (Figure 14.16).

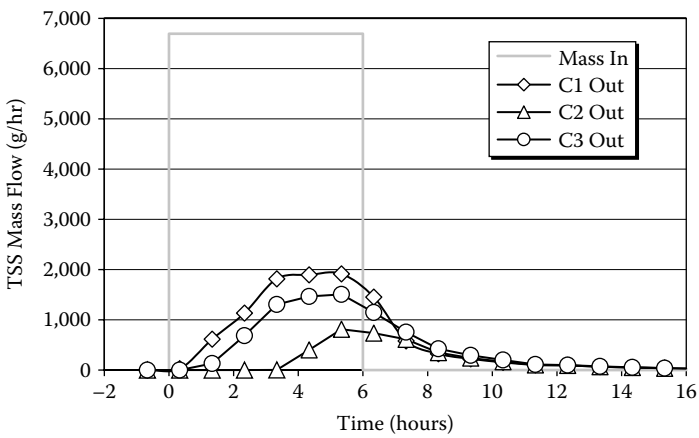
As noted in the discussion of urban stormwater systems, a regression has been proposed that relates TSS effluent concentrations to hydraulic loading and inlet TSS (Equation 14.8). That regression is entirely consistent with the intersystem continuous-flow FWS wetland data (see Figure 7.18 in Chapter 7) and may also be used to represent continuous-flow systems.

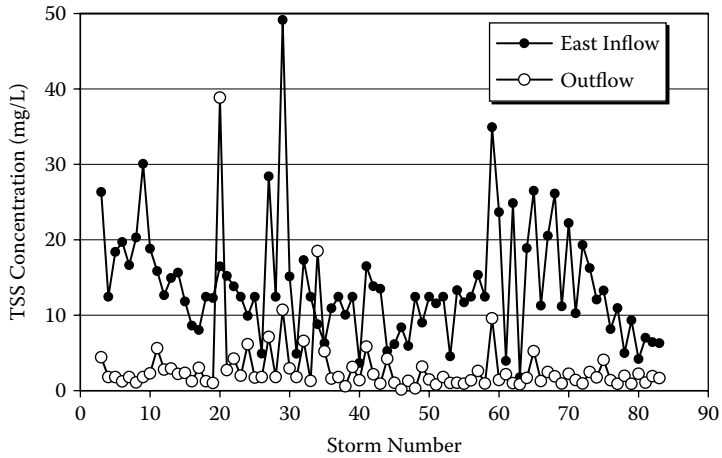
## 14.4 PHOSPHORUS IN EVENT-DRIVEN WETLANDS

Periodic runoff events from fields in agricultural production, or from streets and parking lots, convey phosphorus to receiving water bodies. FWS treatment wetlands have proven to remove phosphorus from event flows as well as from steady flows. Small pulses are very well treated, but those of longer duration receive much less phosphorus removal.

### Flow Pulses

The dynamics of tracer and phosphorus removal and export were studied at the Des Plaines River wetland demonstration site. Wetland pumping events were monitored for all hydrologic variables, including pumping, rain, storage change, and outflow. Tracer input and response were monitored at inflow, outflow, and interior stations. Phosphorus was measured at high frequency (every six hours) for the outflows, and at lower frequency for inflows and interior stations. The events were isolated in time, with sufficient interevent spacing to allow complete equilibration before the subsequent event. A calibrated dynamic water mass balance was developed as the framework for interpreting results (Kadlec, 2001a).





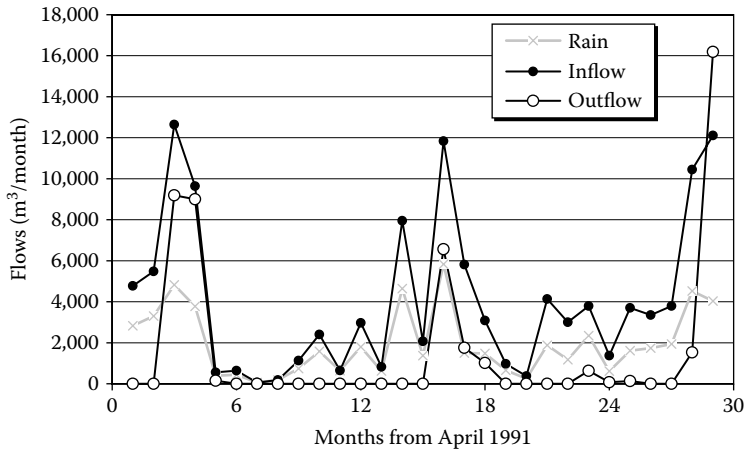


**FIGURE 14.14** Mass inputs and outputs for three wetlands at Des Plaines, driven by a six-hour pumping event. Nominal detention times at the event flow rate were 7.2, 15.4, and 8.2 hours for C1, C2, and C3, respectively. The wetlands were therefore not completely flushed of initial water. Mass removals were 73, 90, and 79%, respectively. (From unpublished data.)

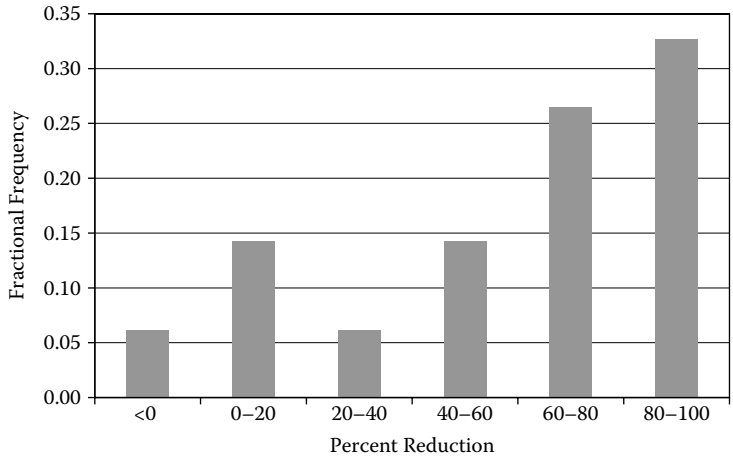

**FIGURE 14.16** Distribution of TSS reductions in stormwater wetlands (N = 49). (Data from Schueler (1992) *Design of stormwater wetland systems: guidelines for creating diverse and effective stormwater wetlands in the mid-Atlantic region*. Metropolitan Washington Council of Governments: Washington, D.C.; Whigham *et al.* (1999) *Nutrient retention and vegetation dynamics in restored freshwater wetlands on the Maryland coastal plain*. Final Report, U.S. EPA Agreement CB-993043-04, Smithsonian Environmental Research Center: Edgewater, Maryland; Carleton *et al.* (2001) *Water Research* 35(6): 1552–1562.)

Internal hydraulics were characterized by tanks in series (TIS) models calibrated to tracer studies. The residence time distribution was describable by five TIS for wetland C1, for instance. Dynamic mass balances were used, in conjunction with a first-order areal removal model, to describe the time sequence of phosphorus concentrations and flows. Parameter estimation produced instantaneous rate coefficients.

A typical response time series and the model representation are shown in Figure 14.17. This two-day pumping event nominally flushed the wetland more than seven times, and the hydraulic loading rate was 87 cm/d. As a result, the outflow concentration during pumping was 213 µg/L, just below that of the incoming water to the wetland, which was 258 µg/L. During the course of pumping, this corresponds to a high removal rate of 14 gP/m$^2$·yr. After the pumping stops, outflow quickly falls to zero, and the phosphorus concentrations in the wetland waters relax down to a background level of about 54 µg/L. Removal is sustained at high levels, with $k$ = 101 m/yr. Prior studies at this site indicated that this high rate of removal is not sustained during continuous-flow operation. The results of this study suggest that great caution must be exercised in transferring steady-flow results to event-driven wetlands. For instance, the calculation approach of Wong and Geiger (1997), using transferred steady-flow rate constants and $C^*$ values, may not be the best descriptor of pulsed treatment wetlands.

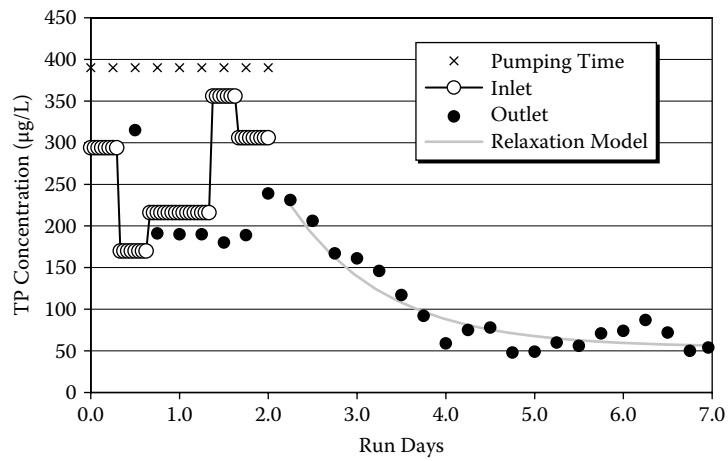

**FIGURE 14.17** Response of wetland C1 at Des Plaines, Illinois, to a two-day pumped-pulse addition. The two-day pumping nominally flushed the wetland 7.2 times. The concentration dropped after pumping to 54 µg/L. The model line has parameters $P$ = 5, $k$ = 101 m/yr, and $C^*$ = 54 µg/L. The incoming river water averaged 258 µg/L TP, and during pumping the average outflow was at 213 µg/L.

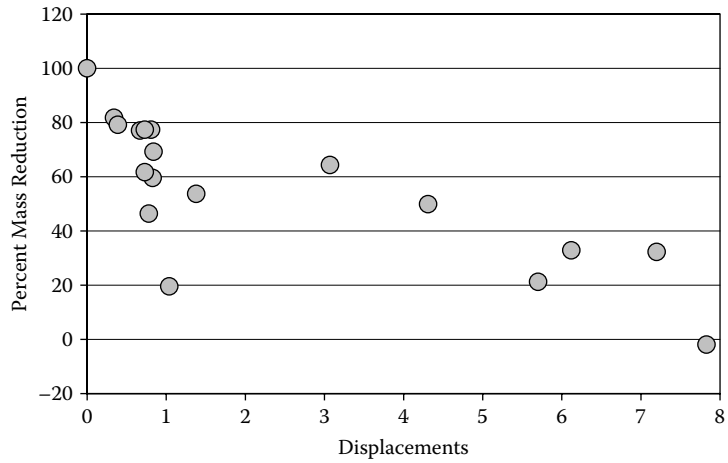

**FIGURE 14.18** The effect of varying displacement on the phosphorus removal efficiency of event-driven wetlands. (From Kadlec (2001a) In *Transformation of Nutrients in Natural and Constructed Wetlands*. Vymazal (Ed.), Backhuys Publishers, Leiden, The Netherlands, pp. 365–392. Reprinted with permission.)

The performance of stormwater wetlands for isolated events is contingent on the flow rate and duration of the event, and the capacity of the wetland. The relevant variable is the number of nominal displacements of the antecedent wetland water that occur, as discussed in the preceding section on capture. When these concepts are applied to the Des Plaines data set, Figure 14.18 results. Phosphorus mass removal decreases as the number of displacements increases. At very low displacement fraction, only a small amount of (treated) antecedent water is "bumped" out of the system. As the number of displacements becomes large, the system approaches continuous-flow performance at the event flow rate.

## Event Sequences

In gravity-fed systems and some pumped stormwater facilities, events are not necessarily isolated but occur in a time series with event-to-event overlap at times. The time series of event treatment may be viewed on a storm-by-storm basis, in which the mass reduction for each event is considered separately regardless of the interevent duration. For instance, the performance of the Hidden River, Florida, wetland was documented for 83 consecutive rain events (Figure 14.19). Because the outlet concentrations depend on event size, wetland storage, and interevent spacing, there is no obvious simple correspondence

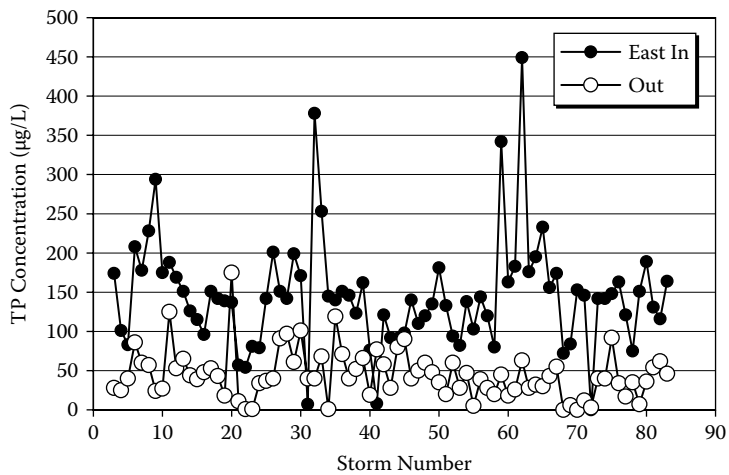

**FIGURE 14.19** Results of a 30-month study of the phosphorus removal performance of the Hidden River, Florida, urban stormwater treatment wetland. Total phosphorus concentrations and flows were monitored for 83 rain events. See Figure 14.15 for the flow time series. (Data from Carr and Rushton (1995) *Integrating a native herbaceous wetland into stormwater management*. Report by the Southwest Florida Water Management District, July 1995, Boca Raton, Florida.)

between outflow concentrations and inflow concentrations and flow rates. Dynamic mass balance modeling is required to analyze this complex set of interactions.

## Urban Stormwater

Over two decades of research directed at stormwater treatment have produced much information on constructed wetland systems to improve runoff quality. Initial surveys tabulated data for natural and constructed systems, receiving either pumped or gravity inflows (1992). Data collections have continued, which build upon previous efforts (Godrej *et al.*, 1999; Carleton *et al.*, 2001). Emphasis here is on constructed or engineered systems that receive gravity flows, because most pumped systems have been discussed under the heading of continuous-flow wetlands. In addition to project reports and published papers, the performance of some treatment wetland systems for stormwater improvement has been catalogued in a Stormwater Best Management Practices (BMP) Database (ASCE, 2003). This database provides access to BMP performance data in a standardized format for roughly 200 BMP studies conducted over the past 15 years, including wetlands. More statistical details on specific systems have been organized in a database by URS (1999).

The amount of phosphorus leaving a watershed during a specific event is often the object of research and predictive models. For example, Brezonik and Stadelmann (2002) found good correlation for event runoff volumes in Minnesota, with rainfall amount, drainage area, and percent impervious area ($R^2 = 0.78$). However, simple correlations for event mean concentrations and event mass loads were weak, and varied strongly with land use.

Urban stormwater wetland studies are hampered by the difficulties involved in tracking flows and concentrations in field situations. In gravity systems, the rainy weather that provides inflows is not conducive to easy sampling. Tracking of just one event requires many inflow and outflow water quality samples and accompanying chemical analyses. Nevertheless, there now exist several very detailed studies, such as that of Carr and Rushton (1995) at the Hidden River, Florida, wetland, which was monitored several times in each of 83 rain events. Similarly, Godrej *et al.* (1999) studied 33 rain events at the Crestwood, Virginia, wetland.

Sample results for reduction of phosphorus from constructed, gravity-fed systems treating urban runoff waters are shown in Table 14.7, which reports information from the summary of Carleton *et al.* (2001) as well as other sources. It must be borne in mind that percent removals, even if based upon load or event-mean concentrations, may reflect a low level of an incoming constituent. Despite such limitations, it is seen that reductions average 40%. WWAR is seen to not be a very good predictor of removals for this data set across multiple sites and conditions, which supports an observation of Schueler (1992).

Equation 14.9 indicates a positive correlation of phosphorus remaining with increases in hydraulic loading rate. This trend is

**TABLE 14.7**

*Note:* All are FWS except for Slovenia, which is SSF.

intuitively correct, but the confidence in such correlations cannot be high because of the numerous factors that contribute to variability.

First-order models are suggested to be used to describe event-driven systems, including urban runoff wetlands (Konyha *et al.*, 1995; Wong and Geiger, 1997; Carleton *et al.*, 2001; Wong *et al.*, 2006). These may be used in the time-average sense, in which annual concentrations and flows are presumed to be treated according to the rate coefficients derived for continuous systems (Wong and Geiger, 1997). Because urban stormwater HLRs are close to the HLRs for point-source-driven wetlands, it is reasonable to expect that stormwater wetlands would perform somewhere near the average for the continuous-flow FWS database set. For instance, the median reduction for nitrate in 282 continuous-flow marsh wetlands was 41% at an average HLR = 4.7 cm/d; the median reduction for constructed stormwater marshes, with a median HLR = 5.6 cm/d, was also 41% (Table 14.7).

### Agricultural Runoff

A fraction of the fertilizers applied to fields is unavoidably lost to runoff and shallow groundwater. Tile drainage systems collect subsurface waters and vent them to receiving streams, where their phosphorus content may cause problems. Wetlands are being used at various points in the agricultural landscape, corresponding to drainage areas ranging from individual fields (U.S. Department of Agriculture, 1991; Tanner *et al.*, 2003), to large regional landscape units of thousands of hectares (SFWMD, 2004). The latter are typified by the stormwater treatment areas in South Florida, which strip phosphorus from agricultural and other runoff to protect the Everglades. Systems that receive pumped water at relatively constant rates have been included under the discussion of continuous-flow (but possibly variable-flow) wetlands. Those that receive water as a result of meteorological events are considered here.

The design concepts for agricultural runoff wetlands vary from very high loadings primarily intended for sediment trapping, to very low loadings intended to provide for nutrient removal via microbiological processes and nutrient cycling. Accordingly, WWARs vary greatly (Table 14.8), from less than 0.1–20%. Runoff total phosphorus varies from 0.07–1.15 mg/L on average. It is difficult to draw generalities from data sets such as Table 14.8, but it is clear that very high loading rates do not allow time for interaction with the wetland biogeochemical cycle. It is also evident that wetlands produce or pass through only very low background levels of phosphorus and therefore may be expected to reduce TP to very low levels if sufficient area is provided.

First-order models may be used to describe phosphorus removal in agricultural runoff wetlands over averaged periods of operation (Walker, 1995; Wong *et al.*, 2006; Tanner *et al.*, 2005b). However, it is advantageous to consider system dynamics; and in design, it may be necessary to utilize Monte Carlo simulation of the incoming event train characteristics that may be expected. There is also the question of the transferability of rate coefficients from continuous-flow systems to event-driven systems.

It is also possible to use dynamic first-order modeling to predict phosphorus concentrations in stormwater wetlands (Walker and Kadlec, 2005). This approach is difficult because it is first necessary to measure (calibration mode) or forecast (prediction mode) the inlet time series of flows and concentrations. The prediction mode, in turn, implies the availability of a watershed model that produces the inlet time series.

## 14.5 NITROGEN IN EVENT-DRIVEN WETLANDS

In the pulse-dynamic mode, nitrogen processing and storages might be expected to exhibit different behavior than for continuous flow. In this section, it is shown that microbial processes can respond very quickly to changing circumstances, but the same is not necessarily true for vegetative processes. Internal hydraulics change with time, from batch operation during interstorm periods to extreme through-flow at the times of intense storms.

In almost all stormwater cases, nitrogen loadings are low enough to place them in the category of agronomic control. However, nitrate is often the dominant species, and microbial processing may be of considerable importance. Often, ammonia concentrations are very low, and it is therefore unclear what proportion of stormwater nitrogen is processed microbially rather than by plant uptake.

### Nitrate Pulses

Studies have been conducted in which wetlands receive pulses of nitrate, either by virtue of a concentration spike at constant flow, or by an increase in flow at constant concentration. In general, the response of the wetland is to reduce such new additions without delay.

#### Concentration Pulses and Nitrate Reduction

Bowmer (1987) used bromide and nitrate spikes in an HSSF wetland at Griffith, New South Wales, Australia, which was treating rendering plant effluent. Nitrate was clearly reduced at all points of the response time series, indicating consumption of nitrate in comparison to bromide. Cooper (1994) followed much the same protocols for an FWS wetland near Rotorua, New Zealand. The nitrate response at the wetland outlet showed considerable removal during passage (Figure 14.20). It may be shown that the ratio of nitrate to bromide should follow the disappearance time curve for batch removal because the nitrate travels with a packet of water whose transit time is characterized by bromide. Therefore, the plot of the ratio (Figure 14.20) follows an exponential decline, according to a first-order disappearance. The rate coefficient so determined is 0.038 $h^{-1}$, or in areal terms, 233 m/yr. This is an *intrinsic* value, based upon actual travel time. If the nominal detention time is used, the rate constants will be

reduced by a factor of 1.8, corresponding to the 56% volumetric efficiency of this wetland. This wetland showed a short circuit path down its central channel (Cooper, 1994). Similar treatment wetland studies have been conducted for constructed and natural HSSF wetlands (respectively, Casey and Klaine, 2001; Burns and Nguyen, 2002). In the case of the constructed wetland, the event tests were not of sufficient duration to clear the wetland of nitrate or tracer, thus making interpretation difficult. In the case of the natural subsurface flow system, there was difficulty in placing wells to sample the outflow. Trujillo (1997) utilized simultaneous bromide and nitrate impulse additions to large FWS mesocosms to determine the hydraulic characteristics and the intrinsic rate of nitrate removal. The short detention times (6–18 hours) implied that plant uptake was not important, and nitrate dose removal was attributed to denitrification. Intrinsic denitrification rate coefficients ranged from 16 to 113 m/yr.

## Flow Pulses and Nitrate Reduction

The dynamics of tracer and nitrate removal and export were studied at the Des Plaines River wetland demonstration site. Wetland pumping events were monitored for all hydrologic variables, including pumping, rain, storage change, and outflow. Tracer input and response were monitored at inflow, outflow, and interior stations. Nitrate was measured at high frequency (every six hours) for the outflows, and at lower frequency for inflows and interior stations. The events were isolated in time, with sufficient interevent spacing to allow complete equilibration before the subsequent event. A calibrated dynamic water mass balance was developed as the framework for interpreting results (Kadlec, 2001a). Internal hydraulics were characterized by TIS models calibrated to tracer studies. The residence time distribution was describable by three TIS for wetland EW3, for instance. Dynamic nitrate mass balances were used, in conjunction with a first-order areal removal model, to describe the

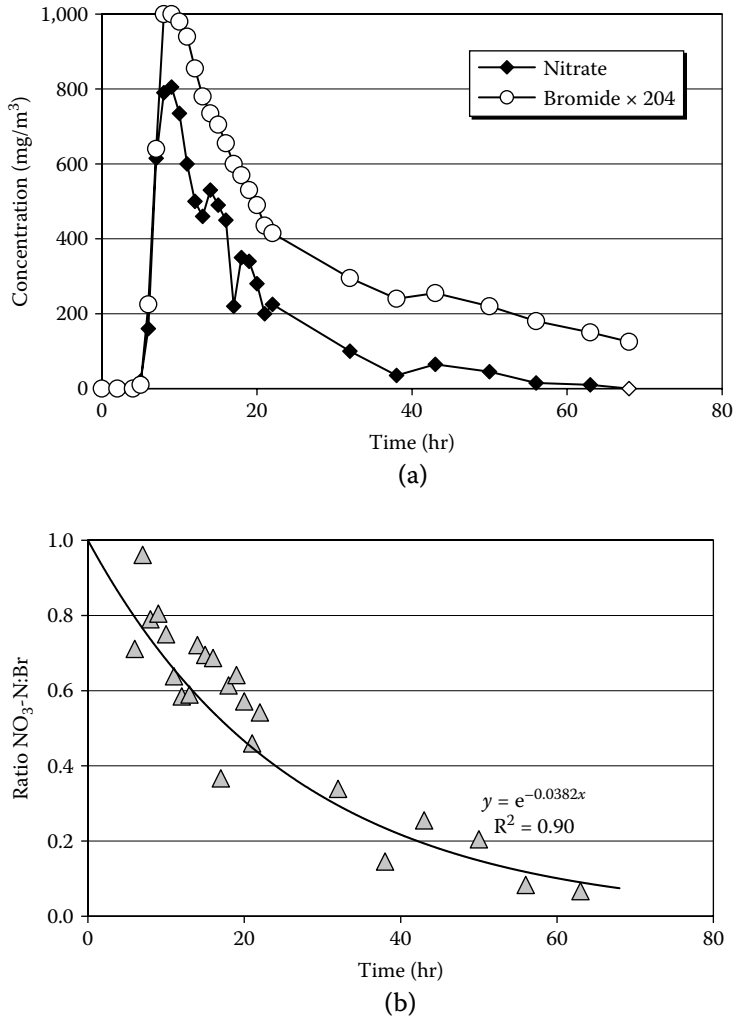

**FIGURE 14.20** Concentrations of nitrate and bromide at the outlet of an *Azolla-Carex* wetland pond at Rotorua, New Zealand. The nominal detention time was 52 hours. Nitrate is scaled to bromide. (Data from Cooper (1994) *Water Science and Technology* 29(4): 141–150.)

time sequence of nitrate concentrations and flows. Parameter estimation produced instantaneous rate coefficients (Werner and Kadlec, 2000b).

A typical response-time series and the model representation are shown in Figure 14.21. For the first day of this two-day pumping event, the outflow builds to equal the inflow, but the outflow concentration is essentially that of the antecedent water in the wetland, about 0.05 mg/L. Both data and the model calibration show that the wetland exports about 0.42 mg/L nitrate, reduced from 1.35 mg/L in the inflow, at the full-flow steady state. However, the early flush of clean antecedent water gives a lesser event-mean outflow concentration of 0.29 mg/L.

The removal rate coefficient is 125 m/yr, but the mass removal is a modest 42 g/m$^2$·yr (116 mg/m$^2$·d) over the duration of the event. It is noteworthy that the wetland response is very fast, both hydraulically and in terms of concentration reduction. Storage in the wetland biomass and sediments apparently is not critical to the response. This is convenient in calculations because only water-phase storages and concentrations suffice to characterize the behavior. However, biomass provides the locus for denitrifiers and their carbon supply.

The performance of stormwater wetlands for nitrate reduction is contingent on the flow rate and duration of the event, and the capacity of the wetland. The relevant variable is the number of nominal displacements of the antecedent wetland water that occur, as discussed in the preceding section on capture. When these concepts are applied to the Des Plaines data set, Figure 14.22 results. Nitrate mass removal decreases as the number of displacements increases. At very low displacement fraction, only a small amount of (treated) antecedent water is "bumped" out of the system. As the number of displacements becomes large, the system approaches its continuous-flow performance at the event-flow rate.

## Ammonia Pulses

It is uncommon that a pulse of ammonia-nitrogen would reach a stormwater treatment wetland, because urban and

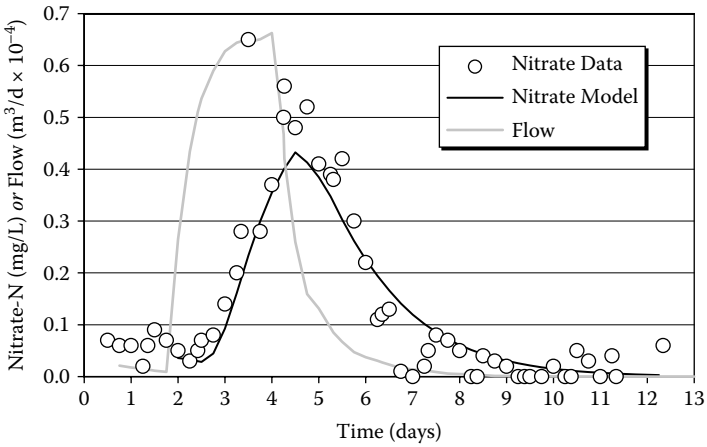

**FIGURE 14.21** Response of wetland EW3 to a two-day flow pulse containing nitrate at 1.35 mg/L at Des Plaines, Illinois.

agricultural runoff do not contain much ammonia. The circumstance arises when pretreatment that includes nitrification fails. For instance, Bavor *et al.* (1995) reported about three such events per year over a four-year period of operation of the Byron Bay, Australia, pretreatment system, some of which reached 20–45 mg/L for brief periods. These were reduced to less than 3 mg/L by the Byron Bay treatment wetlands.

Daily sampling was performed at the Commerce Township, Michigan, treatment wetland, which was preceded by an oxidation ditch pretreatment plant that conducted full nitrification. The mean monthly influent ammonia-nitrogen to the treatment wetland averaged 0.42 mg/L, and the mean monthly effluent ammonia-nitrogen from the treatment wetland averaged 0.35 mg/L over a five-year period. However, these averages were influenced by two WWTP upsets that sent high ammonia to the treatment wetland over 68 days in 2000 and nine days in 2002. These peaked at approximately 13 mg/L and 20 mg/L, respectively. If these months are excluded, the mean monthly influent ammonia-nitrogen to the treatment wetland averaged 0.085 mg/L, and the mean monthly effluent ammonia-nitrogen from the treatment wetland averaged 0.086 mg/L.

The average *k*-value during the period 1999–2003 was 12.0 m/yr, which is close to the median expected value based on other wetlands. The year 2000 event had an event-mean wetland inlet ammonia concentration of 4.1 mg/L, which was reduced to 2.3 mg/L. In the year 2002 event, 5.6 mg/L was reduced to 3.3 mg/L (Figure 14.23). The corresponding ammonia removal rate constant, for 3TIS at the prevailing water temperature of 20°C, was 40 m/yr. This high value, together with the synchrony between the inlet and outlet concentrations, signals a rapid response of the ammonia removal mechanisms within the wetland. Removal may be attributed to microbial processes or to algal uptake. In either case, water-phase storages are adequate for calculations.

## Event Sequences

In many instances, the nitrogen arrives at the stormwater treatment wetland in a complex time series dictated by

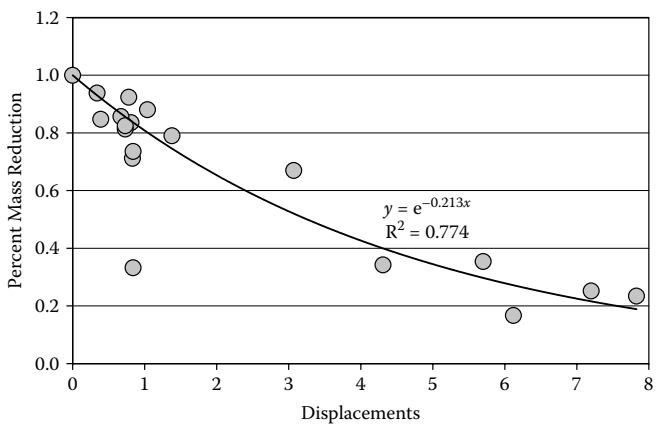

**FIGURE 14.22** The effect of varying wetland water displacement on the nitrate mass removal efficiency of event-driven wetlands at Des Plaines, Illinois. (From unpublished data.)

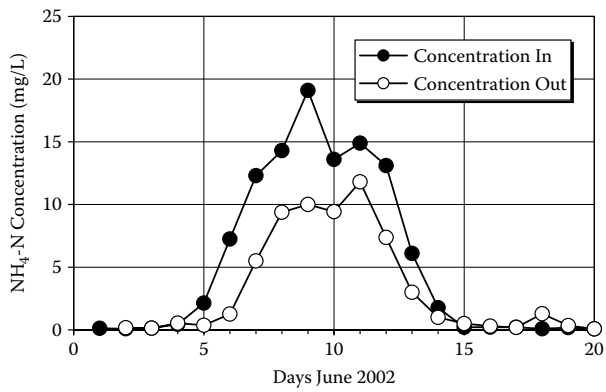

**FIGURE 14.23** Response of the Commerce Township, Michigan, treatment wetland to an ammonia pulse from the wastewater treatment plant in June 2002. (From Commerce Township unpublished daily monitoring data.)

watershed characteristics. An example is the constructed wetland at Toenepi, New Zealand, which treats tile drainage from a pasture. In the case of inorganic nitrogen, especially nitrate, it has been found that treatment tracks the flow and concentration behavior of the inflow (Figure 14.24). This suggests that the removal processes adapt very quickly to the changing inlet conditions, and provide nitrate reduction that is well-described by a first-order removal model.

### Nitrogen Reduction in Urban Stormwater

The same information base that was used for phosphorus is in major part also a source of information for nitrogen species. The reader is referred to the phosphorus section of this chapter for a discussion of those sources.

Sample results for reductions in nitrogen species from constructed, gravity-fed urban systems are shown in Table 14.9, which reports information from the summary of Carleton *et al.* (2001) as well as other sources. It must be borne in mind that percent removals, even if based upon load or event-mean concentrations, may reflect a low level of an incoming constituent. Despite such limitations, it is seen that nitrate reduction has the highest median percentages (45%), compared to ammonia (31%) and TN (30%). This is in accord with the higher nitrate rate constants observed in continuous-flow systems, and with low amounts of incoming ammonia and an irreducible background of organic nitrogen, which affects TN reduction. WWAR is seen to not be a very good predictor of removals for this data set across multiple sites and conditions, which supports an observation of Schueler (1992). Hydraulic loading has been suggested as an appropriate correlator of TN reduction, as given in Equation 14.10 (Wong *et al.*, 1999).

First-order models are suggested to be used to describe event-driven systems, including urban runoff wetlands (Konyha *et al.*, 1995; Wong and Geiger, 1997; Carleton *et al.*, 2001; Wong *et al.*, 2006). These may be used in the time-average sense, in which annual concentrations and flows are presumed to be treated according to the rate coefficients derived for continuous systems (Wong and Geiger, 1997). Because urban stormwater HLRs are close to the HLRs for point-source-driven marshes, it is reasonable to expect that stormwater wetlands would perform somewhere near the average for the continuous-flow FWS database set. For instance, the median reduction for nitrate in 72 continuous-flow FWS wetlands was 53% at an average HLR = 7.1 cm/d; the median reduction for constructed stormwater marshes, with an average HLR = 5.4 cm/d, was 45% (Table 14.9). The median plug-flow areal rate constants reported by Carleton *et al.* (2001) for FWS constructed gravity systems (N = 9) were cited above to be 5.0 m/yr for ammonia, and 6.7 m/yr for nitrate. As noted above, these are very low compared to the *k*-values reported for continuous-flow systems.

It is also possible to use dynamic first-order modeling to predict nitrogen species concentrations in stormwater wetlands (Wong *et al.*, 2006). This approach is difficult because it is first necessary to measure (calibration mode) or forecast (prediction mode) the inlet time series of flows and concentrations. In the prediction mode, this in turn implies the availability of a watershed model that can produce the inlet time series. There is also a question of the transferability of rate coefficients from continuous-flow situations. It is possible, if not probable, that the nitrogen processes that occur on an event time scale of hours are different from those that control on a time scale of months. Therefore, it is necessary to determine if different model calibrations are needed for the event-driven case.

### Agricultural Runoff

The design concepts for agricultural runoff wetlands vary from very high loadings primarily intended for sediment trapping to very low loadings intended to provide for nutrient removal via microbiological processes and nutrient cycling.

*Note:* All are FWS except for Slovenia and Taiwan.

Accordingly, WWARs vary greatly (Table 14.10), from less than 0.1%–20%. Runoff total nitrogen varies 2–20 mg/L on average and is dominated by nitrate in most crop runoff cases. Ammonia-nitrogen is typically less than 1 mg/L entering the wetlands. However, pasture runoff may contain episodically high organic nitrogen. It is difficult to draw generalities from data sets such as Table 14.10, but it is clear that very high loading rates do not allow time for interaction with the wetland biogeochemical cycle, or for microbial processes. The Norwegian and Pennsylvania data in Table 14.10 exemplify this lack of nitrogen removal performance high loading. It is also evident that wetlands produce or pass through a background level of about 1–2 mg/L of organic nitrogen and therefore should not be expected to reduce TKN or TN to below about 2 mg/L, even at low loadings (high WWAR).

First-order models may be used to describe agricultural runoff wetlands over averaged periods of operation (Stone *et al.*, 2003; Tanner *et al.*, 2005b). However, it is advantageous to consider system dynamics; and in design, it may be necessary to utilize Monte Carlo simulation of the incoming event-train characteristics. There may be a question of the transferability of rate coefficients from continuous-flow systems to event-driven systems.

## 14.6 METALS IN EVENT-DRIVEN WETLANDS

Trace metals are typically present in urban stormwaters but are generally not found in levels of concern in agricultural runoff. Zinc is usually the highest, at up to 150 μg/L, copper at up to 40 μg/L, and lead up to 70 μg/L. Cadmium and chromium are usually below 10 μg/L.

The mechanisms of metal removal in treatment wetlands have been discussed in Chapter 11, and these mechanisms are also operational in event wetlands. It may be surmised that most of the removal of metals is associated with particulate settling, partitioning, and formation of precipitates. The effect of cattails on the bulk concentration and partitioning of metals was found to be minimal in FWS-constructed urban stormwater wetlands (Goulet and Pick, 2001). Surface sediments with and without cattails (*Typha latifolia*) had similar concentrations of total metals (Fe, Mn, Zn, and Cu). Generally, half of the total metal concentration in sediments was in the form of metal oxides, monosulfides, and adsorbed onto organic matter, but half of the total Zn was associated with the persistent organic fraction.

The removals of some common trace metals in stormwater wetlands are listed in Table 14.11. Lead and cadmium

have the highest reductions, with a median of 70–75%. Zinc, copper, and nickel are less effectively removed, with median removals of 60, 50, and 40%, respectively. Stormwater wetlands consistently remove a good fraction of metals as long as the WWAR is greater than about 1%.

The removal of metals implies their storage in the wetland or pond used to treat the stormwater. Sediments build up in treatment systems, and so the concentrations in the sediments reflect both storage and sediment accretion. Contaminants can affect the biota that inhabit these sediments. Ontario defines a lowest-effect level as the 5th percentile of a biological test result distribution, and the severe-effects level as the 95th percentile. Studies in Ontario by Wren *et al.* (1997) have determined the levels found in stormwater system sediments in the Guelph region and compared them to Ontario sediment standards (Table 14.12). Some metals eventually

**TABLE 14.12**
**Metals Accumulation in the Sediments of Stormwater Pond Sediments (mg/kg)**

| Metal | Age 6–8 Years | Age 10–17 Years | LEL | SEL |
|---|---|---|---|---|
| Cd | <1 | 1.4 | 0.6 | 10 |

Technical Report Series No. 269, Canadian Wildlife Service: Burlington, Ontario, Canada.

exceeded the lowest-effect level but not the severe-effect level. The studies of Goulet and Pick (2001) found Fe, Cu, and Zn all below the lowest-effect level at two stormwater wetlands of age four and nine years. Thus, although there are buildups to be expected, the amounts of trace metals appear to generally be below levels that would cause concern.

## 14.7 PESTICIDES IN EVENT-DRIVEN WETLANDS

A wide variety of pesticides are often found in agricultural runoff. For some, the removal rates in wetlands have been determined, as discussed in Chapter 13, but usually in continuous-flow systems. One of the most studied is atrazine, by virtue of its pervasive use, and there is a small body of information on its behavior in event-driven treatment wetlands.

Atrazine transport, sorption, and identity loss were studied at the Des Plaines River constructed wetland site and in accompanying laboratory work. Sorption was effective for soils and sediments, but the more-organic materials, such as litter, showed a stronger affinity for atrazine than the mineral base soils of the wetland cells at Des Plaines (Alvord and Kadlec, 1995; 1996). Atrazine was found to degrade on those sediments according to a first-order rate law, with a half-life of 40 to 90 days. However, degradation was faster on cattail litter, precluding a rate measurement. The estimated half-life on cattail detritus was on the order of five days.

Outflows from the Des Plaines wetland cells contained reduced amounts of atrazine compared to the river water inputs. During 1991, atrazine peaked in the river due to two rain events. Only about 25% of the incoming atrazine was removed in wetland cell EW3, but 95% was removed in wetland cell EW4 due to longer detention time. Either time-averaged or dynamic models, both embodying a nonideal mixing model, fit the data for wetland EW3 (see Figure 13.7 in Chapter 13). The value of $k \approx 14$ m/yr calibrated the models to the data.

Runes *et al.* (2003) conducted field experiments near Portland, Oregon, in a constructed wetland consisting of five sequential cells, each approximately 3 m × 40 m filled with a silt loam, and planted with *Typha latifolia* at >75% coverage. Water came from a container nursery facility and was delivered episodically and dosed with atrazine. Flow events were ranked by intensity (low: <250 L/min, medium: 250–500 L/min, high: >500 L/min) and frequency of the events (low: <6 events/week, medium: 6–9 events/week, high: >9 events/week). Atrazine treatment efficiency at the outlet of the constructed wetland during a seven-day period ranged from 76–82% in 1998 (experiments 1–3) and 83–84% in 1999 (Table 14.13), but zero treatment was found in one monitoring period. For all experiments, deethylatrazine and deisopropylatrazine accounted for 13–21% of the initial application. Hydroxyatrazine was rarely detected in the water.

## 14.8 DYNAMIC MODELING

At a simple level, the dynamic hydrologic tanks-in-series model of Equations 14.3 and 14.4 may easily be extended to include one or more contaminants. The segmented *P*TIS model is continued. The dynamic pollutant mass balance for the first segment, for unsteady state, nonuniform flow is

$$\frac{d(AhC)_1}{dt} = Q_i C_i - Q_1 C_1 - I A_1 C_1 - k A_1 (C_1 - C^*) \qquad (14.11)$$

where

$A_1$ = area of tank 1, $m^2$
$C_i$ = inlet concentration, mg/L
$C_1$ = tank 1 outlet concentration, mg/L
$C^*$ = background concentration, mg/L
$Q$ = flow, $m^3/h$
$I$ = infiltration, m/h
$k$ = areal removal rate coefficient, m/h
$t$ = time, h

This equation, together with the dynamic water mass balance, may be solved numerically for a time series of inflows and incoming concentrations. This model has been described and exercised by Alvord and Kadlec (1996) for atrazine, and Kadlec (2001a) for phosphorus. This level of modeling has been utilized for describing phosphorus movement in treatment wetlands and surroundings in south Florida (Munson *et al.*, 2002). An example of a typical model fit for nitrate was shown earlier in Figure 14.21, and for atrazine in Figure 13.7 in Chapter 13.

### The Dynamic Model for Stormwater Treatment Areas (DMSTA)

A dynamic model of more complexity has been developed for phosphorus in agricultural runoff in south Florida (Kadlec and Walker, 1999; Walker and Kadlec, 2005). A simple extension of the *k*-*C** design models is the addition of phosphorus storage in the biota (solids) of the wetland ecosystem. During periods of high phosphorus availability, that storage will increase, and in periods of phosphorus famine, the storage will decrease. At all times, the ecosystem produces the residual sediments containing unavailable phosphorus, such as characterized earlier models (Walker, 1995). This extension has been named the Dynamic STA Design Model

(DMSTA). It is an unsteady state model that removes phosphorus to permanent burial in proportion to the amount of labile phosphorus in storage. There is an implied labile pool of phosphorus in addition to the permanently buried phosphorus. That labile pool is presumed to be drawn down by a return flux, or bleed-back. Temporal variations in the water budget (flows, rainfall, evapotranspiration, seepage, storage) are also simulated.

The goals of this modeling project were to provide a tool with three major attributes:

1. Provide capability for treatment wetland design calculations including dynamic events in pulse-flow systems. The implication is for at least one stationary storage compartment for phosphorus.
2. Allow for hydraulic flow patterns that deviate from the ideal extremes of one stirred tank and plug flow. Physical subdivision of large wetland cells is expensive but carries the implication of better hydraulic efficiency.
3. Allow for variability in, and choices for, the ecosystem community type. There was evidence of superior performance of SAV systems over emergent systems, and a continuing suggestion that periphyton systems could achieve lower phosphorus.

Given these priorities, the model was constructed to embody the concept of maximum simplicity while retaining essential descriptive features. Adding too many compartments and pathways has been found to result in unwieldy computer code and long simulation times (Fitz *et al*., 1996; HydroQual Inc., 1998). DMSTA keeps the size and complexity of the code to a level that permits rapid simulations (i.e., minutes) on a personal computer. Nevertheless, it is easily utilized for simulations of over 30 years' duration.

Phosphorus storage occurs in several compartments: plants, litter, algae, etc. (Wang and Mitsch, 2000). However, the computational overhead for tracking changes in several compartments is large, and calibration data for the many transfers is essentially absent. A single, aggregated storage compartment was therefore used.

Three dynamic mass balances are required at this level of modeling: one for the surface water budget, one for surface water phosphorus, and one for the dynamic, solid-phase phosphorus. To account for flow patterns, a specification is needed for the number of well-mixed units over which these mass balances are computed These considerations fix a model structure but not the rules for transfers. For the water budget, essentially one rule is needed: the stage–discharge relation for the wetland. There are three major phosphorus pathways that require transfer rules. Consequently, the chosen model needs three phosphorus removal parameters, in addition to hydraulic parameters. The model explains approximately 85% of the observed variance across data sets with a standard error of approximately 12% (Figure 14.25). The interested reader may find details at the website http://www.wwwalker.net/dmsta/.

Adaptations of this level of modeling are currently in development, such as a version for nitrogen, the Constructed Wetlands Algorithm for Nutrient Transformation (CWANT) (Howell *et al*., 2005).

### Variability

For event wetlands, the variability in performance is comprised of three contributions: (1) event-to-event inflow and concentration behavior, (2) annual seasonal patterns, and (3) stochastic scatter in removal efficiencies. Stormwater wetland performance variability is further compounded by the flow and concentration variations within events. Here, an example of the resultant variability for the Hidden River wetland in Tampa, Florida, is presented, based upon Carr and Rushton (1995) and the statistical analysis of URS (1999). Event-mean concentrations for 83 events form the basis of the analysis (Table 14.14). The ranges for each nitrogen species, across the percentile points of the distributions, are typically quite wide. Median outlet concentrations are reduced from either the rainfall or the overland flow inputs for nitrate and ammonia nitrogen, but organic nitrogen medians, and consequently TN medians, are higher in the output. The 90th percentile outlet values are higher than the medians by a considerable margin, a factor of 2.5 for oxidized nitrogen and 1.56 for TN. Thus, excursions for individual events may be expected, as is the case for continuous-flow systems. More percentile statistics may be found in URS (1999).

## SUMMARY

Event-driven wetlands include urban and agricultural stormwater systems, batch-operated wetlands, and combined sewer overflows that are treated in constructed wetlands. Most of these systems are FWS, but in Europe, CSOs are treated in HSSF wetlands. Urban and agricultural stormwater wetlands are usually comprised of a sedimentation basin preceding a marsh-pond complex. The amounts of water and pollutants that reach such wetlands are time variable in character. The time series of stormwater systems is driven by regional meteorology and the runoff characteristics of the catchment.

The primary intent of stormwater wetlands is to trap as much sediment as possible in the inlet basin so as not to clog the vegetated portion of the system with accumulated solids. The secondary focus of stormwater systems is the reduction of nutrients. Phosphorus and nitrogen compounds are reduced by the same internal processes as for continuous-flow wetlands. However, the hydraulic sequence for an event-driven wetland is a displacement of antecedent water, followed possibly by a flow through period, followed by batch holding during the interevent period. Metals and pesticides are also reduced in these systems.

Attempts at simplistic performance correlations have been largely unsatisfactory because of the high degree of variability in system designs and flow characteristics. Although it is intuitively obvious that a larger WWAR is desirable, this effect has not been tightly quantified. The use of continuous-flow rate constants holds some promise, but new calibrations are needed. Dynamic modeling seems to be necessary, but is only feasible for large projects. Until more knowledge is gained, technology-based designs are likely to continue to be the rule.

# *Part II*

## *Implementation*

# 15 Evolution of Sizing Methods

The purpose of Part II of *Treatment Wetlands, Second Edition*, is to provide information on how to design, construct, and operate a wetland for the purpose of water quality improvement. It is recognized that wetlands are almost never stand-alone treatment devices but rather form part of a treatment train. Other components may be mechanical, such as clarifiers or filters, or more natural, such as settling basins or lagoons. More than one type of wetland may be involved at the same site—FWS, VF, HSSF, or biosolids systems. In this chapter, historical sizing methods are reviewed and placed in perspective.

Design of treatment wetlands may be roughly divided into two categories: sizing calculations and physical specifications. Sizing procedures may in turn be predicated on the particular application, whether the purpose is for treatment of flows intended for surface water discharge, or for conditioning water for groundwater discharge, or for retaining and treating stormwater runoff. Further, local regulations may require compliance with specific numerical standards (performance-based) or may simply require certain design specifications according to prescriptive criteria (technology-based).

The physical aspects of treatment wetland design seem deceptively simple. Indeed, the basic elements have been on record for over a hundred years.

From Brian Mackney (Australia) via Hans Brix (1994d), an excerpt from an essay written by Nemo to the head of the Hornsby Literary Institute in 1904 reads:

> Anyone who has a little ground about his house can dispose of his dirty water as follows:
>
> Dig up a plot of ground thoroughly to a depth of fifteen to eighteen inches. Cut a channel leading from the kitchen and washhouse into the highest side of the plot and let all the dirty water drain into it. Plant the plot with plants that grow rapidly and require a great deal of water such as Arum Lilies, for instance. The dirty water will be all absorbed by the roots of the plants and a most luxuriant garden will be produced which will defy the hottest weather and will always be green and beautiful. By this means a curse will be transformed into a blessing. Twenty or thirty feet square properly worked would be enough for any ordinary family.

Of course, Nemo did not conceive of the difficulties of scale-up from a single household to all the wastewater from a city of 100,000 population. For even modest-sized systems, there is a need to consider the system layout, the number of individual cells and their arrangement, and how to move water through a large wetland complex. Questions of hydraulic and vegetation efficiency have important economic consequences. Therefore, the subsequent chapters consider the engineering of the wetland.

The first documented use of a wetland within a deliberately engineered treatment vessel appears to belong to Cleophas Monjeau (1901), as shown in Figure 15.1.

Claims for this United States patent (issued in 1901) include distributed vertical flow, a fluctuating water level, and aeration of the wastewater. This would be considered a cutting-edge wetland design even in the 21st century.

Design of wetland systems may be either performance-based or technology-based, depending upon whether the performance expectations are explicit in an operating permit or implicit in a set of statutory design specifications. Large systems are often in the former group, whereas small on-site and urban stormwater systems are in the latter. The primary focus of this chapter is performance-based design.

## 15.1 HISTORICAL PERSPECTIVES

Much of treatment wetland sizing has evolved along very simplistic lines, mostly adapted from civil and sanitary engineering. However, it is become increasingly apparent over the last 20 years that treatment wetlands are much more biologically complex than treatment processes used in the sanitary engineering field, and simplifying assumptions applied to activated sludge, trickling filter, and pond systems do not adequately describe the internal biogeochemical processes that govern treatment performance in wetlands.

Historically, mechanistic wetland models have been of little utility because of calibration difficulties. General rules of thumb for area requirements are used to good avail in conceptual design. Input–output regressions allow calculations of outlet concentrations for specified systems, and scatter plots are available to examine intersystem variability. Several variants of first-order models are now in use. Virtually all of these existing techniques fail to address significant aspects of wetland performance, including effects of hydraulics, meteorology, interactions of biota and treatment, supply-side constraints, and seasonal and stochastic variability. Soil accretion and the sustainable storage and dilution of irreducible constituents are other aspects not covered by existing design methods. There is also great danger of using empirical relations outside the envelope for which they were developed, and of unintentionally exceeding the capabilities of the fundamental wetland processes. Proper use of this imperfect set of design tools is a current design challenge.

Three principal themes have been prevalent in the history of constructed treatment wetland design: consideration of the pollutant and hydraulic loadings, first-order removal models, and regression equations. First, some general history and concepts of wetland design are discussed, and then some specifics for the principal variants of the technology.

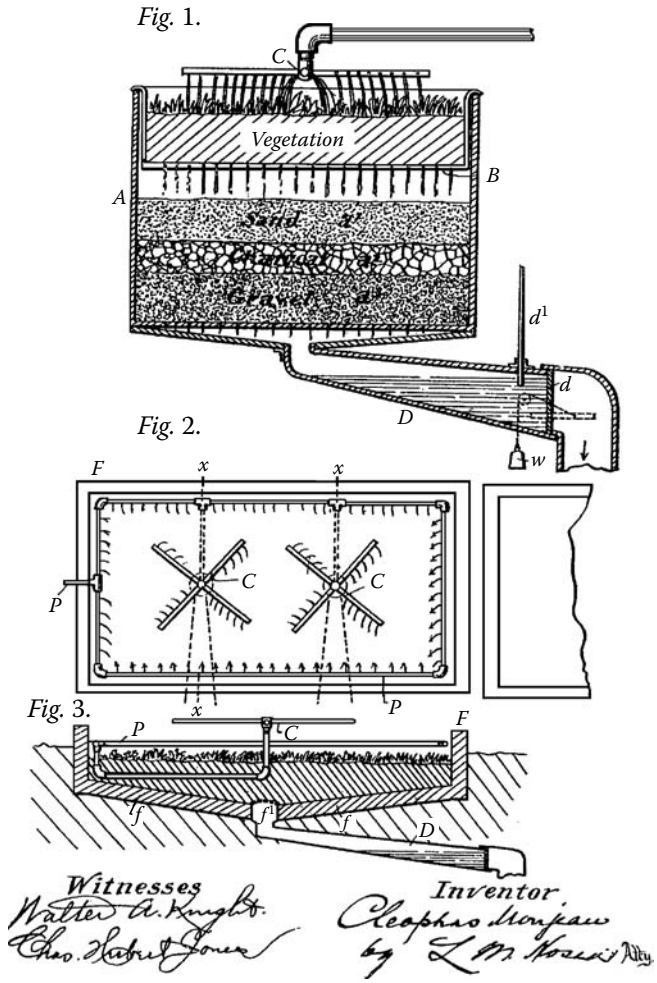

**FIGURE 15.1** 1901 U.S. patent for a treatment wetland system. (From U.S. Patent 681,884.)

## First-Order Modeling

In the mid-1980s, simple first-order models of pollutant removal in wetlands made their appearance in the treatment wetland literature (U.S. EPA, 1983b; Boon, 1985; Kadlec, 1985; Reed *et al*., 1988). This was, in part, a natural extension of models that had earlier been developed for waste stabilization ponds (Marais and Shaw, 1961; Marais, 1974; Thirumurthi, 1974). Some of these early models were founded on shaky ground because they borrowed extensively from nonwetland results and were not well-calibrated to actual treatment wetland data. Over the past two decades, considerable progress in understanding the behavior of treatment wetlands has allowed major improvements in the way that first-order models are constructed and implemented. It is the premise of this book that first-order modeling remains one of the most effective wetland design tools but that other information can and should also be brought to bear on design.

The information in Part I sets forth the many processes affecting pollutant removal in wetlands. Nearly all of the component processes are first-order within some range of constraints that are often met within wetland ecosystems. Therefore, it is not surprising that longitudinal profiles are virtually all describable by such a model, provided proper account is taken of background concentrations and the actual flow patterns observed in treatment wetlands. Further, calibrated first-order models are capable of adequately representing the trends in time series of pollutant concentrations exiting wetland systems. However, it is also the case that the many varieties of treatment wetlands, together with the variations of a given type, should not be expected to produce identical results. Plant varieties and their fractional coverage, media depth, aspect ratio, compartmentalization, and environmental factors vary from wetland to wetland. A distribution of $k$-values is to be expected, and has been observed for all the common pollutants (see Part I). Intersystem variability is thus a fact of life for wetland systems that are intimately connected to their climate and surrounding environment.

It is also true that, without exception, effluent concentrations exhibit random variation. Environmental and biological factors drive behavior on hour-to-hour and day-to-day time scales. Any model capable of describing such rapid phenomena would be quite complex, and in fact no such models currently exist. Therefore, effects such as those of wind, rain, and animal invasions must be dealt with through an understanding of the intrasystem variability present in the performance of a treatment wetland. Because such random effects are a large proportion of the wetland response, that variability must be understood, quantified, and included in design. Deterministic relations, either a rate-constant model or a loading relationship, will produce only the general trend of outlet concentrations and not the random variability.

## Previous Criticism of First-Order Modeling

Reliance on first-order modeling, although nearly universally accepted, has had one severe critic. Because that criticism appears in a U.S. government publication advocating a specific treatment wetland design procedure, it is necessary to examine this lone voice of opposition in more detail.

U.S. EPA (2000a) contended that " … the development of a rigorous model of the process, or parts of it, has not been achieved as is true with many of the wastewater treatment processes designed today."

This statement is no longer correct. Credible treatment wetland models exist at all the levels that they do for activated sludge processes, which are the most advanced in terms of modeling. The work of McBride and Tanner (2000), Langergraber (2001), Wynn and Liehr (2001), Howell *et al*. (2005) and others has carried wetland modeling to an advanced level of detail for municipal wastewater treatment. Stormwater wetland models abound (Fitz *et al*., 1996; Moustafa and Hamrick, 2002; Munson *et al*., 2002; Walker and Kadlec, 2005). However, to our knowledge, these complex models are not often in use for purposes of design, the exception being the dynamic model for stormwater treatment areas (DMSTA) (Walker and Kadlec, 2005).

Indeed, U.S. EPA (2000a) went on to conclude that the design should be based on loading, an approach that:

> … has been used for many decades by environmental engineers in the design of highly complex unit processes, including the activated sludge process and waste stabilization ponds. Only when a carefully designed series of iterative studies have been conducted, and data based on quality-controlled specifications have been analyzed, can rigorous models be provided for use in wetland system design.

It is almost unbelievable that this statement should have been made on the heels of a carefully designed series of iterative studies sponsored by U.S. EPA for the purpose of development of design equations (George *et al*., 1998) for treatment wetland systems.

A compromise position is the use of highly aggregated models that contain major features of the observed behavior of treatment wetlands. That compromise is a first-order model of some sort, possibly with temperature- or season-dependent parameters. A primary message of the U.S. EPA (2000a) is that such first-order removal models should not be used, because these are prominently absent from that manual. That is paradoxical, because the wetland publications of all of the major contributors/authors advocate the use of first-order removal models (Reed *et al*., 1988; Crites, 1994; Reed *et al*., 1995; Kadlec and Knight, 1996; Kemp and George, 1997; Crites and Tchobanoglous, 1998; Campbell and Ogden, 1999).

In recent years, first-order models have been reaffirmed as a useful tool in wetland design. Rousseau *et al*. (2004) performed a review of model-based design of horizontal subsurface-flow treatment wetlands, and concluded:

> At present, the state-of-the-art *k-C** model seems to be the best available design tool if the designer makes sure that all the assumptions are fulfilled and if he is aware of the pitfalls in the model.

Crites *et al*. (2006) reiterate the basic features of both areal and volumetric first-order models for free water surface (FWS) wetlands, and acknowledge that "… they do not directly account for the complex reactions and interactions that occur in wetlands." Crites *et al*. (2006) go on to state:

> Such an approach is the best that can be done with the currently available database and understanding of wetland processes.

In this book, the first-order model is retained as the primary tool in the design process. However, the loading approach is also retained, as a means of accounting for intersystem variability.

## Loading Specifications

An early source of guidance utilized by wetland analysts was the methods used by wastewater stabilization pond designers. A common method was the prescription of a specified areal-loading rate for biochemical oxygen demand (BOD), on the order of 40 kg/ha·d to achieve an outflow concentration of 30 mg/L (Reed *et al*., 1988). BOD loading is still the recommended design method for ponds, although with modifications, that acknowledge temperature effects (Shilton and Mara, 2005; Shilton, 2005). At 3°C, the recommended loading rate is 40 kg/ha·d, which is the winter condition for cold climate systems. As the minimum winter temperature goes up, say, to 20°C for a tropical climate, the allowable loading goes up as well to about 250 kg/ha·d. Reed *et al*. (1988) suggested using the BOD-loading rate to the wetland as a constraint, not for design sizing, with an upper limit of 100 kg/ha·d. It is perhaps coincidental that U.S. EPA (2000a) concluded that the allowable design loading to a fully vegetated FWS wetland should be 40 kg/ha·d, identical to that for temperate pond design.

The areal-loading procedure may easily be converted to a population equivalence (PE), if the person equivalence of the particular wastewater is known. For instance, the per-person BOD generation rate in the United States is approximately 63 g/PE·d (U.S. EPA, 2002c) and in Austria is specified as 60 g/PE·d (Haberl *et al*., 1998). In the United States, BOD generation is also taken to be 60 g/PE·d, but a septic tank (or other primary treatment device) is virtually always used as pretreatment for domestic wastes, and therefore 40 g/PE·d is used as the influent to a wetland (Wallace and Knight, 2006). So, for example, if a design specification is 5 $m^2$/PE for a HSSF wetland treating primary effluent, then the equivalent loading specification is 40/5 = 8 g/$m^2$·d = 80 kg/ha·d.

To compare first-order calculations to loading criteria, the hydraulic loading to the wetland must be known. The rate-constant approach separates the effect of inlet concentration from that of flow rate. The water flow per person equivalent is to some extent independent of the amounts of pollutants generated. Water usage in a typical household varies from 50 to 200 L/PE·d, depending on whether it is situated in an arid or wet location, or in a developed or developing country. Small communities have slightly greater water usage per person.

The relationship between rate-constant specification and areal-loading specification is straightforward, but not unique: the rate approach is strength (concentration) dependent and the loading method is not. The connection for a pollutant with zero background is

$$C_o = C_i \exp\left(-\frac{k}{q}\right) = C_i\left[\exp\left(-\frac{kC_i}{qC_i}\right)\right] \qquad (15.1)$$

where

$C_i$ = inlet concentration, mg/L
$C_o$ = outlet concentration, mg/L
$k$ = rate constant, m/d
$q$ = hydraulic loading, m/d

and

$qC_i$ = pollutant loading, g/$m^2$·d

It is clear from Equation 15.1 that the outlet concentration depends not only on inlet pollutant loading but also on inlet concentration.

Suppose it is required that $C_o < 25$ mg/L, and that $k = 0.1$ m/d. For $C_i = 100$ mg/L, the allowable hydraulic loading is $q = 0.072$ m/d. The corresponding pollutant loading is 7.2 g/m²·d. However, if the inlet concentration is $C_i = 200$ mg/L, the rate model suggests that the allowable hydraulic loading is $q = 0.048$ m/d and the corresponding pollutant loading is 9.6 g/m²·d. Thus, the rate approach gives different area requirements, depending on waste strength. To further complicate the matter, we might consider that the two cases differed only in water use, and that the same number of population equivalents (same mass load) was involved. Suppose PE = 100 and the per capita generation was 50 g/PE·d, for a total of 5,000 g/d. For the weak strength of 100 mg/L (more water usage), the area required would be 5,000/7.2 = 694 m² or 6.9 m²/PE. For the stronger strength of 200 mg/L (less water usage), the area required would be 5,000/9.6 = 520 m² or 5.2 m²/PE. Thus, the loading method and the rate method are not equivalent.

## Regression Equations

The principal variables that determine the outlet concentration ($C_o$) are the hydraulic loading ($q$), or the equivalent detention time ($h/q$), and the inlet concentration ($C_i$). Other influences include temperature, solar radiation, and pH. There is, therefore, the possibility of simply postulating a functional relation, such as a product-power law, and regressing intersystem wetland input–output data to fit that equation. In so doing, some of the power of intrawetland data is lost, because such regression formulae may not represent the observed longitudinal profiles for a specific wetland. However, there can be no doubt that an individual data set can be fit with a reasonable guess at a fitting formula, because there are typically three or more fitting parameters. For example, Kadlec and Knight (1996) set forth linear regressions and power law regressions for different common pollutants. A few examples are:

Gumbricht (1993a), total nitrogen leaving a single FWS SAV system ($R^2 = 0.92$):

$$C_o = 1.63 + 0.78C_i - 1.7\ln(\tau_{nom}) \tag{15.2}$$

where

$C_i$ = inlet concentration, mg/L
$C_o$ = outlet concentration, mg/L
$\tau_{nom}$ = nominal detention time, d

Kadlec and Knight (1996), nitrate leaving several FWS systems of different types ($R^2 = 0.35$):

$$C_o = 0.093\, C_i^{0.474} q^{0.745} \tag{15.3}$$

where

$q$ = hydraulic loading rate, cm/d

Tunçsiper *et al*. (2006), ammonia leaving one square meter HSSF mesocosms with various plants ($R^2 = 0.67$):

$$\left(\frac{(C_i - C_o)}{C_i}\right) = 0.371\ \text{pH} - 0.0048\, q + 0.080\, C_i - 2.286 \tag{15.4}$$

The operational data and multiple linear regression models are shown in Figure 15.2, along with the rate-constant model. Tunçsiper *et al*. (2006) concluded that the multiple linear model was better, but that is not supported by the sum of the squared errors derived from data and models (SSQE = 0.30 for rate-constant model, and SSQE = 1.98 for multiple linear model).

Great care must be exercised in defining the variable ranges of such regression models. The potential extremes of

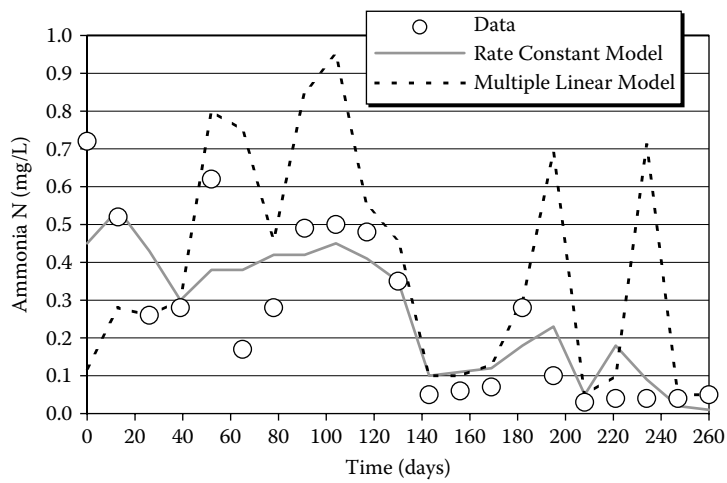

**FIGURE 15.2** Time series of ammonia concentrations exiting HSSF mesocosms, together with rate constant and multiple linear regression models. (From Tunçsiper *et al*. (2006) *Water Science and Technology* 53(12): 111–120. Reprinted with permission.)

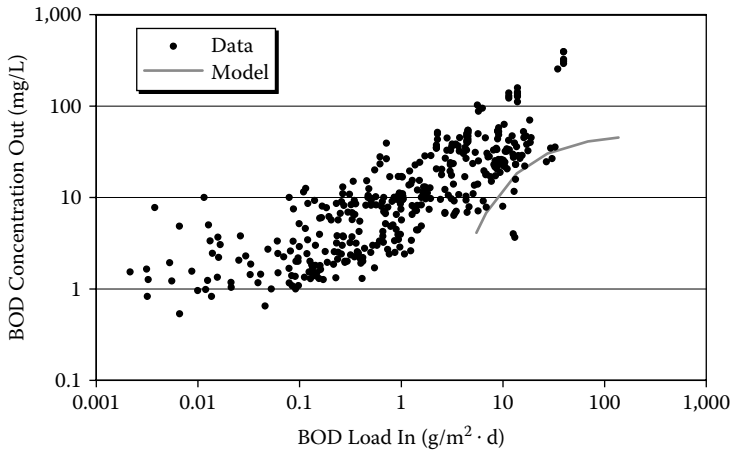

**FIGURE 15.3** A presumptive model line on the BOD-loading graph for an inlet concentration of 50 mg/L. The model is the first-order volumetric with $k_{V1} = 0.678$ d$^{-1}$ and with $C^* = 0$, but truncated at BOD < 5 mg/L per literature recommendation. A free water depth of 45 cm is presumed for the model.

variables can produce unintended anomalies that are a potential trap for designers. For instance, the Gumbricht (1993a) regression (Equation 15.2) produces negative concentrations for long-detention times, a fact that might go unnoticed by a potential user of this equation set. The Kadlec and Knight (1996) regression (Equation 15.3) suggests that $C_o$ increases with decreasing $C_i$ for $C_i < 1.0$ mg/L, which is a highly improbable circumstance. The Tunçsiper *et al*. (2006) regression (Equation 15.4) shows that removal goes up with inlet concentration and, in fact, for $C_i > 10$ mg/L, more than 100% removal is forecast. That $C_i$ is higher than the calibration range, but an unsuspecting designer could easily misapply Equation 15.4 to that condition.

These example regressions contain 3, 3, and 4 parameters, respectively. Any possibility of generalization, and use in design, is hindered by the need to predict all of those coefficients in a new situation. Consequently, regression equations have not found use in treatment wetland design.

## 15.2 FREE WATER SURFACE WETLANDS

Early FWS treatment wetlands were often natural wetlands employed to improve water quality. Although those ecosystems were preexisting, there was no issue of sizing, but rather an issue of how much water could be put into the wetland. Recipes existed, and continue to exist, covering the appropriate hydraulic loading to natural systems (e.g., for Florida). In contrast, FWS constructed wetland design sizing for continuous flows has historically been virtually entirely performance based.

Unfortunately, there has been considerable misinterpretation and misuse of these simplistic models. One of the problems has been unsupported pronouncements of model parameters. When plug flow and $C^* = 0$ are presumed, there is only one parameter remaining, which is here designated as $k_1$ (or $k_{V1}$). For instance, there is an oft-repeated value of $k_{V1} = 0.678$ d$^{-1}$ in U.S. literature for BOD reduction in FWS wetlands at 20°C (Reed *et al*., 1995; Water Environment Federation, 2001; Crites *et al*., 2006). This value is intended for use in an exponential (plug flow) model with a zero background concentration. Although no basis for this number has ever been presented, it is now possible to place it in the perspective of calibrations for large numbers of FWS systems. The suggested value, for a system 40 cm deep, corresponds to $k = 100$ m/year. This ranks at the 98th percentile of $k_1$-values for 386 wetland-years of data for FWS wetlands (Figure 15.3). From Figure 15.3, it is clear that the exponential plug-flow model with $C^* = 0$ has the wrong shape compared to intersystem data, and therefore a different calibration $k_V$ cannot fix it. Most of the time this particular single-parameter model will overestimate removals, as well as the model providing incorrect trends.

## 15.3 STORMWATER WETLANDS

Stormwater wetlands are also FWS systems, but these differ markedly in design philosophy. Early in the brief history of urban stormwater wetlands, data was collected from a variety of constructed and natural systems, and the central performance tendency of these treatment wetlands was determined (Strecker *et al*., 1992; Schueler, 1992). The time-variable nature of stormwater wetlands means that the information was and is quite sparse. Source characterization is difficult and often the result of semiquantitative rules for the amounts of water and pollutants that are washed off of various types of watersheds.

Given this meager performance base, it is not surprising that the earliest sizing rules were empirical. One method involves the specification of the wetland area compared to the contributing watershed area, the wetland-to-watershed area ratio (WWAR). This is a scaling rule, comparable to those in use for continuous-flow FWS wetlands. The implied performance of a particular WWAR is inferred from the performance data from operating systems similar to WWAR.

A second approach relies on the capture and detention of a specified amount of runoff, which is then subject to treatment during the interevent period. For instance, the anticipated runoff from a rain event of specified return frequency may be used to set the wetland water volume. Runoff from larger events is partially bypassed or runs quickly through the wetland. Again, the implied degree of treatment is that associated with holding the water during the interim periods.

A third approach involves adapting the continuous flow rate-constant method to event-driven systems. The use of the *k-C** model, with average flow rates, was suggested by Kadlec and Knight (1996) and by Wong and Geiger (1997). A number of calibrations for stormwater systems were provided in the summary of Carleton *et al*. (2001). More recently, the concept has been extended to the *P-k-C** model by Wong *et al*. (2006).

A drawback of the use of *P-k-C** calculations for event-driven wetlands is that rate constants for continuous-flow situations do not necessarily carry over to the averaged transient-flow situation (Kadlec, 2001a). As a result, dynamic modeling is to be preferred. However, the complexity of dynamic modeling is daunting, partly because of the need to construct input time sequences for a significant period of operation. Nonetheless, for large and costly projects, dynamic simulations may be warranted. Currently, these are in use for the design of the phosphorus removal wetlands in South Florida (Walker and Kadlec, 2005).

## 15.4 HORIZONTAL SUBSURFACE FLOW WETLANDS

Over the last 50 years, multiple variations of horizontal subsurface flow (HSSF) wetlands have been developed, and in more recent years, HSSF wetland technology has made significant advances. As a result, there are a large number of reference documents on HSSF wetlands that contain outmoded concepts and should no longer be used for design purposes. This section provides an overview of HSSF wetland design and how the technology has evolved.

### The Root-Zone Method

In 1952, a German scientist, Kathe Seidel, began investigating the water purification capabilities of bulrush (*Schoenoplectus lacustris*) grown in artificial-rooting environments. In the early 1960s, in collaboration with Seidel, Reinhold Kickuth at the University of Göttingen, Germany, developed a wetland treatment process known as the *root-zone method* (Wurzelraumentsorgung) (Brix, 1994d). Root-zone method wetlands are comprised of a soil media (typically clay loam to sandy clay), and calcium, iron, or aluminum additives were sometimes proposed as additives to the media to increase phosphorus adsorption (Kickuth, 1977). The soil was seen as a reactive media, a concept that has resurfaced with HSSF wetlands using expanded shale and clay aggregates (see Chapter 10). Although no longer considered a modern design concept, many wetlands designed on the principles of the root-zone method exist in Europe.

In most of the root-zone method wetlands, the exclusive use of the common reed (*Phragmites australis*) was based on the theory that root formation would increase the hydraulic conductivity of the soil matrix from approximately $10^{-5}$ m/s to $10^{-3}$ m/s within two to four years (Cooper and Boon, 1987). The intended hydraulic conductivity of the soil ($10^{-3}$ m/s) required many of these wetlands to be considerably wider than their length, and the beds were often tipped at a slope of 1% or greater to increase the gradient in the (mistaken) belief that the tipped beds would force subsurface flow through the beds (Figure 15.4).

After a few years, the collaboration between Seidel and Kickuth ended for personal reasons. Both scientists and their respective schools became rivals. The information produced by the two groups during this period was often conflicting, and resulted in confusion among practicing wastewater engineers and the governing regulatory authorities (Börner *et al*., 1998). By the early 1980s, most wetlands in Germany were being constructed on the root-zone method, although examples of the MPIP (Seidel) system were constructed in St. Bohaire, France (Liénard *et al*., 1990), and Oaklands Park, United Kingdom (Burka and Lawrence, 1990).

### Evolution of HSSF Wetland Design in Europe

In 1984, water utilities in the United Kingdom began to investigate the root-zone method as an alternative for small treatment works (Cooper and Boon, 1987). An effort was made to coordinate research efforts with Denmark, Germany,

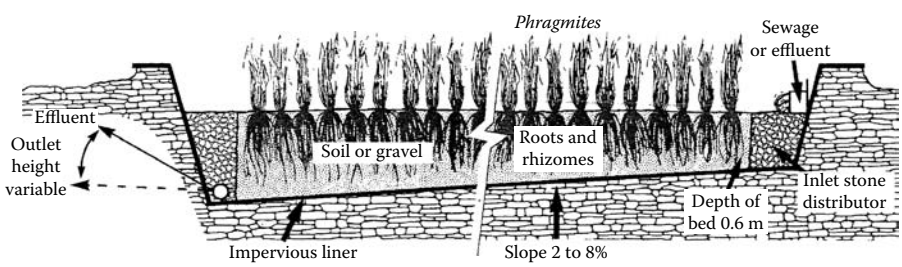

**FIGURE 15.4** Example of an early root-zone method HSSF wetland. (From Cooper and Boon (1987). In *Aquatic Plants for Water Treatment and Resource Recovery*. Reddy and Smith (Eds.), Magnolia Publishing, Orlando, Florida, pp. 153–174. Reprinted with permission.)

France, Spain, and the Netherlands. Early treatment wetlands in Denmark and the United Kingdom had designs based on the root-zone method principles. The claim of hydraulic-conductivity improvement from $10^{-5}$ m/s to $10^{-3}$ m/s did not hold true. Instead, the hydraulic conductivity either remained stable or decreased with time, remaining on the order of $10^{-5}$ m/s (Brix and Schierup, 1989a; Netter and Bischofsberger, 1990; Findlater *et al*., 1990; Coombes, 1990; Bucksteeg, 1990).

Because the anticipated increase in hydraulic conductivity did not occur, the HSSF beds did not have enough cross-sectional area to allow for subsurface flow. As a result, water would pond at the inlet and flow across the surface of the bed. Thus, the hydraulically failed mode of operation for these wetlands was overland flow—essentially a FWS wetland with a very shallow water depth. As it has turned out, there is not a large difference in treatment performance between FWS and HSSF wetlands, so the overland flow mode of operation has often been tolerated because it provides an acceptable level of treatment, even though the systems do not function as intended.

However, some of these systems were constructed with sloping beds (top and bottom surfaces both sloped). When overland flow occurred, the water would channelize, further reducing treatment performance. These experiences led to the creation of design standards for subsurface-flow wetlands based on coarser bed materials and beds with flat upper surfaces (only bottom surface sloped) (WRc, 1989).

Other root-zone method predictions also turned out to be inaccurate. The actual oxygen transfer from the plant root systems was much lower than anticipated (Brix and Schierup, 1990). In addition, actual BOD removal was slower (observed rate removal coefficient of 0.10 m/d versus the predicted 0.19 m/d), resulting in a trend towards larger bed areas (5 $m^2$/PE versus 2.2 $m^2$/PE) (EC/EWPCA Emergent Hydrophyte Treatment Systems Expert Contact Group and Water Research Centre, 1990).

Regional differences in HSSF wetland designs still exist. The practice in Germany is to use relatively fine sand (0.2 mm to 1.0 mm) (Gesellschaft zur Förderung der Abwassertechnik d.V [GFA], 1998) because it is thought to be the best compromise between available surface area for biofilm growth, suitability as a rooting media, and hydraulic conductivity (Geller, 1996). Because they are designed in accordance with Darcy's law, these beds are much wider than they are long. This design tactic minimizes the organic loading across the inlet cross-sectional area. German authorities report that the decomposition of most organic substances is essentially complete within 1 to 2 m of the inlet zone (Geller, 1997). Figure 15.5 is a schematic representation of a HSSF wetland in Germany (Geller *et al*., 1990).

The HSSF wetland systems in Austria, the Czech Republic, and the United Kingdom are usually designed with the media of similar diameter. Austrian standards recommend the use of a gravel media between 4 and 8 mm (ÖNORM B 2505, 1997). HSSF wetlands in the Czech Republic tend to use sand and gravel less than 20 mm (Vymazal, 1996). In the United Kingdom, bed materials of 3 to 6 mm and 5 to 10 mm have been recommended (EC/EWPCA Emergent Hydrophyte Treatment Systems Expert Contact Group and Water Research Centre, 1990). HSSF wetlands using coarser materials are often constructed with a length-to-width (L:W) ratio of greater than 1.0. For example, the average L:W ratio was 1.76:1 for 28 HSSF wetlands in the Czech Republic (Vymazal, 1996).

Wetland systems throughout Scandinavia are typically dimensioned using EC/EWPCA criteria. In Norway, the use of light-expanded clay aggregate (LECA) has been used as an alternative to gravel (Jenssen *et al*., 1994b). Assessment of the performance of these wetlands indicates that LECA has a high-phosphorus sorption capacity (Jenssen *et al*., 1996) compared to natural aggregates. As the technology has gained acceptance in Scandinavia, LECA remains one of the preferred media materials because of its availability and its ability to bind phosphorus (Jenssen *et al*., 2002). Phosphorus removal in LECA wetlands occurs through chemical

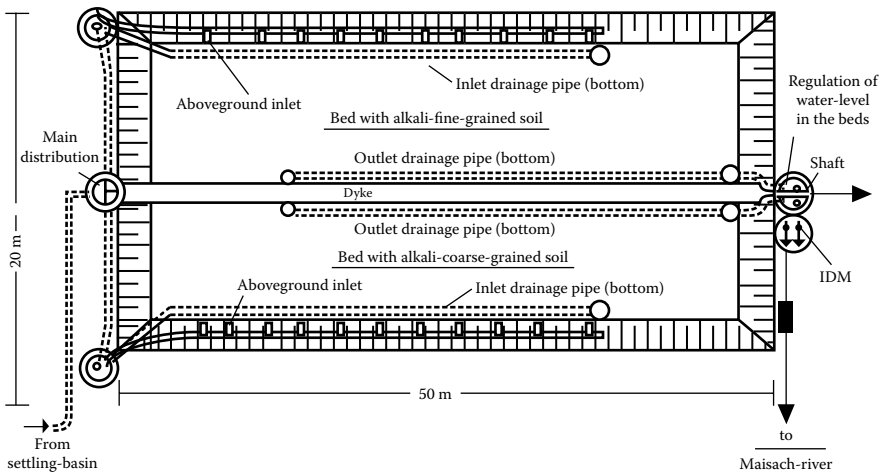

**FIGURE 15.5** HSSF wetland in Germerswang, Germany. (From Cooper and Findlater (1990) *Constructed Wetlands in Water Pollution Control.* Pergamon Press, New York. Reprinted with permission.)

adsorption to the surface of the media (Zhu *et al*., 1997). When the sorption sites are exhausted, phosphorus removal ceases. Studies in Sweden indicate that these adsorption sites are primarily associated with iron and aluminum oxides present on the surface of the particle, and are a function of the parent material and manufacturing process (Johansson, 1997). Materials with similar surface characteristics also display comparable phosphorus removal capabilities (Brooks *et al*., 2000). Phosphorus sorption capacities of various SSF aggregates are discussed in detail in Chapter 10.

The HSSF wetlands are recognized as being effective for BOD removal. However, due to the low-oxygen transfer rates in HSSF wetlands, nitrification is limited. Vertical flow wetlands that are capable of nitrification are being used increasingly in Europe (Cooper *et al*., 1997). Combinations of vertical flow and horizontal flow wetlands are being developed (Platzer, 1996; Cooper, 1999). These hybrid systems are designed with the goal of nitrification (in the vertical flow wetland) and denitrification (in the horizontal flow wetland).

## Evolution of HSSF Wetland Design in North America

In the United States between 1972 and 1976, Frederic Spangler and colleagues studied artificial wetlands (Spangler *et al*., 1976b) in conjunction with a study of the assimilation capabilities of natural wetlands. The earliest artificial marsh cells contained wire frames to support the emergent wetland plants, but this was quickly abandoned in favor of gravel media (19 to 25 mm) covered with smaller pea gravel. These early gravel-filled marsh cells could be operated with the water above or below the gravel surface, although subsurface flow was identified as the preferred mode of operation.

In 1973, Seidel obtained a U.S. patent (Seidel, 1973), and her concepts were more widely introduced in the United States (Wolverton, 1987a). By 1981, B.C. (Billy) Wolverton and his colleagues at the National Aeronautics and Space Administration (NASA), who had been researching floating-plant treatment systems, began to focus on subsurface-flow wetlands (Wolverton, 1983). These rock–reed filters were very long and narrow and used a coarse gravel media of crushed railroad ballast (Wolverton, 1987b). Although these HSSF wetlands were similar to the horizontal stages in the Max Planck Institute Process (MPIP) systems, they operated without the preceding vertical flow wetland cells. Figure 15.6 is a schematic representation of an early rock–reed filter for a single-family home (Wolverton and Wolverton, 2001).

Richard Gersberg and colleagues began to study nitrogen transformations in pilot-scale subsurface-flow wetlands (Gersberg *et al*., 1983) and larger demonstration-scale wetlands (Gersberg *et al*., 1984) in Santee, California. Early studies treated nitrified secondary effluent, although primary effluents were used in later studies. Subsequent work focused on pathogen reduction in subsurface-flow wetlands (Gersberg *et al*., 1987).

In 1988 the U.S. Environmental Protection Agency published a design manual on constructed wetlands that outlined design procedures for subsurface-flow wetlands (U.S. EPA, 1988b). This manual included a first-order plug-flow equation for BOD reduction with a temperature- and surface-area-adjustable removal rate. Media sizes ranged from a $d_{10}$ of 1 to 8 mm, with associated hydraulic conductivities of $4.9 \times 10^{-3}$ to $5.8 \times 10^{-3}$ m/s. The 1988 manual was replaced with updated manuals in 1993 (U.S. EPA, 1993c) and 2000 (U.S. EPA, 2000a).

The Tennessee Valley Authority (TVA) began demonstration of subsurface-flow constructed wetlands in 1986, based on design information obtained from the work of Kickuth, Wolverton, and Gersberg (Steiner *et al*., 1987). This led to the development of a guide for small system and single-family home wetland system design in 1991, which was

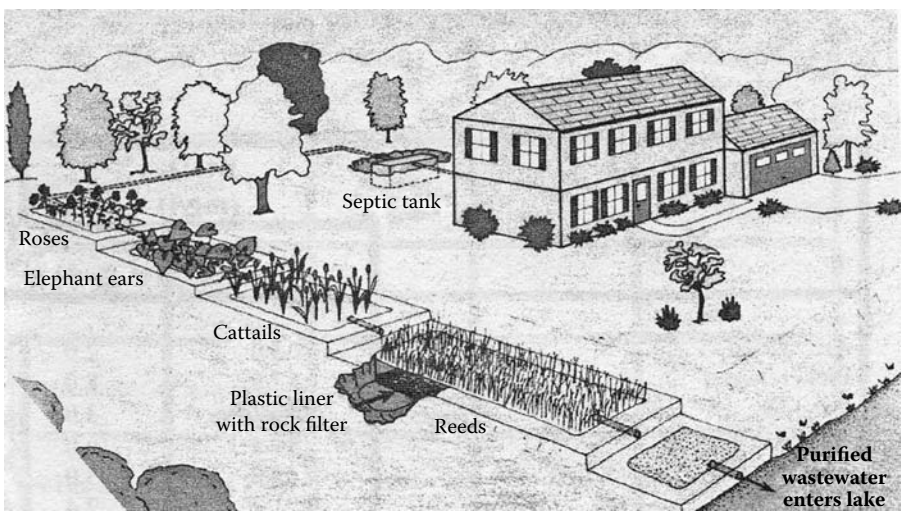

**FIGURE 15.6** Early rock–reed filter concept for treatment of wastewater from a single-family home. (From Wolverton and Wolverton (2001) *Growing Clean Water.* Wolverton Environmental Services, Picayune, Mississippi. Reprinted with permission.)

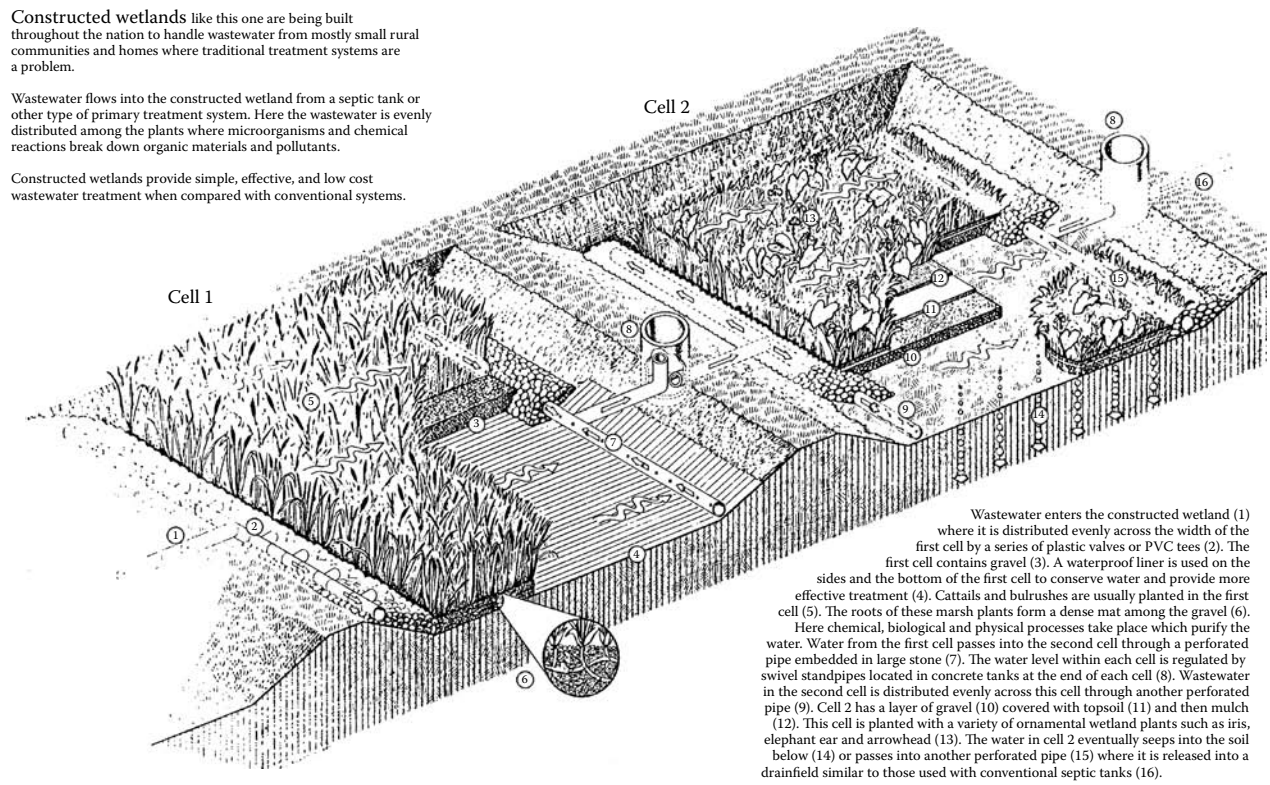

**FIGURE 15.7** HSSF wetland schematic from TVA wetland design manual. (From Steiner and Watson (1993) *General Design, Construction, and Operation Guidelines: Constructed Wetlands Wastewater Treatment Systems for Small Users Including Individual Residences.* Second Edition, TVA/WM-93/10, Tennessee Valley Authority Resource Group Water Management: Chattanooga, Tennessee.)

revised and updated in 1993 (Steiner and Watson, 1993). A schematic representation from this early guide is shown in Figure 15.7.

The sizing criterion was effectively 11 $m^2$/PE. The TVA guidelines recommended a gravel media of 3 to 6 mm, presumed to have hydraulic conductivity of $3 \times 10^{-3}$ m/s, be used to account for clogging in the gravel bed. This guideline also recommended that the cross-sectional organic loading be limited to less than 244 g BOD/$m^2$·d to minimize the potential for bed clogging and associated overland flow.

In 1993, the U.S. Environmental Protection Agency published a technology assessment of subsurface-flow wetlands (U.S. EPA, 1993f) that compared the design methods of Wolverton and TVA. This report recommended a first-order plug-flow equation for BOD reduction, corrected for temperature. Media sizes of 12 to 25 mm with a presumed hydraulic conductivity of $1.2 \times 10^{-2}$ m/d and an L:W ratio of 2:1 were recommended. Also in 1993, Region Six of the U.S. Environmental Protection Agency published design guidelines that originally recommended 50- to 250-mm rock media (U.S. EPA, 1993c); this recommendation was later revised to be in conformance with the 1993 Technology Assessment (U.S. EPA, 1993f).

In 1995, Sherwood Reed and his colleagues published design recommendations for subsurface-flow wetlands (Reed *et al*., 1995), which essentially expanded on an earlier work (Reed *et al*., 1988). Reed's work included thermal design, a first-order plug-flow equation for BOD and ammonia removal, and an empirical relationship for total suspended solids (TSS) removal. Recommended media sizes ranged from a $d_{10}$ of 2 to 128 mm, with presumed hydraulic conductivities between $1.2 \times 10^{-3}$ m/s and 2.8 m/s. Reed's work also recommended that no more than 20% of the clean-bed hydraulic conductivity be used for design purposes.

In 1996, Robert Knight and Robert Kadlec published design recommendations based on an areal-based, first-order equation set with nonzero background concentrations for BOD, total suspended solids (TSS), ammonia, nitrate, total nitrogen, phosphorus, and fecal coliform (Kadlec and Knight, 1996). This approach was later reported in an international guideline (IWA Specialist Group on Use of Macrophytes in Water Pollution Control, 2000).

Kadlec and Knight provided methods for determining hydraulic conductivity based on the grain size of the media, with the recommendation that only 10% of the clean-bed hydraulic conductivity be used for design purposes. Methods to calculate the water surface profile within the wetland were also provided. These methods were applied in a forensic analysis of a HSSF wetland with inlet ponding problems (Kadlec and Watson, 1993).

In 2000, the U.S. Environmental Protection Agency published a new design manual on constructed wetlands

(U.S. EPA, 2000a). This manual provides data on the treatment performance of a few wetland systems. Recommendations included an areal-loading rate of less than 6 g BOD/$m^2$·d to achieve an effluent concentration of less than 30 mg/L, and a loading rate less than 20 g TSS/$m^2$·d to achieve an effluent concentration less than 30 mg/L. Recommended gravel size was 20 to 30 mm. For the first 30% of the wetland bed, no more than 1% of the clean-bed hydraulic conductivity was to be used for design.

In 2006, the Water Environment Research Foundation (WERF) published design guidelines for small-scale HSSF wetlands (Wallace and Knight, 2006). This work substantially expanded on the loading chart concept proposed by U.S. EPA (2000a), by providing statistical confidence bands on the loading charts (although only for a narrow range of loading conditions). The concept of cross-sectional organic loading versus the size of the wetland bed materials was introduced as a means to forecast the clogging potential in the inlet zone of HSSF wetlands.

### Reflections on Old HSSF Design Procedures

Looking back on the development of HSSF design methods, it can be seen that early procedures of sizing HSSF wetlands involved the use of a first-order volumetric rate constant (plug flow, $C^* = 0$) for BOD reduction (Reed *et al*., 1988; Bavor *et al*., 1989; Schierup *et al*., 1990; Cooper 1990). However, in Europe and North America, the vast majority of the applications were for domestic wastewater treatment for small villages or single-family homes (Figure 1.6) for which there was no existing flow or inlet BOD information. Consequently, specifications were driven toward scaling the wetlands based upon population equivalents, which is equivalent to a loading specification. Thus, it is seen that the same two approaches to sizing used for FWS wetlands have also been used for HSSF systems.

The existence of multiple approaches invites comparisons, and the treatment wetland literature does not disappoint. Unfortunately, most such published comparisons are not appropriate. One common theme is to compute outflow concentrations for conditions of a specific (new) data set using the published central tendency rate constant from multiple preceding studies (see, for instance, Liu *et al*. (2000) or Walker and Walker (1990). Of course, it would be an accident if the new data set followed the mean prediction based on a central tendency. The scatter of rate constants among different wetlands has been shown to be quite large in the information presented in Part I (see, for example, Table 8.7) and concentration predictions depend on rate constants in an exponential fashion. A better approach is to compare the calibrated *k*-value from a new data set to the existing, known distribution of such calibration *k*-values.

There has also been a seemingly irresistible urge, in past literature, to either look for or use a single, universal *k*-value. For example, there is an oft-repeated value of $k_V = 1.104$ $d^{-1}$ in U.S. literature, for BOD reduction in HSSF wetlands at 20°C, for $C^* = 0$ (U.S. EPA, 1993c; Reed *et al*., 1995; Crites and Tchobanoglous, 1998; Water Environment Federation, 2001; Crites *et al*., 2006). When plug flow and $C^* = 0$ are presumed, there is only one parameter remaining, which is here designated as $k_1$ (or $k_{V1}$). Although no basis for this number has been presented in the literature, it is now possible to place it in the perspective of calibrations for large numbers of HSSF systems.

This suggested value, for a system 45 cm deep and with 38% porosity, corresponds to $k = 70$ m/year (see Equation 6.62). This ranks at the 80th percentile of $k_1$-values for 200 HSSF wetlands treating primary or secondary wastewaters, so most of the time this particular single-parameter model will overestimate pollutant removals.

Two values of $k_1$ are reported by Cooper *et al*. (1996): $0.06 \times 365 = 22$ m/year for secondary reedbeds, and $0.31 \times 365 = 113$ m/year for tertiary reedbeds. Kadlec and Knight (1996) reported a range of *k* and $C^*$ values. When those same systems are analyzed for $k_1$ values, the range is 20–98 m/year, with a median of 44 m/year. These historical estimates are now supplanted by a much larger worldwide database (Figure 15.8). Although the plug-flow model with $C^* = 0$ (rate constant = $k_1$) should not be used for reasons previously discussed, and it is now clear that historical rate-constant estimates using this model have not stood the test of time as more performance data for HSSF wetlands has become available. Those "old" estimates are for rate constants far higher than those reasonably supported by the modern data set. So, not only is the single-parameter model not particularly suited to HSSF wetlands, but the available calibration estimates do not achieve good data fits, either.

## 15.5 VERTICAL FLOW WETLANDS

Vertical flow (VF) wetlands are a newer type of treatment wetland, having come into widespread use in the mid-1990s. Several variations of the technology exist; pulse-loaded systems (most commonly implemented in Europe), recirculating vertical flow (used in North America but based on old standards for recirculating gravel filters), continuous ponded downflow (for mine water treatment), and fill-and-drain (tidal flow) wetlands.

The treatment performance of all these vertical flow systems is significantly affected by operational factors such as instantaneous loading rates, the frequency of loading cycles, recirculation rates, and the length of resting interval between loading cycles. The relatively short history of technology development and the poorly quantified impact of operational factors on treatment performance have not allowed design methods to evolve beyond the empirical stage.

### Design of Vertical Flow Wetlands in Europe

In 1952, a German scientist, Kathe Seidel, began investigating the water purification capabilities of *Schoenoplectus lacustris* plants grown in artificial-rooting environments. Her discoveries gave birth to modern SSF-constructed wetlands (Börner *et al*., 1998) and led to the development of a wetland

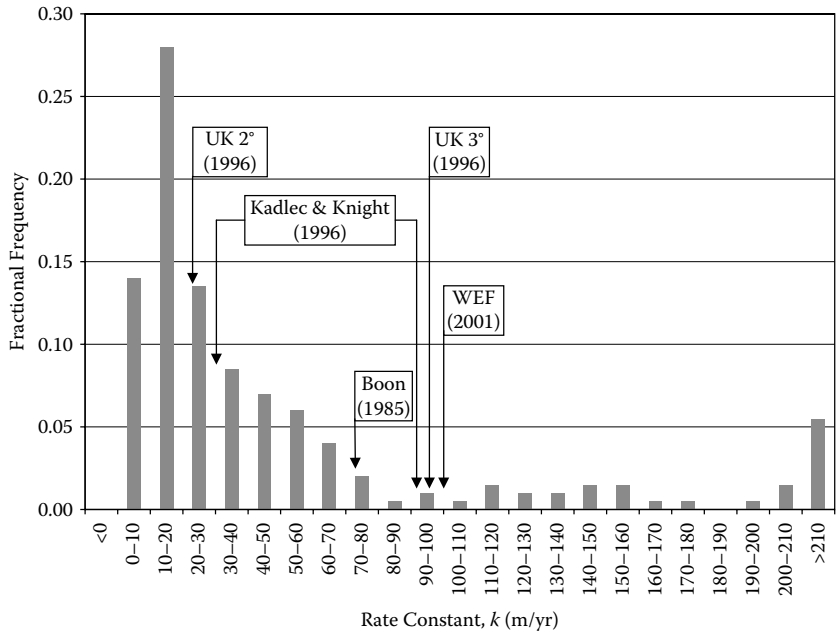

**FIGURE 15.8** Distribution of zero-background, plug flow BOD removal rate constants ($k_1$) for HSSF wetlands. The arrows mark the values from Boon (1985; 70 m/yr), Cooper *et al*. (1996; 22 m/yr for secondary, 113 m/yr for tertiary reedbeds in the United Kingdom), and Kadlec and Knight (1996; these are not the *k-C** values; rather they are $k_1$ values for the same data systems) and the median is 44 m/yr, and WEF (2001; only one number given). The bars represent values from 200 HSSF wetlands that have a median of 24 m/yr.

treatment system known as the Max Planck Institute Process (MPIP), Seidel System, or Krefeld Process (Brix, 1994d), consisting of vertical flow wetland stages followed by HSSF wetland cells (Figure 15.9) (Liénard *et al*., 1990).

In Seidel's system, coarse material (sand and gravel) served as the rooting media for a variety of wetland plants. Vertical flow cells were generally square, and subsequent horizontal flow cells were long and narrow. Plants were thought to be the

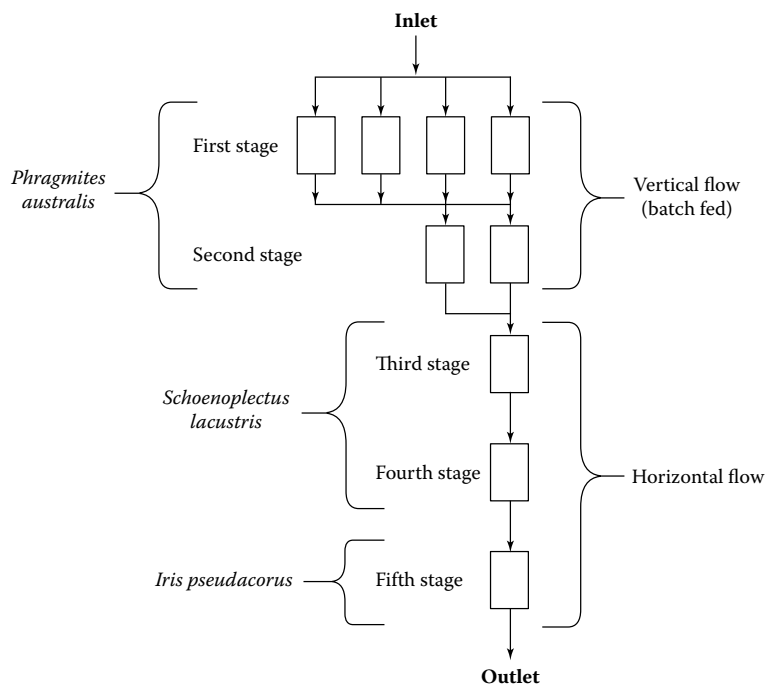

**FIGURE 15.9** Max Planck Institute Process wetland treatment system (plan view). (From Cooper and Findlater (1990) *Constructed Wetlands in Water Pollution Control*. Pergamon Press, New York. Reprinted with permission.)

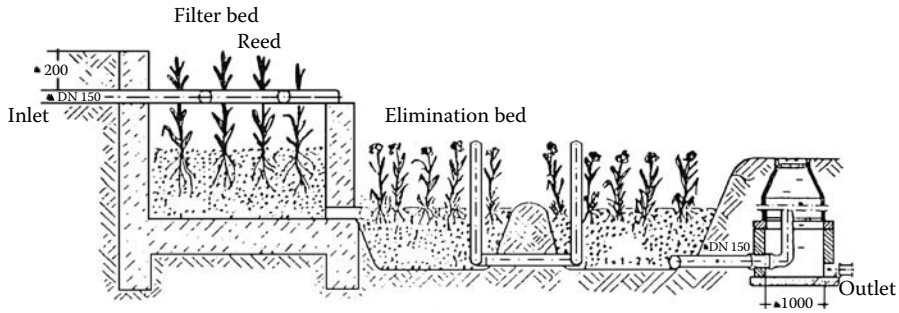

**FIGURE 15.10** Max Planck Institute Process wetland treatment system (profile view). (From Börner *et al*. (1998) In *Constructed Wetlands for Wastewater Treatment in Europe*. Vymazal *et al*. (Eds.), Backhuys Publishers, Leiden, The Netherlands, pp. 169–190. Reprinted with permission.)

main treatment mechanism in this process (Vymazal *et al*., 1998), but those ideas are now disputed (Langergraber, 2005). Figure 15.10 is a profile view of the MPIP process (Börner *et al*., 1998).

The long-term success of MPIP systems in Europe has led to a more widespread application of vertical flow systems based on pulse-loaded designs. These vertical flow cells are almost invariably linked to HSSF wetlands to create "hybrid" wetland systems. The VF–HSSF configuration is the most common, and relates back to the MPIP process, where initial VF wetlands are used to remove TSS and BOD that could create clogging problems in the downstream HSSF stages. However, an alternate configuration of HSSF–VF has been implemented (Brix, 1998), where the initial HSSF wetland is designed for BOD removal, so that nitrification is optimized in the downstream VF stage.

### Loading Specifications

Results from practice have resulted in several "rules of thumb," or scaling rules, that relate sizing of the wetland bed to an implied mass loading, expressed in population equivalents. Loading rates vary based on the implied level of treatment (BOD removal or nitrification). Various parameters have been used to calculate the footprint area of VF-constructed wetlands. Cooper (2005) summarized the most frequently used sizing criteria using the following nomenclature:

$$A = mP^b \tag{15.5}$$

where

$A$ = area of bed required, $m^2$
$b$ = exponent
$P$ = population equivalent
$m$ = scaling factor

Table 15.1 shows the various recommendations for achieving different and often unspecified goals.

### Implied Oxygen Transfer

There have also been attempts to relate VF wetland sizing to the implied oxygen transfer rate (IOTR) necessary for reductions in BOD and total Kjeldahl nitrogen (TKN). However, methods developed to date are based on traditional nitrification/denitrification stoichiometry, which has a higher oxygen demand than alternative nitrogen pathways such as anammox (see Chapter 9). It has often been assumed that reduction of

**TABLE 15.1**

| Weedon (2003) | U.K. | 5.4 | 0.60 | PE < 25 |
| Weedon (2003) | U.K. | 2.4 | 0.85 | PE > 25 |
| Boutin and Liénard (2003) | France | 2.5 | 1.0 | Two stages |
| Fehr *et al*. (2003) | Germany | 4 | 1.0 | — |
| Brix and Johansen (2004) | Denmark | 3 | 1.0 | 95% BOD reduction |
| Molle *et al*. (2005a) | France | 2 | 1.0 | 1.2 in 1st stage; 0.8 in 2nd stage; COD < 60 |
| ÖNORM (2005) | Austria | 4 | 1.0 | — |
| DWA (2006) | Germany | 4 | 1.0 | — |
| Langergraber *et al*. (2006a) | Austria | 4 | 1.0 | — |

BOD is strictly through aerobic mechanisms, although anaerobic reduction is also possible. Also, ammonia produced by ammonification of organic matter is typically not accounted. Further, BOD is utilized in the reduction of oxidized nitrogen, thus relieving the need for extra oxygen transfer to reduce BOD. Conversely, BOD is usually $BOD_5$, which is only about two thirds of the ultimate BOD. As a result, the implied oxygen demand calculated in the literature from these methods should be not considered the same as the actual oxygen transfer rate.

A rough estimation of the implied total oxygen transfer rate across vertical flow stage was presented by Cooper (1999):

$$\mathrm{IOTR} = \left(\frac{Q}{A}\right)\left[(\mathrm{BOD_{in}} - \mathrm{BOD_{out}}) + 4.3(\mathrm{NH_4N_{in}} - \mathrm{NH_4N_{out}})\right] \tag{15.6}$$

where

$A$ = bed area, $m^2$
$BOD_{in}$ = inlet BOD, mg/L
$BOD_{out}$ = outlet BOD, mg/L
IOTR = implied oxygen transfer rate, $gO/m^2 \cdot d$
$NH_4$-$N_{in}$ = inlet $NH_4$-N, mg/L
$NH_4$-$N_{out}$ = outlet $NH_4$-N, mg/L
$Q$ = flow rate, $m^3/d$

Cooper (1999) recognized that this approximation does not allow for BOD removal by settlement/filtration or denitrification, nor for $NH_4$-N lost through (a) plant uptake, (b) volatilization, or (c) adsorption. Additionally, the other factors enumerated in the preceding text are not accounted. The stoichiometric factor of 4.3 used to estimate the $O_2$ needed for ammonia oxidation comes from work on nitrification in activated sludge systems. The author pointed out that $NH_4$-N for a fresh sewage is also an underestimate of the potential $NH_4$-N when all the organically bound nitrogen in urea has been hydrolyzed. Therefore, TKN is a better measure but is not often reported, especially in the European literature.

Platzer (1998; 1999) used an equation similar to Equation 15.6 in which ($BOD_{in}$–$BOD_{out}$) was replaced by 0.7 ($COD_{in}$–$COD_{out}$). Platzer also took account of the $O_2$ recovered by denitrification. The IOTR was 23 g $O_2$ $m^2 \cdot d^{-1}$ for treatment units with a low-hydraulic loading rate and 64 g $O_2$ $m^2 \cdot d^{-1}$ for units with a high-hydraulic loading rate. Platzer (1999) pointed out that in the design of VF beds for nitrification, the most important criterion is that total oxygen input has to be higher than the oxygen demand. The oxygen demand is the sum of OD for decomposition of organic material and OD for nitrification. Platzer (1999) went on to estimate oxygen added by water and induced air flow, but there was no confirmation of these estimates beyond order-of-magnitude agreement with observations.

### Computer Models

A computer model, CW2D, has been developed to predict fate and transport of pollutants in pulse-loaded vertical flow wetlands (Langergraber, 2001). The CW2D is based on the HYDRUS-2D flow model (Simunek *et al*., 1999), which can simulate both saturated and unsaturated flow, and pollutant transformations are assumed to follow the activated sludge model No. 2 (Henze *et al*., 1995). The model contains 12 components and 9 processes. Various calibration studies have been performed (Meyer *et al*., 2006; Sleytr *et al*., 2006; Langergraber *et al*., 2006a; Tietz *et al*., 2006), but the model has not been widely implemented to date as a design tool.

## 15.6 COMMON DESIGN MISUNDERSTANDINGS

### Area- and Volume-Based Rates

Chapter 6 provides a discussion of the two forms of the *P-k-C** model:

$$\frac{(C - C^*)}{(C_i - C^*)} = \underbrace{\left(1 + \frac{ky}{Pq}\right)^{-P}}_{\mathbf{A}} = \underbrace{\left(1 + \frac{k\tau y}{Ph_F}\right)^{-P}}_{\mathbf{B}} = \underbrace{\left(1 + \frac{k_V \tau y}{P}\right)^{-P}}_{\mathbf{C}} \tag{15.7}$$

where

$C$ = concentration at fractional distance $y$, $g/m^3$
$C_i$ = inlet concentration, $g/m^3$
$C^*$ = background concentration, $g/m^3$
$h_F$ = wetland free-water depth, m
$k$ = first-order areal constant, m/d
$k_V$ = first-order volumetric rate constant, $d^{-1}$
$P$ = apparent number of TIS
$q$ = hydraulic-loading rate, ($= h_F/\tau$) m/d
$y$ = fractional distance, unitless
$\tau$ = nominal detention time, days

In these, it is clear that:

$$k_V = \left(\frac{k}{\varepsilon h}\right) = \left(\frac{k}{h_F}\right) \tag{15.8}$$

where

$\varepsilon$ = wetland porosity, dimensionless
$h_F$ = wetland water depth, m

It should be clear that there is no fundamental difference among Equations 15.7A,B,C other than the presumption of the depth variability of the rate constant—which is important. However, some incorrect interpretations of Equation 15.7A have appeared in the following literature.

1. " … detention time is not considered in the model" (Water Environment Federation, 2001). Of course it is; hydraulic loading is just free water depth divided by detention time.
2. " … water depth is not considered in the model" (Water Environment Federation, 2001). Water depth

is in fact considered in a better way than for volumetric models, because $k$ is more invariant than $k_V$ in most cases, as documented in Part I.

3. " … water losses and gains are lumped into the rate constant" (U.S. EPA, 1999). No more so than for the volumetric version. If one chooses to account for flow augmentation by averaging flows in and out to obtain an average detention time (an incorrect procedure—see Chapter 2), then the value of $q = h_F/\tau$ also changes accordingly. In Kadlec and Knight (1996), the correct modifications for augmented flow situations are clearly spelled out.
4. " … because of the internal position of $C^*$, it is not possible to design a system large enough to achieve an effluent with (less than) background concentrations." (Crites *et al*., 2006) True. The alternative is to choose a model that predicts a level of treatment performance that cannot be sustained by the wetland.

### Temperature Coefficients

One of the most baffling aspects of much of the treatment wetland literature is the way in which temperature effects are (not) quantified. To explain, consider the reduction of BOD in FWS wetlands. In the very early days of the emergence of constructed wetland technology, temperature coefficients were "borrowed" from other technologies such as trickling filters. These first guesses were that $\theta = 1.09$ (Tchobanoglous, 1987) or $\theta = 1.1$ (Reed *et al*., 1988; U.S. EPA, 1988b). However, these guesses were subsequently lowered to $\theta = 1.06$ (Crites, 1994; Reed *et al*., 1995; Crites and Tchobanoglous, 1998). However, Kadlec and Reddy (2001) listed 28 theta-factor determinations for 23 FWS wetlands that showed $\theta \approx 0.98$. Only four of the 28 determinations were greater than unity, and the highest was $\theta = 1.04$. Yet, in the face of so much data to the contrary, some literature sources steadfastly maintain that $\theta = 1.06$ (Crites *et al*., 2006).

### Excursion Containment and Safety Factors

Probabilistic effects are important in the utilization of design models for predicting removal performance of treatment wetlands. Regulatory requirements often employ a standard other than a long-term average. There may be a maximum monthly concentration not to be exceeded, or a specified concentration not be exceeded for more than a certain percentage of samples. Addressing wetland system variability in the design process is discussed in further detail in Chapter 16.

## 15.7 A CRITIQUE OF DESIGN METHODS

There are several reasons why existing design techniques for treatment wetlands can no longer be regarded as satisfactory if these are used in isolation. Nevertheless, there are very useful attributes of the two most prevalent approaches, and these will be the backbone of a broader approach presented here. The two approaches are loading specification and exponential decline modeling, both with variations.

### Loading Specification

These sizing methods are area-based scaling procedures in which either the hydraulic load or the pollutant load is set to values believed to meet some performance criteria. Common variants include:

A. For domestic wastewater treatment, the per-person area requirement may be set. Depending upon treatment needs, values in the range 5–20 $m^2$/PE are found in the literature. Domestic daily water usage varies from 100–400 L/PE·d and, hence, the equivalent hydraulic-loading rate to the wetland is 0.5–8 cm/d. The presumptive inlet water quality is that of settled sewage, and the presumptive treatment goal is something similar to secondary quality (30 BOD, 30 TSS). If the inlet BOD is 200 mg/L and personal volume is 300 L/PE·d, and the design is to 10 $m^2$/PE, the BOD loading is 60 kg/ha·d. The specification of square meters per-person equivalent is a traditionally popular method in Europe.
B. For municipal wastewater treatment, the inlet pollutant loading to the wetland may be set. The implied inlet water quality is that produced by a facultative pond or roughly 50–100 mg/L BOD. The presumptive treatment goal is usually slightly better than secondary, 20–30 mg/L of BOD and TSS. This method has been advocated by U.S. EPA (2000a) with criteria of 45–60 kg/ha·d BOD and 30–50 kg/ha·d TSS to achieve these levels.
C. For wastewater polishing of secondary or better effluents, there may be regulatory hydraulic- or nutrient-loading criteria. For example, the state of Florida requires less than 75 g/$m^2$·year total nitrogen (TN) and less than 9 g/$m^2$·year TP for waters treated in impaired natural wetlands.
D. Nominal detention time is an intuitive design specification: the longer the water stays in the wetland, the more treatment it will receive. FWS wetlands often have nominal detention on the order of a week. In some instances, regulation controls or constrains allowable designs. For example, the state of Indiana constructed wetland guidance document recommends a minimum of five days' detention (Indiana Department of Environmental Management, 1997), with agency approval required for shorter detention time. The province of Alberta constructed wetlands guidelines state that a detention time of at least seven to ten days is necessary (Alberta Environment, 2000). South Dakota states a minimum recommended detention time for treatment in an artificial wetland system of seven days, with 14 days being the most desirable (SDDENR, 1991).

E. The inlet hydraulic loading to the wetland is simply related to the nominal detention time: it is the mean free water depth divided by the detention time (see Part 1, Chapter 2). Many FWS wetlands have 30–40 cm of free water depth. Consequently, seven to ten days detention corresponds to 3–6 cm/d inlet HLR. Regulatory requirements for maximum HLR sometimes are set; for example, the State of Florida requires less than 2.2 cm/d HLR for waters treated in impaired natural wetlands.

## Loading-Based FWS Sizing—An Example

The following example is borrowed from U.S. EPA (2000a) and represents only the BOD portion of the sizing.

A FWS is to treat an average flow of 18,920 $m^3$/d of lagoon effluent, with an average BOD = 50 mg/L, to an effluent concentration of BOD = 30 mg/L. What size wetland is needed? (1 mg/L = 1 $g/m^3$)

Design rule: a maximum areal-loading rate of

$$40 \text{ kg/ha·d } (= 4 \text{ g/m}^2\text{·d})$$

Design calculation: $$\frac{(18{,}920\,\text{m}^3/\text{d})(50\,\text{g/m}^3)}{A} < 4\,\text{g/m}^2\text{·d};$$

Therefore, $$A > 236{,}500\ \text{m}^2 = 23.65\ \text{ha}$$

U.S. EPA (2000a) goes on to modify this area for a peak-flow factor and for open-water area inclusion, but the foregoing calculation is the central concept.

## Loading-Based FWS Sizing—Difficulties

These simplistic single-number rules have great appeal because they are quickly applied and easily understood. And, there is a popular misconception that wetlands and other natural systems should be amenable to intuitive quantification. This is certainly not the case, as has been repeatedly proved in wetland science. The structure and function of wetland ecosystems are very complex and require commensurately complex descriptions. The foundation for loading criteria is generally solid with large numbers of wetlands being considered. However, the single-number rules extracted from that information do not convey important details. Some of the problems with an unembellished loading approach are detailed here, as the basis for added steps in a design process.

1. Inlet loading may, in some circumstances, be an inappropriate correlating variable for the effluent concentration from the treatment wetland. This is almost certainly the case for total suspended solids under long-detention time and for nitrate in many situations. In the case of TSS under light loadings, settling is complete in the inlet zone of the wetland; therefore, solids leaving the wetland are most likely to be generated within the wetland and are not remnants of incoming TSS. Therefore, the TSS in the outflow relates to wetland processes, not to inlet loading. In the case of nitrate, if there is no nitrate in the inflow, then it is generated by nitrification. As a consequence, inlet loading has no relevance for outlet concentration except in those instances where the nitrate is the dominant form of nitrogen in the incoming water.
2. Hydraulic loading alone does not acknowledge either the incoming water quality or the goals of treatment.
3. Wetlands respond differently to concentration changes than they do to flow-rate changes. Pollutant loading by itself does not distinguish these separate effects.
4. Most of the numerous controlling features of a wetland are not present in these specifications. System attributes such as aspect ratio, number of cells, and water depth, and environmental factors such as water temperature, season, rainfall, and evaporation, are not explicitly considered. In sum, such factors combine to produce great variability in performance. Often, the single-number criterion represents only the central tendency of a very wide spread of annual results. It must be remembered that when the central tendency of data is selected as a design criterion, the odds are that the design will fail 50% of the time.
5. It is very easy, and very dangerous, to extrapolate designs into areas far outside the conditions that were used to derive the criterion. For instance, the U.S. EPA (2000a) criteria were derived from limited data from systems receiving a fairly narrow range of inlet concentrations, about 30–100 mg/L for BOD, TSS, and TN. Data for polishing wetlands ($C_i$ < 30 mg/L) and animal waste wetlands ($C_i$ > 100 mg/L) provide quite a different basis.

The loading specification approach may be extended to include several target outlet concentrations and the loadings needed to achieve them. This was suggested for animal waste treatment wetlands with a sliding scale from 20 kg/ha·d to produce 20 mg/L BOD, to 100 kg/ha·d to produce 100 mg/L, on average (CH2M Hill and Payne Engineering, 1997). Ultimately, the central tendency of the load–response graph may be represented by a line, either determined from regression (see Figure 7.18) or from a *P-k-C** model (see Figure 8.10).

Despite the intuitive appeal of these single-number approaches, they are often inadequate for final design. They serve only to place a potential wetland size "in the ballpark." Probably the best use of such criteria is simple scaling of wetlands from one source to another identical source of a different flow rate. However, the load–response graph that underlies loading criteria is a useful tool and plays a major role in the expanded design-sizing process advocated in this chapter.

## Exponential Decline Models

Typically, the procedure has been to assume steady and uniform plug-flow hydraulics and pollutant loadings associated only with added water. Then, first-order, volumetric removal rules without background concentrations were applied for sizing (Reed *et al*., 1995; Crites and Tchobanoglous, 1998). Alternatively, first-order, area-based removal rules with background concentrations were applied for sizing (Kadlec and Knight, 1996; Wong and Geiger, 1997). Presumed or measured temperature coefficients are used to "correct" the rate constants for thermal effects.

Some of the problems with these approaches are:

i. Hydraulics typically are not close to plug flow. Numerous tracer studies have repeatedly, without exception, shown that there is a distribution of detention times (Rash and Liehr, 1999; Carleton, 2002). Even if the wetland is hydraulically efficient, the weathering of a pollutant mixture gives rise to the appearance of hydraulic inefficiency (Kadlec, 2003a).
ii. Pollutant removals are not necessarily volume-specific. More often, removal is area specific, resulting in rate "constants" that decrease with increasing depth (Gearheart *et al*., 1989; Kadlec, 1997b).
iii. Removals for some pollutants, such as nitrogen species, reflect the effects of internal spatially distributed loadings. Decomposing wetland litter and sediments thus create an internal loading of some substances, notably BOD, TSS, nitrogen, and phosphorus, by virtue of the large wetland biogeochemical cycle. The result is a nonzero wetland background concentration within and exiting the wetland (Kadlec and Knight, 1996; IWA Specialist Group on Use of Macrophytes in Water Pollution Control, 2000).
iv. Flows are not steady. Many phenomena lead to time variation in flows and concentrations, such as rainfall, evaporation, and daily wastewater generation cycles. These effects are especially important for event-driven wetlands used for stormwater treatment (Wong and Somes, 1995; Werner and Kadlec, 2000b).
v. Flows are not uniform. Rainfall and evapotranspiration lead to spatially variable flows and the attendant-dilution effects (Kadlec, 1989c; Platzer and Netter, 1994).
vi. Rate constants may display either seasonal or temperature dependence or be relatively uniform through the year (Kadlec and Reddy, 2001). Temperature is not always an acceptable surrogate for seasonality for many ecosystem functions. For instance, vegetative uptake in temperate climates is maximum during the spring period, at moderate temperatures; but release via decomposition is maximum during fall, also at moderate temperatures.
vii. Rate constants are sometimes derived from synoptic input–output data, which ignores the important transport delays inherent in long-detention systems.
viii. Rate constants are not constant for a specific wetland. Unavoidably, they vary with depth, pollutant concentrations, and hydraulic loading (Kadlec, 2000).
ix. Rate constants are not constant across all wetland types. Removal-rate constants depend on vegetation type and density, and on substrate size, type, and condition.
x. The first-order concept is valid only within an operating region for which there are no constraints on supplies of critical ingredients for the removal process. For instance, nitrification can be first order in ammonium only when there is sufficient oxygen available.
xi. Removal equations give deterministic predictions. The stochastic component of treatment wetland performance is often equally important and effectively masks deterministic effects over a short-operational period. Results for several years need to be overlain to establish the seasonal trend, if any.

Despite these short-comings, rate-constant models have advantages. They separate the effects of hydraulic loading and inlet concentration. They allow prediction of the gradient in pollutant concentration along the flow direction. They allow for background concentrations. They are easily applied over all water temperatures and seasons. They allow for extrapolation from small data sets, such as pilot studies. Therefore, it is desirable to keep the rate-constant approach as one of the tools of design.

The cure for the ills i–xi is theoretically straightforward: develop more-detailed wetland performance models that are capable of characterizing the several important effects noted in the preceding text. Some very detailed models have been proposed, such as an adaptation of the activated sludge model for treatment wetlands (McBride and Tanner, 2000), and spatially distributed, transient, biologically compartmentalized box-and-arrow constructs (Fitz and Sklar, 1999). However, very rarely does any wetland project measure and record all of the important variables that are required to calibrate such complex models—in fact, it has not yet been done satisfactorily.

The strategy advocated here is to utilize the existing (inadequate) data sets to maximum advantage, while retaining as much simplicity as possible.

Items i–v may be accommodated by relatively minor modifications of the first-order deterministic modeling technique. A distribution of detention times can be implemented by altering the spatial water-mass balance that is the foundation for pollutant removal. Area-based rate constants are used. Internal pollutant loadings can be added to the pollutant mass balance. Dynamic mass balances can be easily constructed. Flow nonuniformity can also be added to the water-mass

balance—but not by averaging flows, which can lead to serious errors (Kadlec, 1997b).

The effects of temperature and/or season vi can be deduced from operating data sets, provided a long enough period of record is available to allow for sorting out the competing deterministic and stochastic effects. The synoptic error vii may be avoided by again using a sufficiently long period of operating data and suitable averaging.

Items viii and ix pose greater difficulty because it seems necessary to include more of the unavailable details in the design model. A less satisfying but more practical approach is to acknowledge rate-constant variability and use a large amount of available data to establish the envelope of expectations, and the density of results within it. To that end, a robust graphical display is suggested in the form of a graph of outlet concentrations versus inlet pollutant loadings.

Item x can be dealt with by examination of the details of each specific suite of removal processes with a view to identification of possible mechanistic supply limitations.

Finally, item xi is incorporated by understanding the probability distributions that have been identified for similar wetland systems. This requires detrending the design data sets for effects of water mass balances, season, and temperature.

The foregoing procedures are more complicated than plugging numbers into a single recipe equation, but the risks of straying from the available knowledge envelope are greatly reduced.

## 15.8 A PERFORMANCE-BASED SIZING ALGORITHM

The methods that are used in treatment wetland sizing vary from type-to-type. Rules of thumb are valuable in preliminary assessment, but final decisions must be predicated either on performance requirements or upon regulatory prescriptions. Here, the performance-based approach is outlined, and that is the primary approach for FWS wetlands, which is detailed in Chapter 17. In Chapter 20, the relationship to existing codes and statutes for HSSF system sizing will be analyzed.

Given the shortcomings of previous methods, a strategy is here proposed that attempts to salvage the good features of past work and to improve upon past methods as much as data can support. The strategy described here is not simpler than previous methods because it includes more pieces; that is, it is an integrated rational approach to sizing. It is assumed that the practitioner will implement the steps via spreadsheet on a desktop computer because that has been standard in the engineering profession for many years.

The key features of the procedure are

*Basis:*

1. Set inlet concentrations
2. Set target concentrations (regulatory limits and exceedance factors)
3. Set inflow and seepage
4. Determine rain, *ET,* and temperature
5. Select wetland type (FWS or SSF)

*Parameter selection and calculation:*

6. Select rate constants and seasonality (Select plant community type)
7. Select DTD (hydraulic) efficiency = *P*-value (Select compartmentalization)
8. Adjust area till goals are all met

*Constraint checks and iteration:*

9. Set estimated growth cycle
10. Check biogeochemical cycles for consistency
11. Check constraints (hydraulic and chemical)
12. Check loading graph for risk assessment
13. Adjust for seasonality

*Iterate on procedure as needed*

The first four of these steps involve identifying the basis for sizing. These are fundamental to all wetland types and are the subject of Chapter 16. The next four involve parameter selection and area calculations. The last five are cross-checks followed by adjustments to parameter selection as necessary to preserve a desired degree of risk. These nine steps are the subject of Chapter 17.

## 15.9 GUIDELINES AND MANUALS

In the early years of treatment wetland technology, the designer had access to only a limited number of guidance documents. The amount of information available to, or utilized by, the various authors was extremely limited. The histories of the various pioneer systems were short, and guesses were too frequently made based upon the judgment of the writers. Although some elements of the early guidance and evaluation documents have survived the test of time, a good many were on very shaky ground. Treatment wetland data and analysis has grown, and continues to grow, at a double-exponential rate. The number of applications has increased greatly to include many new areas such as remediation, animal waste treatment, and many specialized industries. But that has been compounded by the rapidly expanding number of systems in each of those application areas. As a result, the knowledge base has been expanding with an estimated doubling time of perhaps three to five years. The arithmetic then tells us that about 95% of what is known today resulted from studies of the past 15 years. With no criticism intended (although some is perhaps deserved), any summaries or guidelines older than 15 years cannot be regarded as reliable and should no longer be used. In the United States, such early documents include:

With the proliferation of knowledge has come a comparable proliferation of guidelines and manuals. These have originated at all levels of government in North America—cities, states and provinces, and national. This situation is comparable around the globe, with many countries having promulgated design guidelines. To compound the complexity, there are now manuals for individual application areas such as animal wastewater, urban stormwater, and onsite treatment of domestic wastewater. These guidance documents are separate from the various prescriptions for treatment wetland design that have been issued by various levels of government, which will be discussed further in Chapter 20. In general, these documents bear later publication dates than the "old" sources, but the reader is cautioned that, in a number of cases, these "new" documents, in fact, simply reiterate the "old" material, and may therefore be regarded as obsolete.

The reader is encouraged to consult those manuals that are pertinent to the application and geographic region for any specific project, but to be very careful about accepting the pronouncements therein. It is important to separate factual bases from opinions, for which purpose the material in Part I may be used. The listing of manuals that follows is inclusive of the majority of national documents but only illustrative of regional, state, and city publications.

## SUMMARY

Treatment wetlands have taken their place among accepted technologies for water quality management. Many thousands of engineered wetlands are currently operational worldwide to treat many types of wastewaters. These treatment wetlands range in size from a few square meters to thousands of hectares. They treat flows from single-family residences up to entire stormwater volumes from large watersheds. They have been engineered for effective control of a diversity of pollutants, ranging from domestic to agricultural to industrial waste streams. They have also been proven, in many cases, to be the most economical method for achieving water quality treatment goals. In spite of their widespread acceptance for water quality improvement, treatment wetlands are still designed using dozens of different methods. Some designers use rule-of-thumb approaches to size wetlands to meet permitted effluent limits. Others have favorite equations that are based on nonwetland technologies. Many designers build one size to fit all circumstances with no regard to sizing the wetland for an anticipated level of treatment. In addition to the nonconformity of sizing methods, wetland cell configuration varies widely between different designers. Some designers make long, narrow wetland cells. Others use many cells in place of a smaller number of larger cells. Some engineers design treatment wetland cells to operate with deep water, whereas others design with shallow water flows. Other areas of diversity in treatment wetland design include levee construction, types of water control structures, and plant selection.

All of these design approaches are not equal. Some treatment wetlands are too small and do not meet their water quality goals. Many that do meet goals are larger than necessary, and therefore do not meet goals of economy. Some treatment wetland applications (e.g., surface versus subsurface flow) may not be optimal for an existing application. Because designers certainly learn from their mistakes, the impacts of their errors frequently ripple out to other projects and applications. Regulatory officials who have been confronted by a series of failed projects are leery of permitting additional systems, even if proposed by different design engineers. A better, more defensible approach for practitioners embarking in this field is to learn from the operational history of the technology and not to repeat mistakes. The strategy advocated in this book is to utilize the best existing (admittedly incomplete) data sets to maximum advantage, while retaining as much simplicity as possible. The procedures are more complicated than plugging numbers into a single-design recipe equation, but the risks of straying from the available knowledge envelope are greatly reduced. Design may either be performance based or technology based, depending upon whether the performance expectations are explicit in an operating permit or implicit in a set of statutory design specifications. Large systems are often in the former group, whereas small on-site and urban stormwater systems are in the latter.

# 16 Design Basis

The preliminary step in the design of a treatment wetland is to acquire a fundamental understanding of the site of the wetland. Site conditions dictate the physical, chemical, and biological environment of a wetland treatment system. Conditions that should be evaluated during planning of a wetland treatment system include climate, geography, groundwater and its chemistry, soils and geology, rainfall and runoff water chemistry, biology, and socioeconomic factors. The importance of each of these conditions may vary, but all should be investigated to some extent. Detailed studies may be needed to determine the importance of those site conditions that affect technical feasibility.

This book primarily considers performance-based design algorithms. The first steps in the process require the assembly of the basis of the design, which includes the following steps:

1. Determine inlet concentrations and flows.
2. Determine target concentrations (regulatory limits and allowable exceedance factors).
3. Determine allowable inflow and seepage rates.
4. Determine rain, *ET*, and temperature ranges for the project site.
5. Select wetland type (FWS or SSF).

Often, the establishment of flows and concentrations will require the acquisition of data on flows and concentrations, at least to confirm estimates based on prior operations or knowledge of the technology of the source.

There are, unfortunately, numerous examples of inappropriate selection of the design basis for treatment wetlands. The difficulty is often not the misunderstanding of current conditions, but rather incorrect assumptions about future conditions. This may involve actions outside the control of the designer.

For instance the "failed" Gustine, California, system added wetlands to existing lagoons (Walker and Walker, 1990). The source water was a combination of municipal and milk processing wastewaters, the latter having very high biochemical oxygen demand (BOD). The design presumption was that milk wastewater would be discontinued, but this did not occur. Instead of the design influent BOD of 60 mg/L, the wetland actually experienced BOD of approximately 600 mg/L. The wetland could not meet design targets for the unplanned tenfold-higher inlet concentrations. Another example is the "successful" wetland system treating potato wastewater at Connell, Washington (Kadlec *et al*., 1997; Burgoon *et al*., 1999). The system was built according to a design based on operating data from a fixed-capacity processing plant. However, coincident with wetland start-up, the plant implemented water conservation. The loads of pollutants remained the same, but concentrations went up considerably as flows decreased. Fortunately, in this case the wetland system was robust enough to accommodate the change and still achieve goals. These anecdotes serve notice that the basis of design must be carefully set forth, and reasonable changes anticipated in influent flows and loads.

## 16.1 PROJECT SETTING

### Space Considerations: Limited versus Unlimited Space

Free water surface (FWS) treatment wetlands are in the category of land-extensive technologies. At the end of this chapter, it will be seen that horizontal subsurface flow (HSSF) wetlands for the same purpose are not much different in size. However, the site conditions—primarily property boundaries and topography—can limit the potential size of a treatment wetland for a particular source-water volume. This is particularly true of urban stormwater wetlands, which need to be sited in built-up areas and which often utilize high-value lands. Siting of wetlands inside the boundaries of major cities, such as Orlando, Florida (Palmer and Hunt, 1989), or Toronto, Ontario (Helfield and Diamond, 2004), means that the size of the wetland is dictated by existing streets, highways, and buildings, not by the size needed to achieve a particular performance goal.

Topography may also limit the potential size of a treatment wetland. The presence of steep slopes adjacent to the site can preclude construction beyond a certain limit, defined by the practicality of earth moving (Figure 16.1). When the site demands, the treatment wetland may be established in terraces, with elevation drops occurring between the successive cells of the system (Navarra, 1992; Inman *et al*., 2003).

Land ownership can also constrain opportunities for wetland construction. Above and beyond questions of acquisition costs, there is the issue of the willingness of the owner to sell property. Building a treatment wetland rarely falls into the category of eminent domain acquisition, although that has happened in connection with the phosphorus removal wetlands of South Florida. For large wetlands, suitable parcels are often already in agricultural use. Wetlands are frequently viewed as valuable landforms across the regional landscape, but aquatic and terrestrial landforms are also valuable. The construction of a treatment wetland implies the removal of other types of plant, animal, and human communities. Therefore, competing uses may block the construction of a wetland on a particular plot of land.

Perhaps the most serious potential constraint of preexisting landform is the presence of naturally occurring wetlands on property under consideration for a treatment wetland. In

**FIGURE 16.1** The treatment wetlands in the Tucush valley of the high Andes Mountains of Peru (4,100 masl) are constrained to a fixed area by extremely steep slopes. They treat the drainage coming from the wasterock dump of a mine operation. (Photo courtesy Compañía Minera Antamina. Reprinted with permission.)

the United States, it is generally not allowed to build any project that destroys existing wetlands. But what if the project is a constructed wetland? That situation is obviously confusing and unclear, and it is therefore not surprising that a variety of rules and regulations apply in various states.

Sometimes the constructed treatment wetland may be viewed as self-mitigating; that is, it inherently compensates for the loss of preexisting wetlands. That situation has occurred at the West Jackson County, Mississippi, constructed wetland site. It is probably most acceptable when the preexisting wetland is degraded, and of low regional value. However, in many other circumstances, construction in wetlands must be avoided. For instance, HSSF and vertical flow (VF) wetlands do not offer the same type of habitat that occurs in natural wetlands, and construction of these systems in natural wetlands is often blocked by regulatory constraints. Of course, the extreme circumstance is the use of natural wetlands for wastewater treatment, which is outside the scope of this book.

For these area-constrained situations, the design methods described herein are not used to select wetland area, but rather are used to forecast performance of the available wetland area. This predictive mode is readily accommodated in a rate coefficient approach, but is very awkward, if not impossible, for a loading design approach due to the data scatter inherent in loading charts.

## Soils and Geology

For planning purposes, site soils in the United States can be characterized by using USDA Soil Conservation Service soil surveys, which are generally available for most counties within the United States. Other countries often have similar mapping resources. Soil surveys typically include maps of soil types as well as summaries of soil properties, groundwater conditions, climatic information, and plant community information.

Soils are classified by soil scientists based on a complex array of physical and chemical characteristics. Soil information that might be important during project planning includes the presence of hydric soils, which occur in natural wetlands (even if formerly drained) and could be a potential regulatory constraint for a constructed wetland site; soil texture and composition as a suitable medium for berm construction or for impeding leakage to the groundwater; depth to seasonal high groundwater; and depth to confining layers of clays or rock horizons. On-site soils are typically preferred for the rooting media in FWS wetlands. In some cases, the sorption potential of these rooting soils will be a design variable, such as for metal removal.

The construction of wetlands entails the excavation of the wetland basin, including any deep zones, possibly together with conveyance and seepage interception canals. Therefore, the soil thickness above bedrock is an important piece of design information, because that material is movable without blasting. The characteristics of the bedrock are important if such blasting is required (Figure 16.2). Construction in rock is extremely expensive, and is to be avoided if possible.

At the other extreme, on-site materials may be unsuitable for the construction of embankments, because they cannot withstand exposure to the water (Figure 16.3).

## Groundwater

Infiltration of wastewater to the groundwater is important because infiltration affects the wetland water balance and could pose regulatory problems under some conditions. Soil infiltration rates published in soil surveys typically overestimate the actual infiltration rates under sustained, saturated soil conditions and are not reliable for project planning or design. Surface infiltrometer tests or well slug tests provide better estimates of the groundwater leakage that can be

**FIGURE 16.2** Deep zones and canals for South Florida's stormwater treatment areas require blasting of the limestone bedrock. A thin veneer (0.3–1.0 m) of peat overlies the limestone.

**FIGURE 16.3** This collection canal in the Lakeland, Florida, FWS system was built using unstable materials from on site. Despite the attempt to reinforce the embankment with concrete matting, erosion caused the discharge structure to drop into the water.

expected from a full-scale wetland treatment system. Methods for measuring infiltration rates are described by the Soil Conservation Service (SCS) (Hansen, 1980; U.S. Bureau of Reclamation, 1993). Field tests are the most reliable method of estimating groundwater infiltration rates. For constructed wetlands, it may be necessary to construct pilot wetland basins on a proposed site and then instrument inflows and outflows to develop an accurate water balance.

Wetlands can be built on leaky soils as long as regulatory requirements can be met and adequate hydroperiods can be maintained with the wastewater addition and net rainfall. In fact, wetlands have been designed with groundwater recharge as a specific project goal (Ewel and Odum, 1984; Knight and Ferda, 1989). Groundwater infiltration can be eliminated as a project concern for constructed wetlands by using a clay or synthetic impervious liner. Although this approach may not be necessary if the wastewater has received secondary pretreatment, it is recommended when wastewater is less than secondary quality, or is known to contain contaminants of concern for the regional groundwater and its intended uses.

Percolation tests are often used as the basis of sizing infiltration fields for septic tank effluent disposal, although such tests are probably insufficient for ensuring adequate performance of the field (Crites and Tchobanoglous, 1998). The allowable hydraulic loading for the infiltration field is set according to a published table or curve, relating the allowable loading to the time for the water level in a test pit to drop a specified amount (usually 2.5 cm). Data collected from percolation tests are then typically related to a prescriptive hydraulic loading that is usually much less than the observed percolation rate. The reduction in hydraulic loading is to account for the long-term accumulation of microbial biomass and particulate matter in the soil, which substantially reduces the infiltration rate (Tyler and Converse, 1994). Allowable hydraulic loadings are usually in the range of 1–5 cm/d. Additionally, there must be a specified vertical travel distance to the groundwater table, typically about 1 m of unsaturated soil (to allow for the removal of pathogens). These requirements are commonly set forth in local codes and rules, and are enforced as a condition for acceptability of new on-site (septic) systems. These codes are typically intended for single-home treatment systems, but are often extrapolated to larger systems due to a lack of more appropriate regulatory guidelines.

The focus of on-site (septic) system codes is the disposal of primary effluent into the soil matrix. When water is pretreated, organic and pathogen loads are substantially reduced, and soil-based treatment is less critical for regulatory compliance.

Given this basis, constructed wetlands are frequently viewed by the on-site regulatory community as a means for justifying higher loadings or lesser unsaturated travel distances in the infiltration bed, or both. For example, the state of Indiana allows reduction in the size of the absorption field associated with a subsurface-constructed wetland based on the soil loading rate (Indiana Department of Environmental Management, 1997). For soil loading rates less than or equal to 5 cm/d but greater than 2 cm/d, the allowable reduction in field size is 50%. For soil loading rates of less than 2 cm/d but greater than or equal to 1 cm/d, the allowable reduction in the field is 33%. Similar reductions in infiltration area are allowed in other states.

In general, it is beneficial to understand the directions and flows of regional groundwater under the project site. Different levels of hydrogeological surveys may be performed, depending on the requirements of the specific project. Considerable detail is necessary for groundwater remediation wetlands that intercept a plume of contamination, because those studies provide the flows and concentrations needed to determine wetland size or performance. For instance, the design of the Hillsdale, Michigan, project involved multiple monitoring wells, studied over several years, and three-dimensional computational fluid mechanics (Ecology and Environment Engineering, 2004). Modeling at a similar level was necessitated at the Columbia, Missouri, project, because of proximity to the city's potable water well field (Brunner and Kadlec, 1993). If the water leaving the system is transported by unsaturated flow, more complex models will be required (Langergraber, 2001; Davis, 2007).

### Altitude

As the use of treatment wetland technology has grown across the planet, the site conditions have broadened to include a wider range of conditions, among which is the altitude of the project. A few experiences have identified special issues, such as the types of wetland plants that are adapted to high-altitude conditions: *Phragmites* is not a mountain plant! (Navarra, 1992). Other concerns have yet to be explored. For instance, treatment wetlands have now been built at up to 4,000 m above sea level (see Figure 16.1), at which altitude the atmosphere is approximately at half sea-level density. Therefore, the partial pressure of oxygen is half that at sea-level, with potential consequences on the ability of the wetlands to process reactions that require dissolved oxygen, such as nitrification.

### Biological Conditions

The addition of any type of water or wastewater will alter biological conditions at a site. Constructed wetlands frequently replace upland habitats with wetland vegetation. The upland habitats that are lost might include plant communities such as grassland, forest, scrub, desert, or agriculture. The environmental values of these upland habitats should be assessed during project planning. Likewise, wastewater discharge to natural wetlands can cause biological changes of varying magnitudes (see Chapter 3). Existing plant and animal communities in natural wetlands will change depending on the degree of changes to surface water quality and hydrology. Construction-related impacts will result in replacement of part of the existing vegetation by distribution pipes, boardwalks, and monitoring structures. For most constructed wetland projects, site-specific biological conditions do not represent a major technical constraint.

## 16.2 CHARACTERIZATION OF DOMESTIC AND MUNICIPAL WASTEWATER

Wastewater quality varies widely among domestic, municipal, industrial, agricultural, and stormwater categories. Different wastewater sources have unique mixtures of potential pollutants, so that even a single wastewater source category, such as municipal wastewater or urban runoff, may vary considerably depending on local, site-specific circumstances. However, for some chemical constituents, the qualitative and quantitative composition of wastewaters from different sources varies less. In general, any summary of "typical" wastewater concentrations and loads must be considered cautiously.

Site-specific wastewater data showing historical flows and mass loads provide the best information for wetland treatment system design. However, because many treatment systems are designed for new facilities or because historical monitoring may be nonexistent or insufficient, it is useful to know the typical concentrations of major constituents in similar wastewaters. This section summarizes information from a number of sources on the typical pollutant composition of wastewater applied to engineered wetlands. These "typical" concentrations and loads should only be used when site-specific information is not available.

The total municipal wastewater flows from municipal sources undergoing treatment in the United States is $45 \times 10^9$ m$^3$ per year, serving approximately 72% of the population (U.S. EPA, 2007). In addition to industrial and municipal wastewaters, nonpoint source pollution contributes about two thirds of the total pollution load to U.S. inland surface waters (U.S. EPA, 1989). Sources of nonpoint flows include urban and suburban runoff, diffuse agricultural runoff, forestry activities, runoff from concentrated agricultural activities such as feedlots, mine drainage, and runoff from undisturbed areas. However, in certain areas urban runoff or other stormwater sources provide the greatest percentage of uncontrolled pollutants. Wetlands are often used in conjunction with other treatment devices, including septic tanks, lagoons, and mechanical treatment plants (Figure 16.4). In those circumstances, the water quality of interest for the wetland design is that exiting a pretreatment step.

The amount and timing of the water to be treated is the first and foremost item of the design basis. This information should include the possible seasonality of flows and the anticipated progression of flows over the life of the design. This is more important for treatment wetland design than for conventional concrete and steel treatment plants, because of the implied life cycle of the process and the nature of urban and industrial growth. It is customary to plan for a 20-year life expectancy for conventional wastewater treatment plants, because mechanical equipment often wears out during this period. But wetlands clearly can continue to function for far longer periods than two decades; for example, there are receiving wetlands that have been in operation for periods of 70 years (Great Meadows; Yonika *et al.*, 1979) and 90 years

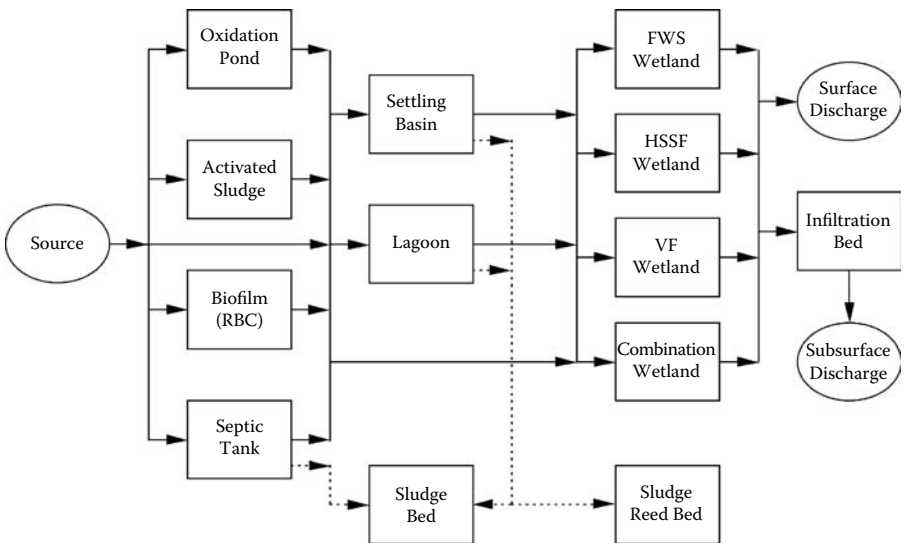

**FIGURE 16.4** Simplified options for treatment trains involving treatment wetlands.

(Brillion; Spangler *et al*., 1976). Projecting flow estimates far into the future is risky, so it is necessary to be explicit about flow capacity at the time of design.

Most of the pollutants that are common to many of these wastewater sources can be effectively treated by wetland systems. The normal concentration range of these pollutants is an important consideration in evaluating wetland treatment system options. This section compares and contrasts these wastewater sources to facilitate initial alternative evaluation.

### Water Quantity

The information on water quantities and timing is assembled into the annual and monthly water budgets for the design, including any seasonal or event storage that may be necessary. Such water budgets are easily prepared within the framework of a spreadsheet program on a personal computer. This information is later linked to the computation of the expected reductions in pollutant concentrations. Interestingly, the addition of a wetland to any of the several forms of pretreatment provides dampening of flow pulses. Although it is necessary to account for the diurnal cycles in the inflows for hydraulic purposes, the wetland will typically "hold" several such daily pulses, because of the extended detention time used in the wetland.

### Small Domestic Systems

Most design information in engineering textbooks is based on large-scale sewer networks that have a continuous base flow. Small-scale wastewater treatment systems often do not have a continuous base flow. On the contrary, low flows are zero (no flow), and peak flows are many times larger than the average flow. These differences in water use patterns raise issues that are not encountered in the design of larger sewage treatment works.

### Small Flows

For design of single-family home treatment systems, the accepted practice in the United States is to base the design flow on the number of bedrooms within the home. These prescriptive flow determinations (typically ranging from 455 to 568 L/d per bedroom) are used to provide a sufficient factor of safety for soil infiltration of septic tank effluent. They do not represent actual water use. Prescriptive flow determinations are commonly interpreted as representing the maximum expected occupancy of the home (two occupants per bedroom) and a corresponding peak flow rate. As a result, peaking factor determinations and infiltration/inflow allowances are typically not necessary when using prescriptive flows based on a bedroom count. Special provisions may apply in some circumstances (Minnesota Pollution Control Agency, 1999).

Flow projections may be based on population for small communities. A prescriptive criterion of 379 L/d per person is commonly used in North America (Great Lakes UMRB, 1997). This per-person flow guideline is intended to represent an average dry weather flow from domestic wastewater sources plus a "normal" amount of infiltration for gravity sewers built with modern construction techniques. If the only available information is the number of homes, an average number of people per household may be used to approximate the total population. The average household size in the United States is 2.7 people (American Housing Survey, 2003), although this varies by geographic location. An appropriate peaking factor must be applied to determine peak flows.

### Patterns of Small Flows

Wastewater flow from individual residences is delivered to a small-scale treatment system via a series of discrete pulses triggered by flush toilets, washing machines, dishwashers, etc. Low flows in small systems will be zero (no flow). Most water use occurs in the morning, evening, and at mealtimes. In the United States, water use from single-family homes has been idealized for design purposes, as indicated in Figure 16.5. As more and more homes are added to the system, flow pulses overlap. If there are enough homes in the collection network, flow pulses overlap to form a continuous base flow, and flow peaks start to attenuate.

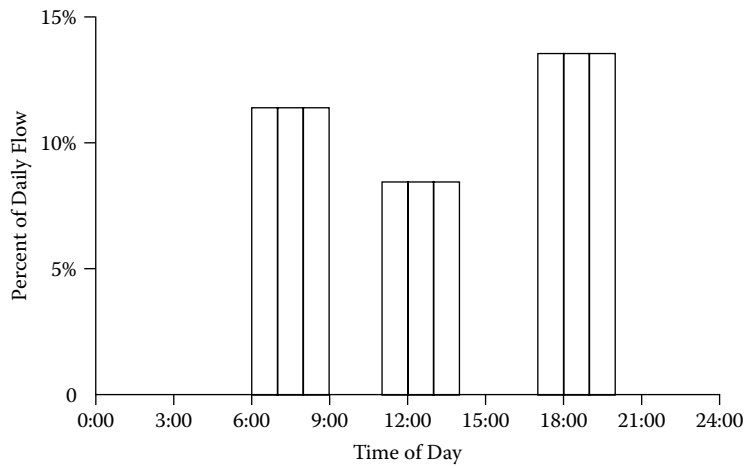

**FIGURE 16.5** Idealized water use pattern for an individual home. (Adapted from NSF International (2000) *Residential wastewater treatment systems*. NSF/ANSI 4–2000, NSF International: Ann Arbor, Michigan. Reprinted with permission.)

For single-family homes, the ratio of the peak flow to the average flow (peaking factor) can be five or higher. Larger treatment systems will experience lower peaking factors due to overlapping flow pulses and the presence of a continuous base flow. In the United States, Recommended Standards for Wastewater Facilities (Great Lakes UMRB, 1997) suggest a formula based on population to determine the ratio of the peak hourly flow to the average daily flow (Equation 16.1). For small populations (less than 100 people), this relationship results in a peaking factor of approximately 4.5.

$$\frac{Q_{\text{peak hourly}}}{Q_{\text{average day}}} = \frac{18 + \sqrt{P}}{4 + \sqrt{P}} \tag{16.1}$$

where

$Q$ = Flow rate, any units
$P$ = Population in thousands

The pattern of peak flow events can be altered dramatically if wastewater is collected and pumped into the treatment system, as might be the case for septic tank pretreatment. Sources of inflow and infiltration from homes (sump pumps, footing drains, roof leaders, and furnace drains) can easily produce much higher flows unless they are identified during the design process with a home plumbing survey program and subsequently separated from the wastewater collection system.

### Actual Water Use

Water use studies in the United States estimate an average daily water use of 189 to 265 L/d per person for homes built before 1994; implementation of standards for water-efficient appliances since then has reduced water use in newer homes to approximately 161 to 227 L/d per person (U.S. EPA, 2002c). Water use is strongly influenced by cultural practices and varies widely from country to country. Across Europe, typical flow rates in small communities (less than 500 people) range from 80 to 120 L/d per person (IWA Specialist Group on Use of Macrophytes in Water Pollution Control, 2000). In Germany, water use rates are much lower than in the United States (Gesellschaft zur Förderung der Abwassertechnik d.V (GFA), 1998), at 100–150 L/d per person. In urban areas of developing countries, water use is approximately 60 L/d per person (Nhapi *et al*., 2003).

## Lagoons

There are many variants on the concept of aquatic units for wastewater treatment, ranging from single-pond units (Water Environment Federation, 2001) to complex arrays of multiple units (Craggs, 2005). Often, other treatment process units are added to complement the pond itself (Middlebrooks *et al*., 2005). The combination of a pond followed by a wetland has been explored at a number of locations (Horne, 1995; Steinmann *et al*., 2003; Tanner and Sukias, 2003; Kadlec, 2003d; Polprasert *et al*., 2005; Wang *et al*., 2005; Kadlec, 2005e). Because the wetland is often an add-on, the flow of the water exiting the pond is often known from performance data.

The prescription for lagoon operation may be continuous discharge, typical of warm climates, or episodic discharge, typical of cold climates. Lagoon systems often discharge to surface waters, for which the goal is to minimize water quality impacts. Maximum dilution occurs at high flow of the recipient, which in turn occurs during freshets, i.e., the spring thaw and the autumn wet season. Therefore, lagoon discharges are traditionally scheduled for those times of maximum dilution. When a wetland is added to the system, there are more options for scheduling the discharge. For instance, the system may be designed for discharges that avoid ammonia toxicity in the recipient (Kadlec and Pries, 2004). Winter storage may be contemplated, provided capacity is present or designed. Therefore, the designer has an added degree of freedom: the total annual volume may be managed to optimize treatment, perhaps at the expense of more pond volume. This design feature is discussed in more detail subsequently.

## Mechanical Plants

Pretreatment systems, such as activated sludge plants, are small-retention devices, which do not typically have much capacity to dampen the incoming flow pulses. Hour-to-hour, day-to-day, and month-to-month flow variations are likely to be passed through the pretreatment system, and thus affect what is entering a follow-on treatment wetland. These pulses will then be partially evened out by an add-on wetland. Flows, whether municipal or industrial, are often seasonal in character. It is necessary to anticipate those patterns, because the wetland must function appropriately under these variable hydraulic conditions. Monthly flow estimates will be required for most point-source projects.

### Infiltration and Inflow

Infiltration is defined as groundwater that seeps into a wastewater collection system. It invariably introduces additional flow into the collection network. Infiltration is strongly influenced by groundwater elevation, workmanship of sewer construction, quality of construction materials, and fraction of the overall collection network that relies on gravity flow. Typical sources of infiltration include poorly installed service laterals, leaking joints on sewer pipes, cracked sewer pipes, and leaking manholes. Exfiltration (movement of water out of the collection system) can also occur. Portions of collection systems that are pumped (such as pressure sewers) have positive internal pressures and are often pressure-tested during construction. As a result, pressure sewer collection systems have a much lower potential for infiltration.

Inflow is defined as extraneous water that is directly discharged to the wastewater collection system. In combined sewer systems, stormwater is a major source of inflow. It is driven by rainfall intensity and amount of impervious surface present within the catchment area. In newer collection networks, stormwater is almost always excluded. In these

situations, major sources of inflow are generally limited to roof leaders, sump pumps, and foundation drains. Because most inflow sources are driven by rainfall, these tend to be high-flow, short-duration events. These "surge" events can have major impacts on treatment systems. The combined effect of infiltration and inflow depend on a number of factors, including the integrity of the sewer system, size of the collection pipes, the presence of high groundwater, and other factors. Typical allowances for combined infiltration/inflow range from 0.09 to 0.9 $m^3$/d/cm/km (Metcalf and Eddy, 1998).

## Water Quality

The concentrations of the pollutants in the water to be treated are critical to the sizing process, and to the prediction of the wetland performance in the face of unknown future variations. A clear definition of the incoming water quality, including the anticipated temporal distribution of concentrations, is essential. There are often seasonal fluctuations for point sources, as well as diurnal fluctuations. Incoming patterns of chemical composition propagate through the wetland and undergo modification, resulting in a spectrum of output compositions. Some of this output variability may be predicted by the design models, namely, those variations that represent responses to moderately slow input changes (those which occur on monthly or less). Faster events involve ecosystem processes that are not included in the design models available at the present time, and therefore will give the appearance of generating stochastic variations.

In domestic and municipal wastewater collection systems, the following components contribute to sewage flow:

- Human excreta (feces and urine)
- Wastewater generated by personal use, including washing, laundry, food preparation, etc. (graywater), and water used as the carrier media for human bodily wastes (blackwater)
- Water that inadvertently leaks into the collection system (infiltration and inflow)
- Wastewater from commercial or industrial sources

Component concentrations of sewage will depend on the individual circumstances of the community. In communities with hand-carried water supplies or limited water resources, graywater is often looked at as an irrigation resource and is not commingled with excreta. In industrial societies, mixing graywater and blackwater to produce "combined sewage" is the norm (Günther, 2000). As a result of these differences in water usage, and hence composition, wetland designers need to consider how the community is utilizing water.

### Small Domestic Systems

There is often no composition data to be used for the design of treatment systems for small systems. It is necessary to resort to estimating methods that consider water use and population in the source community. Untreated human urine and fecal material can introduce a variety of pollutants into the environment. Typical per-person generation rates are summarized in Table 16.1 (Del Porto and Steinfeld, 2000). Graywater includes spent water from bathtubs, showers, washbasins, washing machines, laundry tubs, kitchen sinks, and dishwashers. In developed countries, graywater accounts for 50 to 82% of household water use and represents about half of the organic waste solids produced in the home. When conventional flush toilets are used in a waterborne sewer system, graywater is often combined with blackwater. Relative contributions of pollutants by source (for a combined sewer system) are summarized in Table 16.2 (U.S. EPA, 2002c). Typical constituent concentrations for residential septic tank systems are given Table 16.3.

### Lagoons

Another source of treatment wetland influents arises from pond treatment as the initial component of the treatment train. One or more facultative, anaerobic or aerated ponds or lagoons may be used (Shilton, 2005). Because the wetland is often an add-on, the quality of the water exiting the pond is often known from performance data. If the entire system is constructed at the same time, the lagoon elements should be designed according to the currently accepted

**TABLE 16.1**
**Typical Per-Person Waste Generation Rates**

| Parameter | Urine | Feces | Combined |
|---|---|---|---|
| Volume (L per capita·day) | 1.2 | 0.15 | 1.4 |
| Dry solids (g per capita·day) | 60 | 45 | 105 |
| Moisture content (g per capita·day) | 95% | 70% | — |
| Organic carbon (g per capita·day) | 8.5 | 22 | 30 |
| $BOD_5$ (g per capita·day) | 7.5 | 11 | 18.5 |
| Nitrogen (g per capita·day) | 11 | 2 | 13 |
| Phosphorus (g per capita·day) | 1 | 0.6 | 1.6 |

methods (Shilton, 2005). Lagoon systems are typically designed for reduction of BOD and total suspended solids (TSS), and occasionally ammonia. Data and older models exist for pond pathogen reduction, but have not been recently updated and synthesized (Davies-Colley, 2005). Phosphorus data for lagoon systems are not voluminous, because it is not frequently regulated in lagoon discharges. Some approximations of the effluent characteristics of several types of lagoons are shown in Table 16.4.

## Mechanical Plants

Table 16.5 summarizes the typical quality of medium-strength, raw, municipal wastewater in the United States and provides a range of values for commonly observed constituents. Municipal wastewater is composed of a variable array of components characterized by the presence of biodegradable organic matter (paper, feces, and food), particulate and dissolved solids, and nutrients. Many municipal wastewaters also receive some component of industrial waste. These flows and residential sources may add trace metals and pesticides to typical municipal wastewater.

Table 16.5 also provides a range of estimated treatment efficiencies for conventional primary and secondary treatment processes, and summarizes the typical quality of secondarily treated municipal wastewaters. These removal efficiencies vary widely depending on the types of treatment processes. However, it is generally observed that at least 70% of the BOD and TSS are removed from municipal wastewater during primary and secondary treatment. Treatment requirements have generally increased over the past decades, and many treatment plants now include at least partial nitrification, perhaps denitrification, and phosphorus removal. These blur the terminology, because they range from "advanced secondary" to "tertiary" and beyond. The follow-on treatment wetland may therefore be termed "tertiary" or, as might be supposed, "quaternary."

This summary can be used as a rough estimate of the influent water quality to be applied to a wetland system designed for primary, secondary, or advanced wastewater treatment.

## 16.3 CHARACTERIZATION OF OTHER WASTEWATERS

### Industrial Wastewaters

Although industrial wastewater quality varies among industries, it has a fairly consistent intrasystem effluent quality. Table 16.6 summarizes the typical quality of raw wastewater from a number of industries that have used wetlands treatment technology. Raw industrial wastewater usually receives some level of pretreatment before discharge to a wetlands treatment system. If total concentrations of BOD, suspended solids, and ammonia nitrogen in untreated industrial wastewater are in the concentration range of hundreds to thousands milligrams per liter, it is generally not acceptable for wetlands discharge without additional pretreatment.

### Landfill Leachates

Treatment and disposal of liquid leachates is one of the most difficult problems associated with the use of sanitary landfills for disposal of solid waste. Leachates are produced when rainfall and percolated groundwater combine with inorganic and organic degraded waste. In unlined landfills, leachates

frequently discharge to groundwater or appear as surficial drainage around the base of the landfill. In modern lined landfills, leachates are collected from the lined cells and routed to treatment units. The use of constructed wetlands to treat these landfill leachates is a well-developed technology, currently undergoing rapid expansion in application. This application is discussed further in Chapter 25.

The highly variable nature of solid waste, differences in age and decomposition, and the diversity of chemical and biological reactions that take place in landfills result in a wide range of chemical quality of leachates (McBean and Rovers, 1999). Reviews of "average" landfill concentrations of COD, volatile acids, and nitrogenous compounds show increases during the first few years of operation and then decline over ten or more years. Table 16.6 provides typical ranges encountered in landfill leachates. Flows are generally low, but vary depending on management and minimization of percolation from rainfall. Clearly, the expected volume and chemical quality of a landfill leachate is highly site-specific, may change over time, and must be estimated on a case-by-case basis for wetland treatment system design. A detailed discussion of the leachate quality that may reach a treatment wetland is found in McBean and Rovers (1999).

### Pulp and Paper Wastewater

The pulp and paper industry converts wood products including pines, spruce, poplar, beech, birch, and aspen, as well as recycled paper, into liquefied cellulose pulp and paper. Raw wood and wood chips are converted to pulp (cellulose fibers) by mechanical grinding (ground wood) or through chemical degradation and leaching (sulfite and Kraft processes). At an increasing number of pulp and paper mills, this pulp is bleached to delignify and decolorize the cellulose fibers before paper manufacture. About 29–34 $m^3$ of raw wastewater is produced for each metric ton of pulp and paper produced (Britt, 1970). Total wastewater flow for the U.S. pulp and paper industry is about $20 \times 10^6$ $m^3/d$ (Greyson, 1990). Table 16.6 summarizes the typical composition of this wastewater, although different manufacturing processes result in different wastewater qualities. This flow is equivalent to a raw organic matter ($BOD_5$) load of about $15 \times 10^6$ metric tons per day (Greyson, 1990).

Raw wastewater from pulp and paper mills typically receives primary treatment through settling, either in ponds or in primary clarifiers. When required to meet discharge limitations, secondary treatment at most pulp and paper mills includes biological conversion of $BOD_5$ and additional solids settling in aerated lagoons or in conventional activated sludge treatment systems. To meet reduced effluent limitations, some pulp and paper mills are being required to provide treatment beyond the secondary level. The goals of additional treatment depend on site conditions, such as the quality of the effluent after secondary treatment and water quality permit limits in the receiving water. One goal may be to further reduce $BOD_5$, TSS, nitrogen, phosphorus, color, chlorinated organics (such as adsorbable organic halides or dioxin), and whole effluent toxicity. Constructed and natural wetland treatment systems have been used at a number of pulp and paper mills to provide this advanced secondary or tertiary treatment (Knight *et al*., 1994; Knight, 2004).

### Mine Drainage

During and following mining operations, runoff and leachate from tailings and from abandoned tunnels and shafts dissolve trace metals, contaminating nearby surface waters. Leachates from coal and metal mines contain residual trace metals, notably iron, manganese, and aluminum from coal mines (Table 16.6). Seeps from abandoned mines typically received no treatment in the past, but there is an increasing emphasis on corrective measures (Younger *et al*., 2002). Constructed wetlands are used as a technology to reduce metal concentrations in mining wastewater (Younger *et al*., 2002; PIRAMID Consortium, 2003a, 2003b). As discussed in Chapter 11, metals are precipitated and sequestered in sediments, and taken up by plants in wetlands. Wetland design for metals removal is sometimes limited by the need to avoid toxic concentrations in tissues that could subsequently accumulate in the food chain. Information necessary to evaluate the ability of wetlands to provide treatment of these waste products is summarized in Chapter 11 and in the references listed previously. Both removal rate specification and rate constants have been used in design, but the available level of detailed design data support is not as large as for municipal wastewater treatment.

During coal mining, iron pyrite and other metal-bearing minerals are exposed to percolating water, which leads to the release of acidic leachates to surface water. These drainages typically have low pH and elevated concentrations of dissolved iron, sulfate, calcium, and magnesium. In addition, the drainages have variable and somewhat elevated concentrations of aluminum, copper, manganese, nickel, and zinc (Table 16.6). Many of the streams and impoundments in the Appalachian coal mining region of the United States are affected by acid mine drainage. Conventional treatment of leachates at these sites includes surface grading and recontouring to reduce or divert flows and chemical buffering and precipitation with mechanical treatment plants to improve water quality. Because these processes have relatively high capital and lifetime costs, there has been considerable interest in developing more cost-effective alternatives. Beginning in the early 1980s, research focused on the potential of aerobic wetlands for precipitation of ferric sulfate to neutralize pH and reduce dissolved ferrous iron concentrations. Constructed wetlands are now used at many sites in the United States and Europe to increase the pH and reduce concentrations of iron and manganese at coal mine sites (Kleinman and Hedin, 1989; Younger *et al*., 2002; PIRAMID Consortium, 2003a, 2003b) of coal mine drainage.

### Petroleum Industry Wastewater

Because of the diverse processes at refineries and associated transportation facilities, and the storage of flammable

liquids, land area requirements are large and include many kilometers of piping and hundreds of tanks and storage areas. Wastewater is generated by manufacturing processes, cooling tower blowdown, water and sludge drainage from tanks, and stormwater drainage and runoff (UNEP, 1987). Typical wastewater pollutants at petroleum refineries include $BOD_5$, COD, oil and grease, TSS, $NH_4$-N, phenolics, $H_2S$, trace organics, and heavy metals. Concentrations of many of these pollutants are reduced through source control and preliminary treatments such as sour water stripping, oxidation and neutralization of spent caustics, and cooling tower blowdown treatment. Table 16.6 lists some examples of pollutant concentrations remaining in refinery wastewater.

Raw wastewater from petroleum refineries typically receives additional treatment including gravity separation of oils and greases, primary clarification, dissolved air flotation, and secondary treatment, including oxidation ponds, aerated lagoons, activated sludge, trickling filters, and activated carbon. The API separator process typically removes 60 to 99% of the oil and grease, and smaller proportions of other pollutants. Primary treatment removes 20 to 70% of the $BOD_5$ and TSS and 10 to 60% of the COD. Secondary treatment will reduce 40 to 99% of the $BOD_5$, 30 to 95% of the COD, 40 to 90% of the TOC, 20 to 85% of the TSS, 60 to 99% of the oil and grease, 60 to 99% of the phenol, 9 to 99% of the $NH_4$-N, and 70 to 100% of the sulfide (ANL, 1990).

As described in Chapter 13, constructed wetlands are providing advanced secondary and tertiary treatment of process water and stormwater at a large number of refineries (Knight *et al*., 1999; API, 1999). Constructed wetlands typically will reduce remaining concentrations of $BOD_5$, COD, TSS, $NH_4$-N, oils and grease, phenols, and metals to advanced treatment levels.

### Animal Industry Wastewaters

Animal industry wastewater contains high $BOD_5$, COD, TSS, and nutrients and is qualitatively similar to municipal wastewater. Mass loadings from animal feed lots and other concentrated agricultural activities require intensive treatment systems to provide environmental protection. Traditional treatment methods such as anaerobic lagoons and spray irrigation are not always adequate to provide high-quality water for off-site discharge. Constructed wetlands are being used in a growing number of cases to receive pretreated dairy and swine wastes (NADB database, 1998; Knight *et al*., 2000). These wetland treatment systems must be designed with reasonable organic loadings to prevent plant mortality, odors, and poor treatment efficiencies. Treatment wetlands are a compatible component of on-farm, total waste management. Their land intensiveness is not a serious limitation in most instances. Farmers typically have the equipment and skills necessary to build their own wetlands and operate them successfully. Table 16.7 summarizes the composition of wastes from animal operations, both entering and leaving treatment wetlands.

### Stormwater Runoff

Concentrations of most parameters in stormwater are time dependent. Stormwater concentrations and loads are cyclic

with periods of dry fall and deposition, then the first flush of runoff after rain, followed by exponential decreases in runoff constituent concentrations as storages rinse from the landscape, and finally dry conditions and deposition until the next storm event. Chapter 14 provides a more complete description of the expected flows and concentrations for such event-driven systems.

Table 16.8 provides typical mean concentrations for constituents. The averages are flow-weighted to provide realistic estimates of the total constituent load that escapes during multiple storm events. Instantaneous concentrations will be considerably higher than these averages. Pollutant concentrations and loads generally range from low levels, from undeveloped and park lands to low-density residential and commercial, to agricultural, to higher-density residential and commercial, and finally to high-density commercial, industrial, and agricultural land uses. Mean concentrations per event for $BOD_5$ vary from 1.45 mg/L for undeveloped lands to 20 mg/L for high-density urban areas. TSS concentrations vary from 11 mg/L for undeveloped areas to 150 mg/L for high-density urban areas.

The mass loading rates provided in Table 16.8 represent normalized pollutant loads that are somewhat independent of local rainfall amounts. Because pollutant loads per area per time are relatively constant between similar land use areas, variable local rainfall washes these loads off the land in a few large events or over many smaller events. Urban pollutant loads increase with the imperviousness of the watershed. Although 20 to 40% of the material on street surfaces is organic, it does not biodegrade easily because

it comes from leaf and wood litter, rubber, and road surface material (Novotny, 1992). The high metal content of highway solids comes from vehicle emissions. Novotny (1992) reported that the average total nitrogen load from urban lands is 5 kg/ha·yr (1 to 38.5 kg/ha·yr), and the total phosphorus load averages 1 kg/ha·yr (0.5 to 6.25 kg/ha·yr). Urban and residential runoff is being treated with wetland detention basins (Kehoe, 1993) and constructed wetlands (Carleton *et al*., 2001).

## 16.4 TREATMENT GOALS

Wastewater treatment and disposal are regulated by an ever-increasing number of federal, state (provincial), and local laws, rules, ordinances, and standards. In some cases, the most challenging part of implementing a wetland treatment project is complying with regulations through the permitting process. A detailed knowledge of the pertinent regulations is essential to evaluate the feasibility of a wetland treatment project, and to design it properly. An up-to-date, detailed survey of federal, state, and local ordinances should be conducted to determine those that might be relevant to specific projects.

Treated water may be destined for one of three primary receivers: surface water, groundwater, or irrigation (reuse). There are often stringent specifications of quality that must be met to allow discharges to these recipients, and they are quite different. The intent of specifications for surface water discharges is the preservation or improvement of the designated uses of those waters. No matter what the receiving ecosystem or post-wetland treatment element, proper design requires a clear statement of the required water quality leaving the treatment wetland.

### Receiving Water Standards

In the United States, the Clean Water Act created the National Pollutant Discharge Elimination System (NPDES) permitting program. An NPDES permit is required for nearly all point discharges of water or wastewater into waters of the United States, including municipal and industrial wastewater. NPDES permits specify allowable flows and chemical quality of discharges into waters of the United States based on established water quality standards for those receiving waters. The Clean Water Act guides water quality standards, which are promulgated individually by the states. Water quality standards vary among water bodies within a state and among states, depending on specific receiving water resources. Many wetland treatment systems discharge to surface waters, and therefore must meet the conditions of a discharge permit. The conditions of the permit dictate the required performance of the wetland, and therefore govern its sizing.

Traditionally, permits have been developed to control both flows and loads of pollutants. There are typically annual averages and monthly and weekly maxima, perhaps adjusted seasonally. The relation between averages and maximum allowable concentrations may have been determined from other technologies, and may be inappropriate for a wetland system. Similar procedures are in place for other countries.

Discharge in some circumstances is directed to downstream wetlands, which are often a combination of surface and subsurface waters. These wetlands are often federally regulated waters, and subject to appropriate regulations. However, the upstream treatment wetland is a treatment system, typically regulated according to a different set of rules. The design goals for the treatment wetland therefore become the water quality and quantity desired for the management of the downstream, jurisdictional wetland. These are likely to be stricter than for discharge to a large river, for example (due to lower dilution factors in the natural wetland environment).

### Groundwater Discharges

Groundwater discharges are regulated via either the codes for single-home on-site (septic) drainfields or the rules for infiltration of treated wastewaters from municipal treatment plants. The septic drainfield codes are not based explicitly on water quality, and typically use a prescriptive approach based on a presumed reduction in pathogen counts. Larger systems typically target specific water quality parameters, such as nitrate, and hydrogeologic modeling is often required to determine the fate and transport of these parameters in the subsurface environment.

Groundwater discharges of treated water are feasible in a number of circumstances. The problems of avoidance of eutrophication of surface receiving waters are replaced by problems of ensuring proper quality for the aquifer to be recharged. If the groundwater beneath the wetland, or a follow-on infiltration bed, is a drinking water source, then attention must be paid to nitrate, pathogens, and metals, as well as to trace organic chemicals. However, many aquifers are not, and will not be, used for potable water supply. Wetlands, therefore, have a role in pretreatment for conventional rapid infiltration basins (RIBs) and in posttreatment for nitrate removal from underdrained RIBs.

The primary concepts of regulation of groundwater discharges concern nitrates, pathogens, and perhaps salts. The limit of 10 mg/L nitrate-nitrogen as a drinking water standard in the United States results in specifications of nitrate, or by implication, total nitrogen in such discharges. The need to regulate pathogens if any drinking water use is present is obvious. Salt content is of concern if it is a perceived threat to potable water supplies. Groundwater discharges may be a preferred alternative because of the phosphorus-binding potential of many soils. Land application has a long tradition as a means of wastewater disposal. But it is often plagued by a surplus of nitrogen, which escapes crop utilization and nitrifies during transport to the groundwater. Wetlands have the potential to strip excess wastewater nitrogen before land application. In this application, wetland design targets the requirements of the subsequent treatment process (i.e., land application).

The design of the treatment wetland interfaces with the design of the infiltration system. Several sources discuss the design of rapid infiltration systems (Crites and Tchobanoglous, 1998; Water Environment Federation, 2001; Crites *et al*., 2006).

### Interfacing to Reuse

In many parts of the globe, water is in short supply. As treatment technologies improve, it has become possible to consider the treated water as a resource, with a variety of potential beneficial uses. The irrigation of agricultural crops is the leading consumer of treated water. Crops include trees, pastures, and fodder crops in North America, but food crops are irrigated with treated water in other parts of the world. The key consideration is the potential for passing of pathogens to consumers of the crop. Treatment wetlands have been used to help condition the water for these applications (Crites and Tchobanoglous, 1998). Landscape irrigation is another reuse candidate, with applications for ornamentals and golf courses. Again, treatment wetlands have been employed as conditioners in this application (Wallace and Kadlec, 2005).

The reuse water quality standards to be met vary from state to state in the United States. U.S. EPA has guidelines for various categories of reuse (U.S. EPA, 2004). State regulations or guidelines are in place in virtually all states, and typically apply to several categories: (a) unrestricted urban use, (b) restricted urban use, (c) nonfood crops, and (d) food crops. Some of these regulations contain extremely low requirements for solids and pathogens. For instance, the state of California requirement is for turbidity less than 2 NTU, and total coliforms less than 2.2 MPN/100 mL, for the highest reuse category (which incidentally includes use for flushing toilets) (California Code of Regulations, 2001). Other states have less stringent requirements; for instance, Colorado allows unrestricted irrigation of water with a BOD less than 20 mg/L, fecal coliform bacteria less than 25 MPN/100 mL, and TSS less than 40 mg/L (Colorado Department of Health Water Quality Control Division, 2005). States that are driven primarily by liability concerns tend to have very stringent reuse limits, whereas states driven by water scarcity often have less strict limits to reduce the economic barriers to water reuse.

In water-scarce areas such as Mediterranean countries, water scarcity may be a driving factor for reuse, and lower levels of treatment may be acceptable (e.g., control of parasites but not bacterial or viral contaminants). In these cases, alternate treatment guidelines will apply (Korkusuz, 2005).

Clearly, there is a lower limit to the treatment achievable in constructed wetlands, because natural processes create background concentrations that may be in excess of local regulatory requirements for water reuse.

### Excursion Containment and Safety Factors

All treatment technologies possess a spectrum of effluent concentrations, which is predictable only in the probabilistic sense. Therefore, in addition to the mean effluent concentration (which may vary in a deterministic way with temperature and loading), there is an associated bandwidth of concentration. Regulations may constrain both the mean and the maximum of the band, via specification of a limit on the maximum daily, weekly, or monthly value, together with a limit on the average annual value. In design, care must be taken to accommodate the most restrictive of multiple averaging tests given by the regulation.

The average system performance will depend on either the season of the year or the water temperature, or both. These are deterministic variations; that is, they may be predicted from the seasonality of the removal rate coefficient or, more directly, from information on observed trends in treatment wetland outlet concentrations. Theta factors and trend properties (given in Part I) allow the designer to forecast seasonal deterministic trends. There remains the variability not predicted by such seasonality (see Chapter 9, Figure 9.48, for example).

Probabilistic effects are important in the utilization of design models for predicting removal performance of treatment wetlands. Regulatory requirements often employ a standard other than a long-term average. There may be a maximum monthly concentration not to be exceeded, or a specified concentration not be exceeded for more than a certain percentage of samples. To illustrate, consider the representation of Figure 16.6, showing the hypothetical reduction curve for a typical wetland. The information in Part I is unequivocal; as wetland size increases, there is a downward trend in pollutant concentration.

However, there is also a scatter in the individual measurements that make up the trend. During any specified part of the year, the concentration of a pollutant follows a decreasing curve, with wetland size (detention time), and has an associated bandwidth of scatter in expected values (Figure 16.6). In this hypothetical example, that scatter is shown as a uniform distribution about the trend line, with a bandwidth proportional to the trend value. It is supposed that the regulatory limit is a concentration of 30 mg/L, as a maximum allowable. The trend model tells us what size wetland is needed to meet 30 mg/L as a long-term average, which is a detention time of 6.1 days. However, the scatter is such that half the time the measured values will be higher, up to 42 mg/L. The exceedance frequency is expected to be 50% because the design is based on the mean performance. As this level of excursions is likely to be quite unacceptable from a regulatory standpoint, it would be necessary to increase the size of the wetland.

At a detention time of 9.1 days (almost a 50% increase in wetland size), a large majority of excursions are contained (95% this hypothetical example) below the regulatory limit, and the system would experience exceedances only 5% of the time. In this case, the 50% increase in size is needed for excursion containment of an expected, quantified scatter. At the size that contains excursions (9.1 days' detention), the trend value is 21 mg/L, or 70% of the limit value for the design. This fraction is called the *coefficient of reliability*

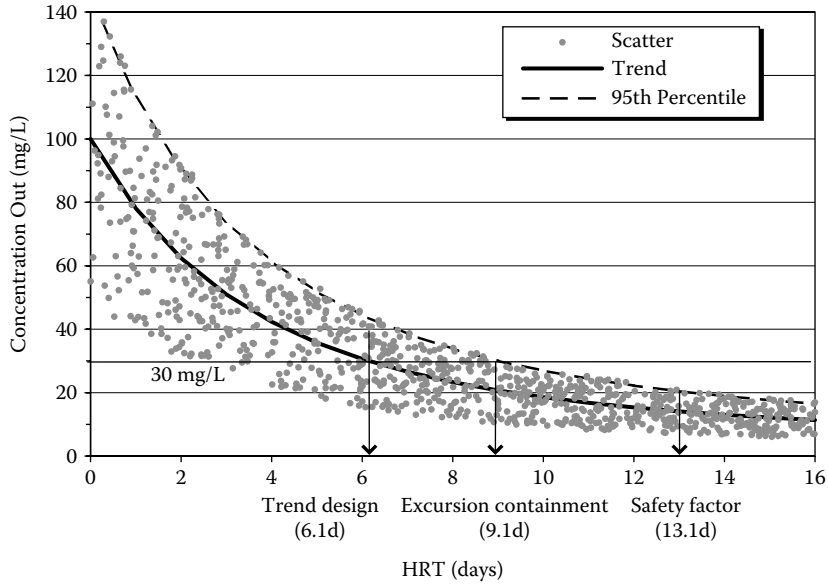

**FIGURE 16.6** A hypothetical example of design for excursion containment. The trend represents $P = 3$, $C^* = 5$ mg/L, and $k = 30$ m/yr. The scatter is a uniform distribution with a ±50% bandwidth. On average, a goal of 30 mg/L can be met with 6.1 days' detention. To avoid exceedances at the 95% level (one time in 20), the detention time should be 9.1 days. More wetland area (more detention time) may be added as a safety factor; i.e., 13.1 days should contain outlet concentrations to less than 20 mg/L most of the time.

(COR). Crites and Tchobanoglous (1998) present a method for its estimation from the coefficient of variation (variance/mean) of one or more datasets, adapted from activated sludge technology. In this book, an exceedance multiplier is used, which is just the reciprocal of the COR:

$$\textit{Exceedance multiplier} = 1 + \Psi = \frac{1}{\text{COR}} \qquad (16.2)$$

where

$\Psi$ = additive fraction of trend of a given exceedance frequency, dimensionless

Values of such multipliers were determined for many pollutants for many wetlands, and the average values are tabulated in Part I for various exceedance frequencies. The relationship between monthly trend average effluent concentration and the 90th percentile monthly concentration for typically regulated constituents is given in Table 16.9, which is extracted from the various results in Part I.

Exit concentrations fluctuate with an amplitude of about 1.75 times the mean for the 90th percentile, meaning that this percentile is about 75% higher than the mean. (Fecal coliform bacteria are a separate case; the multiplier for FC is on $\log_{10}$).

Beyond excursion containment, standard engineering practice is to allow a margin for the unexpected. There are no fixed rules for the selection of a safety factor for wetlands. Water Environment Federation (2001) suggests that an extra 15–25% area is required for treatment wetlands. Equivalently, the designer may elect to design to a more stringent standard than that specified in the regulation. For instance, in the example in Figure 16.6, it could be decided to contain excursions below 20 mg/L instead of 30 mg/L. That leads to a yet larger area requirement, corresponding to 13.1 days' detention in this example.

**TABLE 16.9**
**Trend Multipliers Required to Contain the 90th Percentile of Excursions around Trend Means for Various Pollutants**

| Parameter | FWS | HSSF | VF |
|---|---|---|---|
| BOD | 1.80 | 1.78 | — |
| TSS | 2.21 | 1.84 | — |
| $NH_4$-N | 1.89 | 1.76 | 3.03 |
| $NO_x$-N | 1.74 | — | — |
| TN | 1.53 | — | — |
| TP | 1.94 | 1.66 | — |
| FC ($\log_{10}$) | 1.23 | 1.48 | — |

*Note:* Other percentiles can be found in the pollutant chapters of Part I.

Historically, Kadlec and Knight (1996) determined multipliers corresponding to the 100th percentile of monthly means from the NADB. These were relative to the long-term mean value for a particular wetland, and therefore seasonal variations, whether temperature driven or not, were included in the multiplier. In this book, an annual trend is computed as the basis of the multiplier, thus excluding seasonal phenomena from this measure of random scatter. Further, wetland data may sometimes contain sufficient intrasystem variability to place the 100th percentile above the median inlet concentration. For wetlands with very low inlet concentrations, it may not be possible to design a wetland to totally avoid the possibility of monthly exceedances. Consequently, multipliers for various frequencies of occurrence are tabulated in Part I, and are used in Part II for design purposes.

Curiously, the use of a COR has been ascribed as an attribute of areal first-order models but not an attribute of volumetric first-order models (Water Environment Federation, 2001; Crites *et al*., 2006). Incredibly, the absence of a COR in a volumetric model has been described as an advantage, because then it has "no limiting impact on the mathematical results of design models" (Crites *et al*., 2006). Conversely, Crites *et al*. (2006) portray the use of a COR to adjust the design goal as a disadvantage of the areal model, because it "may result in excessive wetland sizes to achieve low concentrations." Of course, the use of a COR has nothing to do with how one determines the trend values, as is apparent from its use with the volumetric model (Crites and Tchobanoglous, 1998). And there is no doubt that the larger wetland sizes needed to contain excursions are required to achieve an acceptable level of regulatory compliance.

## Other Design Parameters

Some of the specifications of regulatory permits or licenses are outside the commonly encountered groups of rational design parameters, which include BOD, TSS, nitrogen compounds, phosphorus pathogens, metals, organics, and temperature. These do not have loading charts, nor do they have *k*-values.

### pH

There is often a specified range of allowable pH for discharges to surface waters, typically 6.0–9.0. Most treatment wetland applications are not likely to exceed such ranges, as detailed in Chapter 5. Exceptions are the acid mine drainage wetlands, in which the design goal includes raising the pH of the incoming water. Treatment wetlands are not particularly effective at neutralizing strong acid, whereas they are quite good at creating circumneutral pH for more benign influents, such as food wastewaters. Other exceptions include industrial processes, for which a neutralization step is included as part of pretreatment.

### Toxicity

The U.S. Clean Water Act prohibits the discharge of toxic substances to waters of the United States. For this reason, whole effluent toxicity (WET) monitoring is included in the NPDES permits for many municipal treatment plants. WET tests are the standardized procedure to detect levels of acute and chronic toxicity in municipal and industrial effluents. Individual pollutants that contribute to toxicity may be monitored in some instances, such as for nitrite and ammonia, but biomonitoring is required to assess the overall net potential for acute and chronic toxicity to receiving water biota or surrogates.

The short-term chronic toxicity tests that were eventually developed by the U.S. EPA are a relatively inexpensive method of assessing WET (U.S. EPA, 1994). Freshwater chronic toxicity tests utilize three organisms:

- The water flea (*Ceriodaphnia dubia*)
- The fathead minnow (*Pimephales promelus*)
- The green alga (*Selenastrum capricornutum*)

Test methods require a seven-day (96 hours for the algal test) testing period, with renewals of the testing solution using the tested effluent three times during that seven-day period. For the water flea, the test encompasses three reproductive cycles, involving three broods of young (neonates). The adult water fleas are typically fed three times per day during the testing period. Acute toxicity is assessed via mortality. Chronic toxicity is assessed via the number of young produced per female. Tests may be conducted using just control water and 100% effluent, or one or more diluted effluent concentrations.

Fathead minnow testing utilizes larval fish, tested over a seven-day growth period with test water renewals. Acute toxicity is assessed through observed mortality of the fish. Chronic toxicity is assessed by measurement of the final dry weight of the tiny fish at the end of the test period. Laboratory controls are utilized and one or more effluent concentrations are tested to assess the lethal and sublethal effects of the effluent on the fish. Some states have specific protocols that vary from the federal WET guidelines, because of the use of other vertebrate and invertebrate species. Two alternate species are rainbow trout (*Salmo gairdneri*) and a different water flea, *Daphnia magna*. Fathead minnows may be replaced with indigenous fish species such as the bluegill (*Lepomis macrochirus*) or the bannerfin shiner (*Cyprinella leedsi*).

## Toxicity Reduction in FWS Wetlands

A number of studies have shown that constructed wetlands can be effective in reducing toxicity (Knight *et al*., 1997; U.S. EPA, 1999; Wetland Solutions, Inc., 2003). U.S. EPA-sponsored synoptic studies at six constructed treatment wetlands in the United States (McAllister, 1992; McAllister, 1993a; McAllister, 1993b), including standardized toxicity tests. The Collins, Mississippi, wetland had significant acute and chronic toxicity at the wetland inflow, probably due to high unionized ammonia concentrations, but acute and chronic toxicity were absent in the wetland outflow. West Jackson County, Mississippi, had slight acute and chronic toxicity to the water flea at the wetland inflow but no toxicity

at the outflow. Survival and reproduction of the water fleas were increased by the Lakeland, Florida, constructed wetland. No chronic toxicity was present at either the inflow or the outflow of the Orlando Easterly, Florida, wetland.

No toxicity was detected at the inflow of the Incline Village, Nevada, wetland, but the water in the terminal cell of this near-total evaporative wetland was acutely and chronically toxic to the water flea. A similar reduction in reproduction was observed with passage through the Show Low, Nevada, constructed wetland, another near-zero discharge (evaporative) system. It is likely that toxicity was increased in these wetlands (Incline Village and Show Low) as a result of evaporative concentration of salts and other constituents.

Toxicity test results are reported for four treatment wetlands in the NADB v. 2.0 (U.S. EPA, 1999): Santa Rosa, California; Minot, North Dakota; American Crystal Sugar Company in Hillsboro, North Dakota; and Arcata, California (Wetland Solutions, Inc., 2003). An average of 9% mortality in rainbow trout was observed in samples collected at three points in the Santa Rosa wetland system, but there were no influent data. At the Minot constructed wetland outlet, no significant mortality was recorded for water fleas and fathead minnows for test dilutions up to 87.5% effluent. The Hillsboro sugar processing wastewater treatment wetland produced effluents slightly toxic to fathead minnows (15% mortality) and to water fleas (16% mortality). No wetland influent data were available from this site. At the Arcata wetland, data indicated little change in survival between the wetland inlet and outlet (94 to 96%).

Whole water toxicity was measured with water fleas and fathead minnows in quarterly tests of operation in six wetlands treating paper mill wastewaters (Knight *et al*., 1994). No acute toxicity to either organism was found. Influent samples were chronically toxic to the water flea in all cases, but reduced by the wetlands in 10 of 11 comparisons. No chronic toxicity to fathead minnows was observed in any of the wetland outflow samples.

A number of petroleum facilities have reported the reduction of toxicity by treatment wetlands (API, 1999). These include refineries at Richmond, California (Duda, 1992), and St. Charles, Louisiana (Hawkins *et al*., 1995), as well as oil transfer terminals and oil sand processing facilities (Bishay *et al*., 1995).

The Tres Rios constructed wetlands at Phoenix, Arizona, have been extensively studied for toxicity reduction (Wetland Solutions, Inc., 2003). Acute and chronic toxicity in both incoming pretreated water and the wetland outflows was nearly nonexistent or difficult to detect. It was concluded that use of full-scale constructed wetlands for final effluent polishing of the 91st Avenue WWTP final effluent reduced the frequency and magnitude of WET. The wetlands typically reduced low levels of toxicity when they occurred in the WWTP effluent, and did not add to toxicity. However, high levels of toxicity passed through the wetlands with minor alteration, probably due to the very short hydraulic residence times in this system.

In summary, there exist studies indicating that treatment wetlands generally reduce levels of acute and chronic toxicity if present in the inflow. However, the limited amount of wetland data, variation in influent toxicity, and the variability among test protocols preclude forecast modeling of wetland effects on WET. It is not currently possible to calculate the required size of a treatment wetland for a specified level of toxicity reduction.

## 16.5 CLIMATE AND THE WATER BUDGET

Performance-based design rests upon the water budget for the system. The amount of water to be treated is only one part of the hydrologic setting for the project, with precipitation, evapotranspiration, and seepage being the other principal components. These variables are in turn components of the site climate. Another critical component of climate is temperature, which is a driving force for the rates of some wetland processes.

### Climate

Climate cannot be controlled when selecting a specific site for a constructed or natural wetland project. However, climate is important during project planning and alternative selection because it affects the type and size of wetland that will be used. Latitude is the most critical determinant of climate because it determines seasonal temperature ranges. Other climatic factors that are important during project planning include rainfall, insolation, wind direction and velocities, and evapotranspiration. In the United States, climatic information can be obtained from the National Aeronautic and Atmospheric Administration (NOAA) at the following Web address:

National Climatic Data Center
U.S. Department of Commerce
http://www.ncdc.noaa.gov/oa/climate/climateproducts.html

For the entire world, a summary overview of annual patterns of temperature and precipitation may be obtained (free of charge) at:

Climates of the World
National Oceanic and Atmospheric Administration
National Climatic Data Center
Asheville, North Carolina
http://www.ncdc.noaa.gov/oa/documentlibrary/pdf/climatesoftheworld.pdf

Weather and climate data for specific sites across the planet can also be obtained through Web sites such as Weather Underground (http://www.wunderground.com/).

Wetland hydrology is affected not only by the volume of applied wastewater but also by the net balance between rainfall and evapotranspiration. Wetland designers in areas with high net precipitation must take this incremental added water volume into account when deciding on wetland volume, flow control structures, and freeboard of berms. In

areas of high evapotranspiration, wetland design calculations need to consider water loss to the atmosphere. In some cases, the decision may be made to allow the wetland to leak, and seepage can become an important feature of the water budget and have a strong effect on treatment calculations. Chapter 2 presents examples of water balances for FWS wetland treatment systems.

### Rainfall

Figure 2.2 provides a map of the annual average precipitation for the United States. More detailed information concerning the average monthly net precipitation values for the project location should be used to estimate the typical monthly water balance for a continuous flow wetland under extreme seasonal conditions. Historical values of monthly mean precipitation may be found, for 1–10 divisions per state, in the following free Internet publication:

Climatology of the United States No. 85
Division Normals and Standard Deviations of Temperature, Precipitation, and Heating and Cooling Degree Days
National Oceanic and Atmospheric Administration
National Climatic Data Center
Asheville, North Carolina
http://hurricane.ncdc.noaa.gov/cgi-bin/climatenormals/climatenormals.pl

In cold climates, snowfall occurs in the winter months, and accumulates on the wetland during the early winter. The spring melting period causes this stored water to enter the wetland, often as a fairly brief pulse lasting a few days only. Snowfall and snow depth records are available from the National Climatic Data Center (NCDC) for the United States.

As discussed in Chapter 14, rainfall is the primary driving force for stormwater wetlands, and yet more detailed data is therefore desirable. Site-specific information on the intensity and duration of rains, and the interevent spacing, is needed to perform design calculations.

### Evapotranspiration

The mechanisms by which a wetland loses water to the atmosphere have been detailed in Chapter 2. Methods of estimation and data sources have also been detailed in that chapter.

As an example of the kind of information that wetland designers have available, Figure 16.7 shows the various climate zones of the state of California. Table 16.10 lists the monthly *ET* for each zone. Note that arid regions have an annual *ET* loss of 1,819 mm/yr, whereas wet, coastal regions have only 838 mm/yr. The peak *ET* rates are in midsummer, and range up to 9 mm/d for the warm arid zones. For states that do not have irrigation information services, the designer can obtain pan evaporation data for locations in the United States from the NCDC.

The transpiration component of *ET* moves downward into the root zone of a FWS wetland, and thus represents a withdrawal of water and pollutants from the surface water body. In that regard, this transpiration flux resembles infiltration, and can be treated as such in FWS design. In SSF systems, water passes through the rhizosphere, and consequently both evaporation and transpiration losses are withdrawn from the flowing water.

As discussed in Chapter 2, evaporation affects both the flow rate (detention time) and the concentrations of pollutants (evaporative concentration). Therefore, it is inaccurate to merely average the inflows and outflows to account for effects, because that misses the evaporative concentration effect. The flow is slowed, and pollutants become more concentrated. The reverse is true for rainfall: velocities are increased, and pollutants are diluted. The mass balances used in this book for design correctly account for both velocity and dilution effects.

Extreme examples of systems in which *ET* is a dominant factor include lightly loaded wetlands in arid climates. The Incline Village, Nevada, system evaporates nearly all the incoming water, and *ET* was the key factor in project design (Kadlec *et al*., 1990). The Saginaw, Michigan, project operates only in the summer, during which there is an excess of *ET* over rainfall even for this moderately wet climate (Kadlec, 2003c). In another example, on the order of half the water entering the Roblin, Manitoba, FWS wetland system is, by design, lost to net evapotranspiration (PFRA and Town of Roblin, 2003).

### Seepage

Although many treatment wetlands are contained, either with clay or synthetic liners, there are a number of situations in which containment is not needed or not feasible. Any water that leaks vertically downward, or horizontally outward under and through containment berms, represents a water loss that slows flow and contributes to pollutant loss from the wetland water body. Infiltrated water moves into and with the regional groundwater, and may reemerge at nearby locations as groundwater discharge. During passage through the soils under and around the wetland, these seepage waters may receive some additional treatment, by microbial degradation or adsorption, for example. However, not all potential contaminants are subject to soil and aquifer treatment.

The design procedures described herein pertain to the wetland water body and the planned outflows that occur as discharges from structures. This is not to say that infiltration flows can be ignored; instead, the projects with significant seepage are to be viewed as dual-discharge projects. The seepage should meet groundwater requirements, and the structure outflows should meet the appropriate goals, which may be for surface water recipients or infiltration.

Examples of systems in which *ET* is a nontrivial factor include the stormwater treatment areas of South Florida (Nungesser and Chimney, 2006), which lose and/or gain up to about 20% of the flow from groundwater. The New River

**FIGURE 16.7** Reference evapotranspiration for the state of California. See Table 16.10 for the annual pattern for each zone. (Adapted from California Irrigation Management Information System; http://www.cimis.water.ca.gov/cimis/info.jsp.)

wetlands in Southern California infiltrated 47% of the inflow at the Brawley site, and 39% at the Imperial site, over a four-year period of operation (TTI and WMS, 2006).

The wetlands at the Sacramento, California, site (Nolte and Associates, 1998) infiltrated 12.4 ± 4.0% of the inflow for four cells in 1998. The infiltration rates for the site soils were determined prior to the project to be less than 0.15 cm/h for two loams, and 0.15–0.50 cm/h for two clays. For the four wetland cells, in their fifth year of operation, the rates were 0.028 ± 0.008 cm/h, considerably less than those of the parent soils.

Three of the four wetlands at the Tres Rios, Arizona, site had minimal infiltration, but the fourth was built on very coarse river gravel bed materials (Wass, Gerke and Associates, 2001), and the majority of the water leaked vertically downward. Of interest in this project are the trends in the infiltration rates over the first few years of the project history (Figure 16.8). Wetlands H1 and H2 were built on former agricultural soils, and possessed modest infiltration losses of 1.5 and 1.9 cm/d, respectively. Wetland C2 was built on coarse river gravel with a topping of agricultural soil, and the agricultural soils sealed the wetland to about the same leakage rate as H1 and H2: 1.7 cm/d. Wetland C1 was built on coarse river gravel, and leaked at an average rate of 19.7 cm/d. There was a decrease in the infiltration in the cobble wetland C1, from 25.3 to 14.0 cm/d based on the trend line. However, the other three cells maintained a relatively constant infiltration rate. Based on these limited results, only minimal self-sealing should be anticipated in treatment wetlands. If infiltration is not an allowable operating condition, the use of clay or synthetic liners should be considered.

## Temperature

As shown in the design equations provided in Chapter 9, water temperature is important when sizing wetland treatment systems for removal of all forms of nitrogen. Figure 16.9 provides a map of mean annual temperatures in the United States. However, more detail is desirable, and monthly mean temperature is a good estimator of monthly mean water temperature (see Chapter 4), which allows the interpretation of thermal effects on some microbial components of treatment.

**TABLE 16.10**
**Monthly Reference Evapotranspiration by Zone for the State of California**

Historical values of monthly mean air temperatures may be found, for 1–10 divisions per state, in Climatology of the United States No. 85 (previously discussed in the subsection titled "Rainfall" in this chapter).

For planning purposes, the long-term average temperature during the coldest month of the year has been found to be a good estimator of the critical low water temperature that will be experienced in a wetland treatment system. For areas

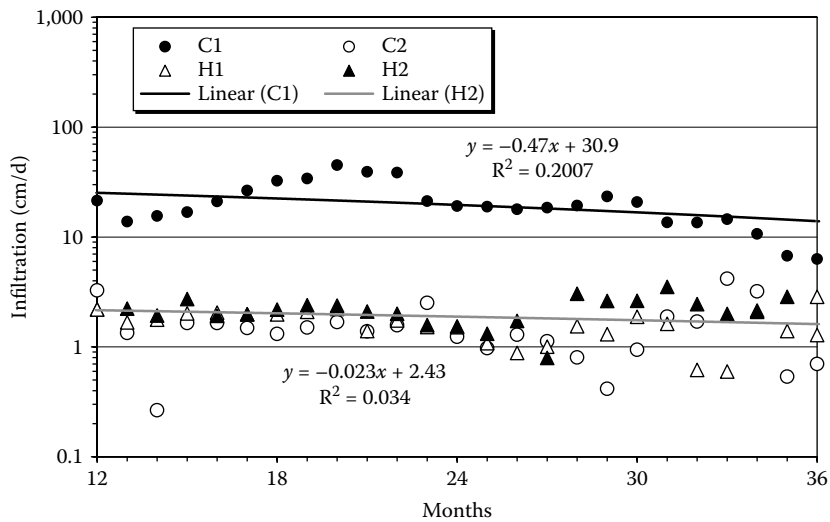

**FIGURE 16.8** Infiltration rates at the Tres Rios FWS wetlands.

| Cell | Soil | Infiltration Rate (cm/d) | Percent of Inflow |
|---|---|---|---|
| C1 | Cobble | 19.7 | 74 |
| C2 | Silty loam over cobble | 1.7 | 12 |
| H1 | Silty loam | 1.5 | 12 |
| H2 | Silty loam | 1.9 | 14 |

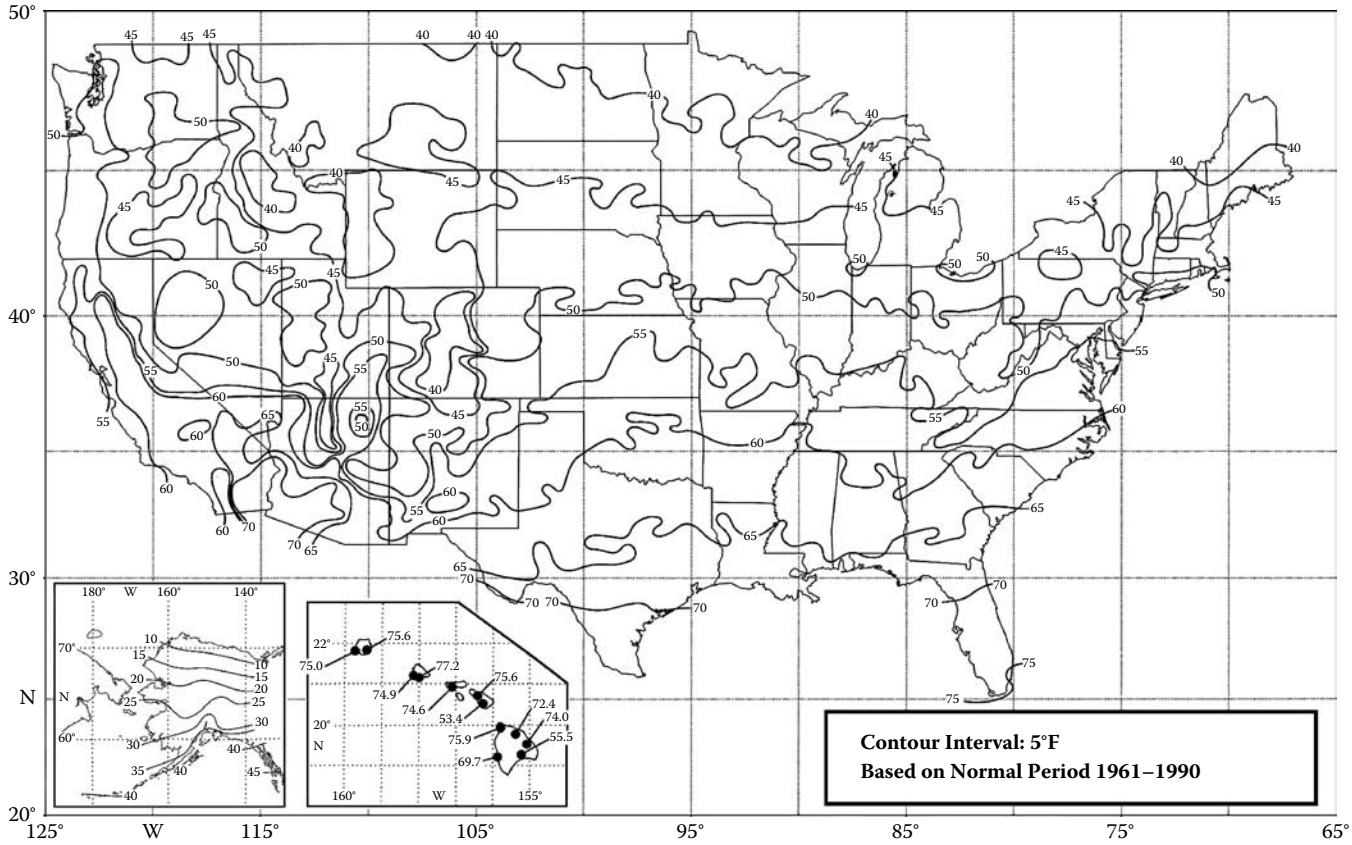

**FIGURE 16.9** Mean annual air temperatures in the United States (°C = (°F – 32)/1.8). (From National Climatic Data Center (2007) at http://www.ncdc.noaa.gov/oa/climate/climateproducts.html.)

in which the average monthly temperature is less than zero, it can be assumed that the minimum wetland operational temperature will be slightly above zero under an ice cover (see Chapter 4 for more information).

## 16.6 SELECTION OF WETLAND TYPE

The type of wetland selected varies with a number of factors, and the best choice may require alternatives evaluation. There are some over-arching concepts that can assist in the selection.

### "Natural" versus "Engineered" Systems

Treatment wetlands can be designed to be "au natural" or complex. Examples of designs along a full spectrum from almost zero fossil-fuel input to highly engineered and managed systems can be found around the world. In this book we term these design and operation strategies as Type *A* and Type *B* wetlands. Type *A* systems are at the most natural, low-energy end of the scale. They have the minimum number of structures, and may often be gravity fed. Vegetation may be allowed to proceed by natural recruitment (Figure 16.10). Type *B* wetlands are higher energy and more highly engineered systems. Pumps are likely to be present, for recycle as well as other water transfers, and piping can be complex. Special media may be involved, and the system may be mechanically aerated in some cases. Vegetation is likely to be highly specific, such as a monoculture of planted *Phragmites* (Figure 16.11). There are good reasons to slide on this scale of design and management complexity, depending on project goals.

Type *A* wetlands are the preferred solution when:

- There is sufficient treatment potential with a Type *A* approach.
- Relatively inexpensive land area is abundant and land is not a limiting factor.
- There is insignificant potential for unauthorized human interaction with the wastewater in the wetland.
- Habitat and aesthetic benefits outweigh the potential for nuisance conditions related to mosquitoes or other wildlife.

Type *A* wetlands are typically constructed FWS marshes, relatively low-tech HSSF wetlands, and natural treatment wetlands. They are always less costly to operate than Type *B* treatment wetlands, and may be less costly to construct, depending on the local situation.

The Type *B* treatment wetland design and management strategy is preferred when one or more of the factors listed previously are limiting the design. Specific examples of Type *B* treatment wetlands include:

**FIGURE 16.10** Type *A* constructed wetlands may be built by berming off a plot of ground and allowing natural regrowth to vegetate the system. This wetland at Onaway, Michigan, is used for ultra-polishing of a lagoon effluent that has had post-sand filtration and phosphorus removal by chemical precipitation.

- HSSF wetlands augmented with saturable media intended for phosphorus or metals removal
- Addition of aerators in constructed HSSF wetlands for improvement of nitrification
- Addition of VF components to HSSF constructed wetlands to improve nitrification (potentially with flow recirculation)
- FWS or HSSF wetlands and aquatic plant treatment systems with plant harvesting
- High solids treatment wetlands with frequently cleaned forebays, or frequent refurbishment and restarting, as for sludge reed beds

Type *B* wetlands are more expensive to operate, and may be more expensive to construct, compared to Type *A* wetlands, and consequently there needs to be a clearly demonstrable need for the added complexity and energy consumption.

## FWS or HSSF?

The two most prevalent types of treatment wetland, especially during the early history of the technology, are FWS and HSSF wetlands. The mind-set in North America was often to emulate the natural habitat wetlands (duck marshes) for ecological reasons. In Europe, there prevailed, and still does, the concept that HSSF flow systems are more efficient, and will require a smaller footprint for an equivalent level of treatment performance.

An analysis of performance data suggests that HSSF wetlands are not more efficient than FWS systems. Earlier

**FIGURE 16.11** This small-scale vertical flow wetland system, near Aarhus, Denmark, consists of a below-ground sedimentation tank, two vertical flow *Phragmites* beds, three phosphorus removal beds, four pumps in pump wells, and complex interconnected piping. It qualifies as a Type *B* constructed wetland system. (Photo courtesy H. Brix.)

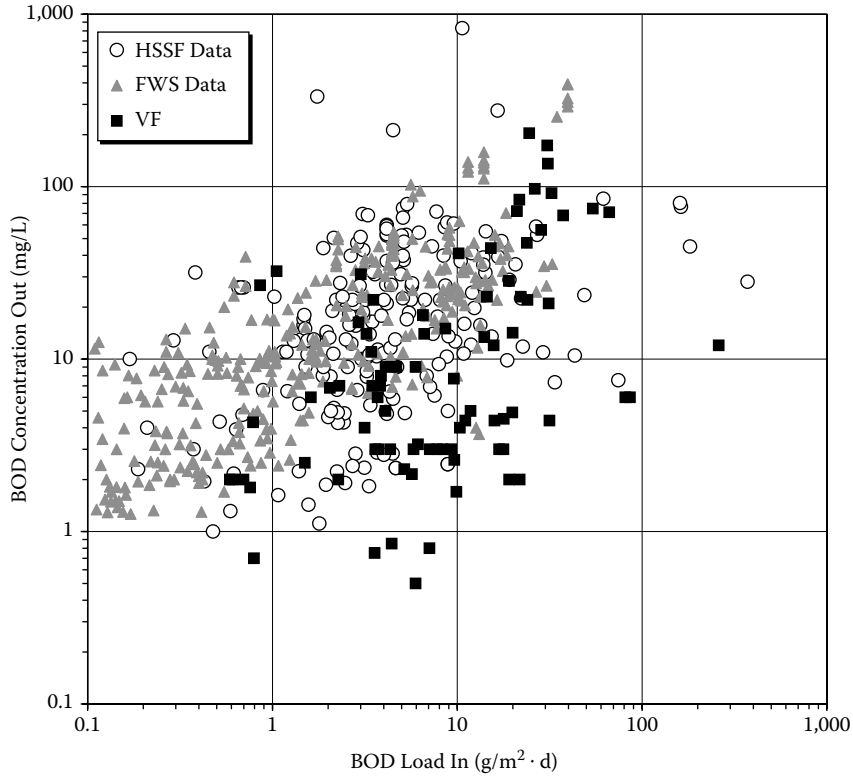

**FIGURE 16.12** Overlay of FWS, HSSF, and VF BOD loadings and effluent concentrations.

analyses, such as that in Kadlec and Knight (1996), suffer from two difficulties: the North American experience of 15 years ago was very limited in numbers of systems and the length of their operations, and the calibration ranges of FWS and HSSF systems were quite different. To compare types, FWS calibrations had to be extrapolated to higher loadings, and HSSF, to lower loadings. As is now known, such extrapolations are not warranted, and can be greatly in error (Kadlec, 2000).

At the time of this writing, there are much more extensive and numerous data sets available, so that comparisons need not rely on extrapolations. The foundation for accomplishing this comparison has been set down in Part I for the various common pollutants. There are two obvious avenues of comparison: loading charts and *k*-values, which were both used in Kadlec and Knight (1996). However, both can now be updated based on much more information. In the case of loading charts, the (desirable) overlap in loading ranges has increased. In the case of *k*-values, the underlying hydraulics can now be better accounted.

Superpositions of the loading data for HSSF, FWS, and VF wetlands are shown in Figure 16.12, 16.13, and 16.14 for BOD, ammonia, and fecal coliforms, respectively. Other pollutants behave similarly. It is clear from these scatter plots that the respective data clouds overlap virtually entirely for HSSF and FWS wetlands. There is no difference when they are compared on this areal basis. At the level of this broad perspective, this means that a square meter of FWS will do the same job as a square meter of HSSF. However, VF wetland data are set apart on these graphs, with VF systems typically providing lower outlet concentrations at equivalent loadings. This has, of course, been well documented in the literature for reduction of ammonia.

The loading chart method does not separately account for changes in inlet concentrations and hydraulic loading (or detention time); but first-order areal rate coefficients do. Therefore, it is useful to examine the various calibrations that have been set forth in Part I. Table 16.11 provides the central percentiles of the distributions of *k*-values for the various common contaminant targets. For BOD, FWS rate coefficients are higher, except for the tertiary application zone. FWS is also better for $NH_4$-N, TKN, and TN, but slightly worse for $NO_x$-N. The horizontal subsurface systems appear slightly better for fecal coliform reduction. Overall, the message is that there is not a large difference between *k*-values for FWS and HSSF wetlands, and the advantage may be to either type, depending on which contaminant is under consideration. From the standpoint of treatment performance per unit area, as embodied in the *k*-values, there is little discrimination. This is supportive of the same conclusion reached from the loading chart approach.

VF wetlands appear to be slightly better for removal of BOD and ammonia, but because the nitrate reduction is not much different, the reduction of total nitrogen is not superior. This is also supportive of the same conclusion reached from the loading chart approach.

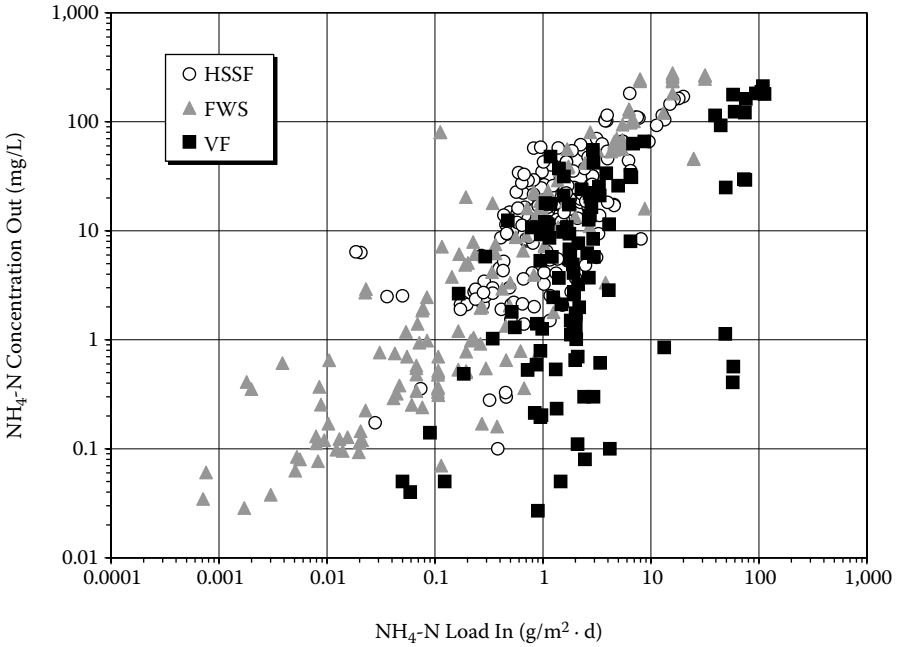

**FIGURE 16.13** Overlay of FWS, HSSF, and VF ammonia loadings and effluent concentrations.

As discussed in Chapter 23, it is not just economics alone that favor the choice of HSSF wetlands. Factors other than reduction performance are also important in the selection process. The principal reasons for selecting the HSSF option over the FWS option are concerns about:

- Human health via contact with untreated waste-water
- Mosquito control
- Odor control
- Minimizing wildlife interactions within the wetland

In the United States, human health regulations do not allow the potential for contact between humans and raw wastewater. The perceived risk of contact with pathogens is too great. This in turn means that no treatment system can allow such contact. The raw sewage facilities at mechanical plants and lagoons are strongly fenced, with required setbacks from human activities. If wetlands are to be used for raw wastewater (or primary effluent), and are unprotected from human access, then the HSSF option is necessary to ensure that there will be no human contact with the water being treated.

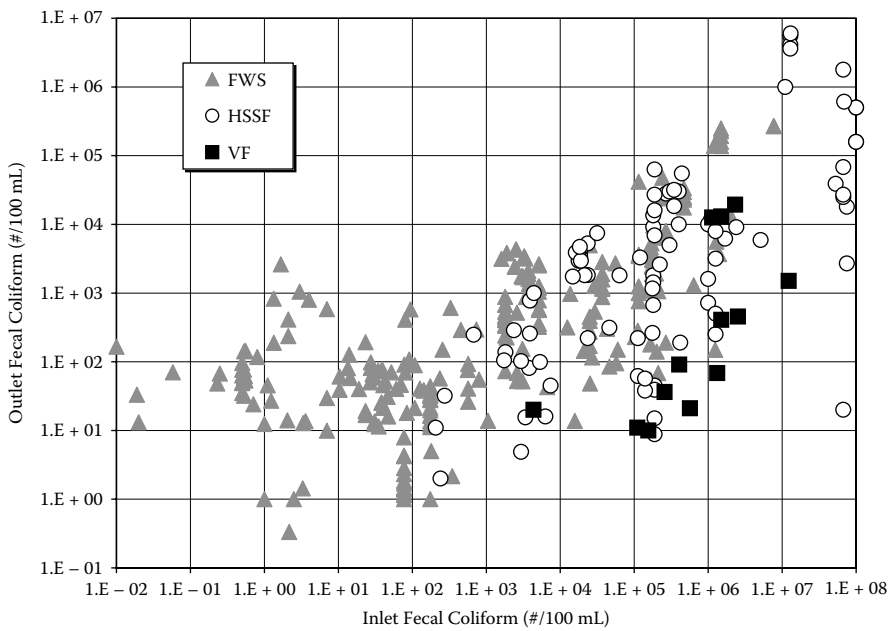

**FIGURE 16.14** Overlay of FWS, HSSF, and VF influent–effluent fecal coliform concentrations.

* = insufficient data to determine parameters.

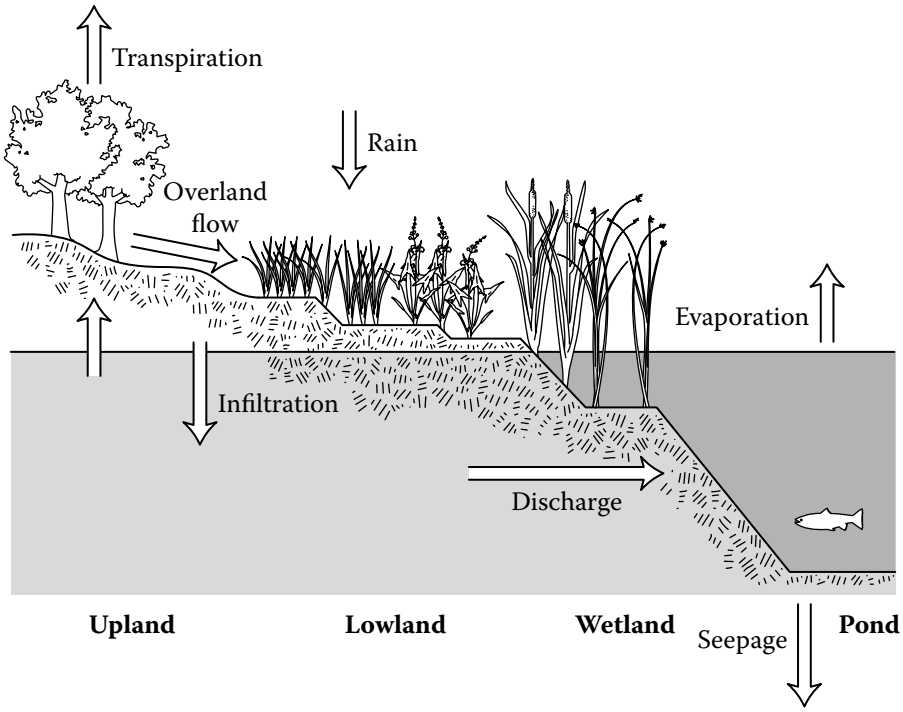

**FIGURE 16.15** Natural systems for wastewater treatment borrow from natural gradient and hydrologic regimes.

Although insect management is possible to a degree in FWS wetlands (see Chapter 22), there are potential nuisance and health problems, particularly from mosquitoes. Mosquitoes require surface water of some sort to breed and develop, and hence FWS wetlands may provide suitable habitat. The degree to which this added habitat exacerbates the regional milieu is very site specific, with greater possibilities for real and perceived problems in warm arid climates where there are few natural wetlands. The choice of HSSF wetlands in these situations can provide an acceptable alternative to costly control measures in FWS systems, such as expensive larvacide and adulticide applications. In a similar way, the choice of a HSSF system avoids gross oversizing (as has sometimes occurred in the southwestern United States) to allow for hydraulic and vegetation patterns that are inimical to mosquito activity.

Raw wastes also can emit significant odors, usually due to reduced sulfur compounds or decomposition of organic matter. Because wetlands function with a vegetative cycle that includes decomposition of organic matter, they are a potential source of odors under most circumstances, even with no wastewater added. However, natural wetland odors are typically not viewed as objectionable, whereas the sulfurous emanations of wastewater are universally disliked. Odor emission is also present for wastes other than sewage. For example, potato and other food processing wastewaters can create extreme odors, not only aesthetically objectionable, but also in some cases intolerable for human activity (Burgoon *et al*., 1999). Wetlands are no worse in this regard than the pretreatment lagoons that may precede them, but nonetheless odor situations are to be avoided. Setbacks and other measures can help in control, but keeping the water below ground, and under a vegetative canopy, is probably the easiest odor control measure.

Wildlife invariably interacts with treatment wetlands, and to a greater degree for FWS systems (see Chapter 19). Although such interactions are usually favorably looked upon, that is not always the case. For instance, flying waterfowl are a distinct threat to aviation if they occur in large numbers near airports (Naval Facilities Engineering Service Center and Wetland Solutions Inc., 2004). In other applications, wildlife represents a potential threat to system operation, and may require oversizing of FWS systems to accommodate their impacts (Kadlec *et al*., 2007). SSF wetlands are less attractive to many sorts of birds and animals, and choosing HSSF or VF wetlands will minimize animal interactions in most cases.

## Other Natural Systems

Wetlands of various kinds form a subset of natural systems technologies. A spectrum of constructed ecosystems have been devised, all of which emulate some portion of the gradients and hydrologies found in nature (Figure 16.15). In this book, the focus is on those ecosystems that contain emergent plants that are obligate to the definition of an inundated or periodically saturated wetland environment. However, it has been suggested that on the dry end of the spectrum, overland flow systems resemble FWS wetlands, and in fact may be described by the same sorts of models (Wong *et al*., 2006). At the wet end of the spectrum, wetlands transition into ponds, and there are not large differences in observed performances

in pollutant reduction for many contaminants between ponds and wetlands (Kadlec, 2005e). Consequently, the designer is faced with a decision process that may be heavily conditioned by the regulatory political "climate." Alternatives often need to be compared, and a combination of unit ecosystems given consideration.

There are many literature sources that may be consulted for information on the performance of the various unit ecosystems (Table 16.12). Many of these sources have been updated within the past few years. Infiltration systems may be variously identified as slow-rate, rapid, on-site or soil-aquifer treatment. All rely on processes associated with vertical movement of water in the unsaturated or saturated zones of the soil. Slow-rate systems may also rely on plant uptake and harvest. Overland flow consists of vegetated fields with very shallow (a few centimeters), and perhaps intermittent, flow at moderately steep slopes (1–8%). Plants need not be wetland obligates, and most often are not; rather, upland grasses are employed. The design of such systems is usually on a rudimentary loading basis.

Ponds are typically deep enough to preclude the presence of emergent plants, often on the order of one to two meters. If the water is on the order of half a meter deep, and the system has no emergent plants, it may be termed either a shallow lagoon or an unvegetated FWS wetland. Design guidelines abound, with the most recent compilation in Shilton (2005).

There are new unit ecosystems that show promise for appropriate niches in treatment trains. These include intensively managed and harvested algal systems, termed algal turf scrubbers (Craggs *et al*., 1996a), and periphyton dominated systems for phosphorus reduction (Kadlec and Walker, 2004).

Finally, we separate natural wetlands from the category of constructed natural systems. This is done for two reasons: current wetland protection regulations preclude the use of natural wetlands in the large majority of situations in North America, and natural wetlands in general fit nicely into the performance projections for constructed FWS systems. Natural wetlands are impacted by the addition of either more water or more contaminants than they have historically been exposed to. Thus, the use of natural wetlands typically requires an assessment of the impacts of the potential wastewater addition on the ecology of that wetland. A sizeable performance database exists, because of past projects that have used existing wetlands as receiving waters for partially treated discharges. In the past, this has often been a matter of convenience, rather than design, because of the proximity of a project to wetland receiving waters (for example, Brillion, Wisconsin [Spangler *et al*., 1976], or Kinross, Michigan [Kadlec and Bevis, 1990]).

It is usually not optimal to utilize a wetland as the sole element of a natural system to meet final requirements. The integration of the wetland into an engineered natural system often makes better economic sense. The phosphorus-binding capacity of soils, and their nitrification potential, can complement the wetland's capabilities for anaerobic

processes and denitrification. Ponds can provide sedimentation and water storage in a more land-economical way. The techniques presented in this treatise are applicable to wetlands used as pieces of integrated natural systems. Various combinations of treatment wetlands of different types, as well as other unit ecosystems, are considered in Chapter 24. Here, the designs of the three common types of wetlands are considered as individual elements of the integrated treatment system.

## 16.7 PRE- AND POST-TREATMENT REQUIREMENTS

Wetlands are not capable of entertaining all levels of all pollutants, because they are biological systems that can only exist in a certain envelope of potential concentrations of certain contaminants. Therefore, the designer must adhere to the requirements of the selected ecology, or the wetland may suffer injury or destruction. Inflows may require pretreatment to allow a functioning ecosystem to exist. The discharge requirements of receiving waters may be outside the range that the wetland can produce, due primarily to wetland background concentrations. Thus, posttreatment may be needed to meet regulatory limits.

### Pretreatment

FWS wetlands in North America normally receive municipal water of approximately secondary quality or better. This is in contrast to the subsurface technology (HSSF and VF) in Europe, which typically treats settled or primary influents. Urban and agricultural runoff waters are also relatively dilute influents. Industrial wastewater treatment wetlands are usually added to the end of a "conventional" treatment process. Some fairly strong food processing wastewaters are being treated with integrated natural systems, but these systems usually have some form of primary treatment, such as a clarifier, lagoon, or filter. Pretreatment may also be required to ensure the survival of the treatment wetland.

### Wetland Survival Limits

As treatment wetlands are used in new and challenging applications, there is an increasing risk of inadvertently designing for conditions that the wetland cannot tolerate. A few of the basic considerations are listed here.

### Excessive Solids

Sediment accumulation is one of the few processes in wetlands treatment that has a foreseeable requirement for maintenance. Sooner or later, sediment accumulation will require some sort of removal activity or reconfiguration of the wetland. Based on present experience, such maintenance will be on the schedule of decades for FWS wetlands unless there is an unusually high content of settleable solids in the incoming water. In that event, a settling basin or pond is a logical pretreatment device. Stormwater wetlands typically embody such elements. For HSSF wetlands, there is an increasing body of knowledge that indicates the cross-sectional loading is a critical design parameter (see Chapter 21). For VF wetlands, it is apparent that resting intervals between loading periods are necessary to control solids accumulation and associated bed clogging problems (see Chapter 21).

Upsets in pretreatment elements of the overall treatment train can episodically pass large quantities of TSS to downstream treatment wetlands, which can pose difficulties for both FWS and HSSF wetlands. In the case of HSSF systems, the solids can form a blanket that smothers the vegetation, probably by overpowering the plants' abilities to modify their rhizosphere to avoid oxygen deficiencies. Figure 16.16 shows this phenomenon at the Hardin, Kentucky, HSSF facility, which has a package activated sludge plant for pretreatment. Sludge overflows blanketed the inlet, clogging the bed and killing the vegetation. This problem also occurs for FWS wetlands, as evidenced in Figure 16.17 for the Listowel, Ontario, facility.

Iron precipitates can form precipitates that can be problematic in treatment wetlands. Wastewaters may contain reduced iron compounds that can become oxidized in the wetland environment. Under aerobic conditions, oxyhydroxides precipitate to form ochreous sludge that can coat plants in a FWS wetland, or potentially clog the media in an SSF system (Figure 16.18).

Inlet deep zones may serve to protect a FWS wetland from TSS overloads, but not if such loads are sustained (see Figure 7.13). Solids overload protection is thus a necessary part of treatment wetland design.

### Phosphorus Precipitates

Phosphorus reduction is one of the least efficient processes in wetland treatment. Low TP concentrations can

**FIGURE 16.16** The Hardin, Kentucky, HSSF *Phragmites* and *Schoenoplectus* (*Scirpus*) wetlands received periodic sludge overflows from the pretreatment device (Imhoff tank). As a result, the inlet to the bed became a sludge bed with no live plants.

**FIGURE 16.17** The Listowel, Ontario, FWS *Typha* wetlands received episodic sludge overflows from the pretreatment device (primary lagoons). As a result, the inlet to the wetland became a sludge bed with no live plants. Incoming water forms a rivulet across the sludge.

be reduced to even lower ones, but large phosphorus load removal requires a large wetland area. Consequently, some pretreatment for the reduction of high TP concentrations is normally cost effective. Iron and alum addition are the most frequent choices, both of which directly or indirectly remove phosphorus, by precipitation and co-precipitation respectively. The settling of these solids is often increased by the addition of polymeric flocculating additives. In the case of FWS wetlands, the point of addition needs to be upstream of the wetland, because there is not an effective way to provide chemical contacting in the wetland itself. However, if the precipitates carry over into the wetland, they can create unacceptable conditions in the sediments, because of aluminum toxicity or because co-precipitation produces the ferric materials discussed previously.

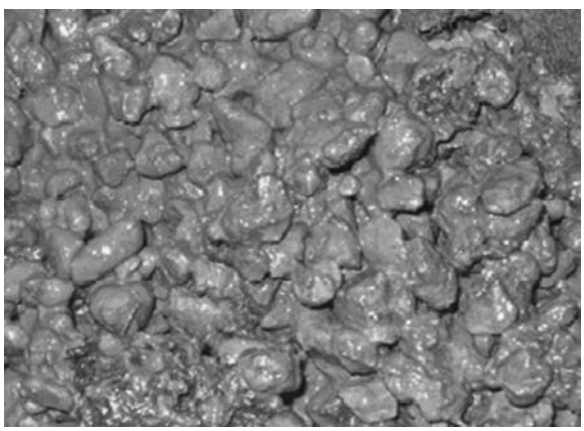

**FIGURE 16.18** The Anamosa, Iowa, HSSF wetland, vegetated by a mixture of local species, received landfill leachate with a moderately high iron content. As a result, the media became clogged with iron precipitates. (Photo courtesy J. Nivala.)

### Excessive Nitrogen

Nitrogen concentrations of wastewaters are among the most variable across various possible sources. For instance, nitrified secondary waters may have ammonia at less than 1.0 mg/L, but landfill leachate can reach 1,000 mg/L. At the extreme low end, there may not be enough nitrogen to sustain wetland vegetation after the developing ecosystem has "mined" the available preexisting soil nitrogen. At the extreme high end, inorganic nitrogen of over 100–200 mg/L may pose a threat to vegetation, because of fertilizer "burning" effects. Therefore, the introduction of strongly ammoniacal influents to treatment wetlands must be avoided. Fortunately, the fairly simple expedient of recycling effluent flows to dilute influent concentrations can usually solve this problem (Kadlec, 2003c). Other nutrients, phosphorus and potassium, have not been observed to create similar difficulties.

### Strong Specialty Chemicals

Treatment wetlands are increasingly used for treating waters that contain individual chemicals, which, if in excess, can threaten the wetland ecosystem. As an example, a chemical plant effluent at Estarreja, Portugal, is successfully treated using a HSSF *Phragmites* wetland. However, a high-concentration pulse of nitric acid found its way into the wetland, causing the destruction of vegetation in the inlet zone (Figure 16.19).

It is noteworthy that wetland plants have evolved to include varieties that can withstand extreme conditions. Low pH varieties can live in acidic conditions, down to pH = 2 to 3, as demonstrated by the acid bog vegetation of northern latitudes. Conversely, other wetland plants can live in very basic waters, such as those adapted to alkaline fens and some of the prairie potholes. Thus, it is necessary to consider the tolerances of the selected wetland plants to the conditions

**FIGURE 16.19** The Estarreja, Portugal, HSSF *Phragmites* wetland received an accidental discharge of nitric acid from pretreatment. As a result, the inlet to the wetland (right) became devoid of living plants. The outlet zone (left) maintained a healthy stand.

that they are to endure. Acid mine drainage wetlands are in the category of those that require consideration of strong chemical content.

### Excessive Sulfide

Freshwater wetland plants are intolerant of sulfide (Lamers *et al*., 2002; see the sulfur section of Chapter 11). Therefore, if the water entering a treatment wetland contains sulfate, there exists the possibility of reaching high levels of sulfide in anaerobic treatment wetland sediments. This has the potential to be devastating to FWS plants, and has been implicated as a possible cause of the total demise of vegetation (*Scirpus*) at the Tres Rios wetlands (Figure 16.20). Yet, other wetland plants can endure stronger sulfidic conditions, as evidenced by the ability of *Phragmites* to survive in waters nearly saturated with sulfate, and the attendant sulfide created by anaerobic conditions.

### Oxygenation of Wetland Influents

Intuitively, it seems that adding oxygen to waters entering treatment wetlands is a useful strategy. Several wetland processes, such as BOD reduction and nitrification, are oxygen dependent. The incoming water may be oxygen-poor because of pretreatment processes. Therefore, preoxygenation has been used in some applications (Figure 16.21). However, it is only possible to raise the oxygen content of the water to saturation by this technique, typically 6–10 mg/L (see Chapter 5). For a hydraulic loading rate of 6 cm/d (central tendency), the

**FIGURE 16.20** The Tres Rios, Arizona, FWS *Scirpus* wetlands received nitrified secondary wastewater from an activated sludge plant. After two years, the vegetation died, possibly due to sulfide toxicity.

**FIGURE 16.21** The Lakeland, Florida, FWS inlet cascade.

addition of 5 mg/L of dissolved oxygen (DO) only adds 0.3 $gO/m^2 \cdot d$. That is a small proportion of the DO needed for aerobic microbial processing in most treatment wetlands.

### Postwetland Requirements

A common regulatory requirement is the reduction of fecal coliform bacteria to low levels in the wetland effluent. Because FWS wetlands are frequented by warm-blooded animals and birds, the background levels of fecal coliforms often do not comply with typical receiving water standards. This particular bacterial indicator does not distinguish the animal of origin, and hence the conservative regulatory stance is to ascribe the total measure to human origins. Therefore, the attainment of low fecal coliform levels may need to be accomplished by postwetland disinfection, via chlorination, ozonation, or UV irradiation. In the event that chlorination is used, there remains an issue of the residual chloramines that are formed, as well as the levels of residual chlorine (see Chapter 12). Concerns for the effects of disinfectants, such as chlorine, upon the treatment wetland microbial consortia that conduct much of treatment have resulted in dechlorination facilities in some cases.

The low amounts of dissolved oxygen found in many FWS and HSSF treatment wetland effluents may also violate receiving water standards in many cases. In Europe, the DO content of receiving streams is not usually a restriction. Natural wetlands (meaning those not used for treatment) do not often meet the DO requirement of approximately 5 mg/L required for many receiving streams in the United States. For instance, the lightly loaded wetlands used for Everglades protection in Florida, which have essentially no BOD load nor any ammonia load, have a high exceedance rate for DO (SFWMD, 2006). These systems do not on average meet the 5 mg/L level required by the Class III water standards of the state of Florida, thus necessitating new rules and regulations for wetlands. In general, wetlands fail DO regulatory requirements, and some form of postwetland aeration may then be required. If the site topography permits, this can be a simple aeration cascade, as previously illustrated in Figure 16.21.

The peculiarities of discharge regulations can lead to other posttreatment steps. For instance, the Lakeland, Florida, system was subject to a very low TSS discharge requirement of 5 mg/L annual average, because of the Grizzle–Figg law in Florida. The last element in the train of wetland cells was a water hyacinth cell (*Eichhornia crassipes*), which lost full cover due to insect attack. The resulting open water allowed phytoplankton development, with resulting TSS of 7.6 mg/L. As an interim measure, a dye (Aquashade™) was added to block the radiation needed by the algae. Subsequently, the wetland cells were reconfigured to avoid the terminal open water, and compliance was regained.

## SUMMARY

In this chapter, the information-gathering phase of treatment wetland design is described. Design of wetland treatment systems or any other pollution control technology depends on the best possible knowledge of influent wastewater characteristics. Some general guidelines are presented for pollutant concentrations and loads from a variety of wastewater categories that might be applied to wetland treatment systems. Site-specific conditions, and their potential constraining effects on design, are collected and analyzed. The meteorology that the wetland will experience is determined. Importantly, the goals that need to be accomplished are to be carefully set down for use in subsequent design calculations. In the performance-based design of the wetland, all of this information plays a quantitative role.

Table 16.13, adapted from the Alberta 2000 guidelines, provides a sample checklist of the factors that affect the selection and sizing of the wetland (Alberta Environment, 2000). It documents the basic information required to determine the feasibility of using a treatment wetland for polishing of a wide variety of industrial, agricultural, and municipal wastewater discharges. It is intended to act as a general screening tool. General information including soil type, permeability, and site topography must be confirmed with testing, surveying, etc., prior to the final stage of design. Data include site location, type of wastewater pretreatment, pretreated water quality, hydraulic loading, soil conditions, land availability, effluent water quality objectives, current land use, topography, and climatic factors. The collected data must be reviewed, and contaminant loadings determined and compared to provincial guidelines. Further treatment of the wastewater may be required prior to inflow to the wetland system, either in the existing wastewater treatment plant or as a separate treatment unit. It must also be determined if portions of the treatment wetland system will be accessible to the public. This will have some bearing on the type of treatment wetland that will be most suited to the treated wastewater source.

# 17 Sizing of FWS Wetlands

A performance-based procedure is unavoidable for FWS wetlands because they address too many applications with varying degrees of source strength and pretreatment. In general, the targets are also variable because of the differences in regulatory requirements among countries, states, and discharge recipients. Loading specifications, whether as pollutant kilograms per wetland hectare per year or as wetland hectares per person equivalent, have not, and, in general, cannot be developed to deal with the spectrum of situations created by FWS diversity of applications. It is not an exaggeration to say that each FWS wetland is unique.

Design of FWS wetlands may be roughly divided into two categories: sizing calculations and physical specifications. Sizing requires characterization of the incoming water and regional meteorology as well as the goals of wetland treatment, as discussed in Chapter 16. Here, a comprehensive sizing strategy is presented, based on the information assembled. Chapter 18 will deal with physical considerations, including the number of cells, layout, depth, bathymetry, soils and plants, structures, and lining. It is recognized that wetlands are almost never stand-alone treatment devices, but rather form part of a treatment train. Other components may be mechanical, such as clarifiers or filters, or more natural, such as settling basins or lagoons. More than one type of wetland may be involved at the same site—FWS, VF, and HSSF. This chapter focuses on only the FWS component of treatment systems.

Based on the performance-based sizing algorithm introduced in Chapter 15, the key features described in this chapter are the following:

Parameter selection and calculation

6. Select rate constants and seasonality. (Select plant community type.)
7. Select DTD (hydraulic) efficiency = *P*-value. (Select compartmentalization.)
8. Adjust area till goals are all met.

Constraint checks and iteration

9. Set estimated growth cycle.
10. Check biogeochemical cycles for consistency.
11. Check chemical constraints.
12. Check loading graph for risk assessment.
13. Adjust for seasonality.

Repeat this procedure as needed to meet design goals.

The complexity of wetland behavior and, hence, of the sizing calculation is such that a single equation for wetland area cannot be written. At this point in the evolution of the treatment of wetland design, the sizing procedure must move out of the realm of the pocket calculator and into the world of spreadsheet computations. The single formula, black-box approach will not suffice.

## 17.1 POLLUTANT REDUCTIONS AND PERFORMANCE COMPUTATIONS

The information collected is utilized as a basis to forecast the area needed to achieve the goals of the project. The procedure outlined here is for a steady-flow situation. Different flows may need to be considered to deal with daily or seasonal peaking. Different seasons may need to be considered, so that the "bottleneck" period of the year is identified and analyzed.

Many literature sources provide single equations into which anyone may insert numbers to compute a wetland area. Although such an option would be very convenient, it is not realistic except for a few highly specialized cases. Accordingly, the procedure given here explores the effect of changing wetland area (or equivalently, detention time) on the forecasted effluent concentrations of contaminants. It is presumed that the designer will conduct the design calculations via a computer spreadsheet so that design changes may be easily explored.

Wetland hydrology is first determined as a necessary precursor to area calculations. Annualized calculations are considered first; the effects of season will be considered later in the chapter.

### Water Budget

The annual water budget forms the basis for understanding pollutant reductions and the area required. Assuming a constant water level, the flows out of the wetland may be computed from the inflow and meteorological data. Some infiltration is also assumed here if leakage is present in the wetland. The relevant equations are

$$Q_o = Q_i + A \cdot (P - ET - I) \tag{17.1}$$

$$q_o = q_i + (P - ET - I) \tag{17.2}$$

where

$A$ = wetland area, $m^2$
$ET$ = evapotranspiration rate, m/d
$I$ = infiltration rate, m/d
$P$ = precipitation rate, m/d
$q$ = hydraulic loading rate, m/d
$Q$ = flow rate, $m^3/d$

The inlet hydraulic loading will be increased by rainfall (≈0.5–1.5 m/yr) and decreased by evapotranspiration (*ET*) (≈ 0.5–1.5 m/yr). However, there may be seasonal imbalances. These amounts are important if the wetland is to have a very low hydraulic loading or, correspondingly, a long detention time. The ratio $a = (P - ET)/q_i$ is the atmospheric augmentation.

Evapotranspiration (rain) has two effects: lengthening (shortening) of detention time and concentration (dilution) of dissolved constituents. The use of an average flow rate compensates for altered detention time but not for dilution or concentration. The fractional error in a first-order model prediction of concentration due to flow averaging is approximately equal to $a$, for $a > -0.5$. Thus, if 25% of the inflow evaporates, use of a first-order model with average flow predicts concentrations 25% lower than required by the mass balance. If rain adds 25% to the flow, use of a first-order model predicts concentrations 25% higher.

A possibly important feature of *ET* is that the transpiration carries water into the root zone (see Part I, Chapter 4). Therefore, if the pollutant mass balances are done on surface water, then the transpiration component is the same as infiltration: it carries materials into the soil. For a fully vegetated wetland, somewhat more than half of *ET* is attributable to transpiration. Transpiration is typically about one half to two thirds of *ET* (Kadlec, 2006c):

$$T = (ET - E) = \alpha ET \tag{17.3}$$

where
$E$ = evaporation, m/d
$T$ = transpiration, m/d
$\alpha$ = transpiration fraction of *ET*, dimensionless

The pollutant mass balances will be conducted on a cells-in-series basis (see Figure 17.1). Results of the overall water mass balance are apportioned to the cells according to the chosen number of TIS. For the first unit in the series:

$$Q_1 = Q_{in} + A_1(P - ET - I) \tag{17.4}$$

where
$A_1$ = area of tank number 1, $m^2$
$Q_1$ = flow rate out of tank 1, $m^3/d$

Flows are thus computed sequentially, from inlet to outlet, for the number of tanks chosen (*P*TIS).

The input data requirements for water mass balances are

1. Inflow ($Q_{in}$)
2. Rain ($P$)
3. Evapotranspiration ($ET$)
4. Infiltration ($I$)
5. Area ($A$)
6. Apparent number of tanks in series ($P$-value)

An example is detailed in Table 17.1. This hypothetical example is configured to include small rainfall, considerable *ET*, and some infiltration; in other words, a leaky arid region system. The net loss of incoming water is 41%, of which 44% is *ET* and 56% is infiltration.

## Pollutant Mass Balances

The TIS model is then carried forward via a sequential calculation of pollutant concentrations for each "tank" in the chosen hydraulic model (Figure 17.1).

A first-order areal model with rate constant $k$ is selected with necessary wetland background concentration $C^*$. A volumetric first-order model may also be chosen for which $k = \varepsilon h k_V$. The pollutant mass balance for the first of the wetland segments, designated by subscript "1" for steady-state,

| Nominal detention (d) | 13.7 | 5.3 | 6.3 | 7.7 | 19.2 |
| HLR (cm/d) | 2.08 | 5.40 | 4.55 | 3.70 | — |

*Note:* Sequential tank-to-tank calculations are based on Equation 17.4; this example has a combined detention time of 19.2 days, whereas averaging the flows leads to 17.2 days; the required input data are shown in bold.

nonuniform flow is

$$Q_1C_1 = (Q_{in}C_{in}) - (I \cdot A_1C_1) - (\alpha ET \cdot A_1C_1) - \left(k \cdot A_1 \cdot (C_1 - C^*)\right) \quad (17.5)$$

In this simple version, rainfall has been assumed to have zero pollutant concentration, but it is easy to add an atmospheric input of the pollutant if it exists. Infiltration is assumed to occur at the outlet concentration. Transpiration flow of the contaminant has been included. Combining Equation 17.4 with Equation 17.5 gives the concentration exiting the hypothetical segment number one:

$$C_1 = \frac{Q_iC_{in} + (k \cdot A_1 \cdot C^*)}{Q_1 + \left((\alpha ET)A_1\right) + (I \cdot A_1) + (k \cdot A_1)} \quad (17.6)$$

Or

$$C_1 = \frac{q_{in}C_{in} + (k \cdot C^*)}{q_1 + (\alpha ET) + I + k} \quad (17.7)$$

Note that the hydraulic loading rates in Equation 17.7 are the individual tank loading rates, not the overall system loading rates. This computation is then repeated sequentially for the remaining segments, using, in each case, the outlet concentrations and flows from the preceding unit. The wetland outlet concentration is that exiting the final hypothetical segment.

Outgoing pollutant loads are calculated as the product of the volumetric outflow (m³/d) and the outflow concentration (kg/m³).

The additional input data requirements for the pollutant mass balances are

7. Input concentration ($C_{in}$)
8. Background concentration ($C^*$)
9. Rate coefficient ($k$)
10. Transpiration fraction ($\alpha$)

The hypothetical example presented for the water budget is extended to illustrate these calculations, continuing the choice of $P = 3$ TIS. Phosphorus is chosen as the pollutant of interest, entering the wetland at 2.00 mg/L. The value of $C^*$ is chosen to be low, 0.01 mg/L. The rate constant is selected to be the median shown for phosphorus in FWS systems in Table 10.11, $k$ = 10 m/yr. Because the transpiration flux is presumed to draw phosphorus into the root zone, the fraction of *ET*, that is, transpiration, must be selected, and in the example it is picked as $\alpha = 0.5$.

The computed phosphorus concentration in the surface outflow water is $C_o = 0.62$ mg/L, or a concentration reduction of 69% (Table 17.2). However, the existence of *ET* losses and infiltration creates a different result for mass removal: 82% of the phosphorus entering does not leave with surface water. If infiltration water departs vertically downward without further treatment, then 15% of the phosphorus mass removal is due to infiltration. Thus, it is seen that load reduction and concentration reduction are two different goals, which may lead to different designs. Both these types of design sizing require mass balance computations for water and rate calculations for pollutants.

**TABLE 17.2**
**Phosphorus Budgets for a FWS Design Example**

**Parameters**

**$C_i$ = 2.00 mg/L**
**$C^*$ = 0.01 mg/L**
**$k$ = 10 m/yr**
$k$ = 0.0274 m/d
Area/tank = 80,000 m²
**Theta factor = 0.5**

| | Inflow | Tank 1 | Tank 2 | Tank 3 = Outflow | Removed | Reduction |
|---|---|---|---|---|---|---|
| Concentration (mg/L) | 2.00 | 1.42 | 0.96 | 0.62 | — | 69% |
| Load in surface water (kgP/yr) | 3,650 | — | — | 666 | 2,984 | 82% |
| Load infiltrated (kgP/yr) | — | 207 | 140 | 90 | 437 | 15% |
| Load stored (kgP/yr) | — | — | — | — | 2,547 | 70% |

*Note:* This example is based on the water budget shown in Table 17.1; sequential tank-to-tank calculations are based on Equation 17.6; the required input data are shown in bold; the shaded cells represent potential design targets.

## Interconnected Pollutants: The Case of Nitrogen

Nitrogen species interconvert, thereby linking the mass balances for organic, ammonia, and oxidized nitrogen. It is sometimes possible to disconnect these species, as, for instance, in the case of wetlands that receive nitrate but little or no organic or ammonia nitrogen. However, in many cases, it is necessary to account for the (internal) production of ammonia from organic sources, i.e., from either the incoming water or the decomposition of wetland necromass, and the internal production of oxidized nitrogen. A simple, presumed chemistry is

$$\text{ORG-N} \rightarrow \text{NH}_4\text{-N} \rightarrow \text{NO}_x\text{-N} \rightarrow \text{N}_2 \qquad (17.8)$$

In a simplified version of analysis, uptake and return from biomass is not included. The effects of the biogeochemical cycle on nitrogen will be explored in a subsequent part of the design process. The three mass balances then become linked, and the tank equations are:

$$Q_1 C_{O1} = (Q_{in} C_{O,in}) - (I \cdot A_1 C_{O1}) - (\alpha ET A_1 C_{O1}) - k_O A_1 (C_{O1} - C_O^*) \qquad (17.9)$$

$$Q_1 C_{A1} = (Q_{in} C_{A,in}) - (I \cdot A_1 C_{A1}) - (\alpha ET A_1 C_{A1}) - k_A A_1 (C_{A1} - C_A^*) + k_O A_1 (C_{O1} - C_O^*) \qquad (17.10)$$

$$Q_1 C_{N1} = (Q_{in} C_{N,in}) - (I \cdot A_1 C_{N1}) - (\alpha ET A_1 C_{N1}) - k_N A_1 (C_{N1} - C_N^*) + k_A A_1 (C_{A1} - C_A^*) \qquad (17.11)$$

where
$C_O$ = organic N concentration, mg/L
$C_A$ = ammonia N concentration, mg/L
$C_N$ = oxidized N concentration, mg/L
$k_O$ = organic N rate coefficient, m/d
$k_A$ = ammonia N rate coefficient, m/d
$k_N$ = oxidized N rate coefficient, m/d

and the subscript "in" denotes parameters associated with the influent flow for each nitrogen form.

These may be rearranged to solve the outlet concentrations for each tank:

$$C_{O1} = \left( \frac{Q_{in} C_{O,in} + k A_1 C_O^*}{Q_1 + (\alpha ET) A_1 + I A_1 + k_O A_1} \right) \qquad (17.12)$$

$$C_{A1} = \left( \frac{Q_{in} C_{A,in} + k_A A_1 C_A^* + k_O (C_{O1} - C_O^*)}{Q_1 + (\alpha ET) A_1 + I A_1 + k_A A_1} \right) \qquad (17.13)$$

$$C_{N1} = \left( \frac{Q_{in} C_{N,in} + k_N A_1 C_N^* + k_A (C_{A1} - C_A^*)}{Q_1 + (\alpha ET) A_1 + I A_1 + k_N A_1} \right) \qquad (17.14)$$

Equation 17.12 is a direct analog of Equation 17.7 for an unspecified generic pollutant. Equations 17.13 and 17.14 contain extra production terms from ammonification in the ammonia balance—and nitrification in the oxidized nitrogen balance. The three must be solved sequentially—Equation 17.12 followed by Equations 17.13 and 17.14.

## Design Parameters: Sources of Information

The *P-k-C** design model is the basis for this sizing analysis; it is therefore necessary to select values of these three parameters for all pollutants of concern.

### Background Concentrations

Wetland systems are dominated by plants (autotrophs), which act as primary producers of biomass. However, wetlands also include communities of microbes (heterotrophs) and higher animals, which act as grazers and reduce plant biomass. Most wetlands support more producers than consumers, resulting in a net surplus of plant biomass. This excess material is

typically buried as peat or exported from the wetland (Mitsch and Gosselink, 1993). The net export results in an internal release of particulate and dissolved biomass to the water column, which is measured as nonzero levels of biochemical oxygen demand (BOD), total suspended solids (TSS), total nitrogen (TN), and TP. These wetland background concentrations are typically denoted by the term $C^*$. Enriched wetland ecosystems (such as those treating wastewater) are likely to produce higher background concentrations than oligotrophic wetlands. These elevated background concentrations are largely due to increased biomass cycling resulting from the higher levels of nutrients and organic carbon in the wastewater. Even land-locked wetland basins, which only receive water inputs through precipitation, will have nonzero background concentrations.

Consequently, many pollutants are not reduced to zero in treatment wetlands—including BOD, TSS, organic nitrogen, and phosphorus. However, it is important to distinguish between artifacts of data fitting and real wetland processes. Short-circuiting can lead to high values of data-fit $C^*$ for heavily loaded systems, but these high $C^*$ can be dealt with by improving the hydraulics. Independent of hydraulics, the wetland can manufacture water-phase organics and solids, and cycle nutrients into and out of the water body. The chapters of Part I contain estimates of the $C^*$-values for the common pollutants, and many literature sources provide ranges of background concentrations (U.S. EPA, 1999; IWA Specialist Group on Use of Macrophytes in Water Pollution Control, 2000; U.S. EPA, 2000a; Wallace and Knight, 2006; Crites *et al*., 2006). A summary is given in Table 17.3.

Some individual exotic chemicals are foreign to typical wetland environments and are not expected to exhibit background concentrations. Examples include halogenated hydrocarbons and pesticides.

### Number of Tanks to Be Used in the Model

The performance of the wetland depends on the number of tanks (TIS) selected—very strongly if the design is to approach wetland background concentrations or high degrees of removal (see Chapter 6). If a high degree of removal is required, it will necessitate a very large wetland with poor hydraulics, or a smaller wetland with good hydraulics. Figure 17.2 illustrates this high degree of sensitivity in the region of low $P$ for large reductions. This chart quantifies the fact that a tiny fraction of the water following a fast short-circuit will carry enough unreacted material to the outlet to make 99+% reduction almost impossible to achieve. Low $P$ numbers represent flow patterns that, by virtue of either fast forward mixing or velocity profiles with high-speed elements, carry fractions of unreacted material directly to the outlet.

The $P$-value is somewhat at the discretion of the designer. More cells and greater length-to-width ratios can increase the $P$-value. As an illustration of the design decision to be made, consider a hypothetical case relative to Figure 17.2. Suppose the wetland is to achieve a 90% reduction. It is possible to consider a one-cell wetland, with a presumptive $P = 3$ that needs 84 $m^2/(m^3/d)$. Or, the designer can opt for two cells in a series, each with a presumptive $P = 3$ that needs 68 $m^2/(m^3/d)$. The question might be resolved based on the economics, i.e., does the cost savings of 20% area reduction outweigh the added cost of the divider berm and structures? This illustration carries a zero background concentration, but the concepts are applicable to any pollutant, provided the reduction fraction to background is used instead of percentage removal.

It should be remembered that the designer can control the $N$-value for the wetland (inert tracer tanks in series) but cannot entirely control the $P$-value. Pollutants that are mixtures, which may undergo weathering in the wetland, act to reduce the applicable $P$-value. Table 6.3 provides some guidance on the apparent $P$-values to be selected relative to tracer $N$-values.

**TABLE 17.3**
**Summary of Background Concentrations for FWS Wetlands**

| Parameter | Lightly Loaded | Heavily Loaded |
|---|---|---|
| $BOD_5$ (mg/L) | 2 | 10 |
| TSS (mg/L) | 2 | 15 |
| Organic N (mg/L) | 1 | 3 |
| Ammonia N (mg/L) | <0.1 | <0.1 |
| Oxidized N (mg/L) | <0.1 | <0.1 |
| Total phosphorus (mg/L) | <0.01 | 0.04 |
| Fecal coliforms (CFU/100 mL) | 10–50 | 100–500 |

*Note:* In the case of fecal coliforms, lightly/heavily loaded refers to animal use.

### Rate Coefficients

In this initial, annualized analysis, the appropriate rate coefficients are those (shown in the chapters of Part I) as the result of the fitting of annual data from existing wetlands. Those are variable across wetlands and years, thus producing frequency distributions of the fitted $k$-values. These are to be found as follows:

- $BOD_5$ — Chapter 8, Table 8.2
- Organic N — Chapter 9, Table 9.11
- Ammonia N — Chapter 9, Tables 9.17 and 9.20
- Total Kjeldahl nitrogen (TKN) — Chapter 9, Table 9.12
- Oxidized N — Chapter 9, Table 9.23
- Total N — Chapter 9, Table 9.14
- Total P — Chapter 10, Table 10.11
- Fecal coliforms — Chapter 12, Table 12.3

Conspicuously absent from this list is the common constituent TSS. Some individual system data were presented in

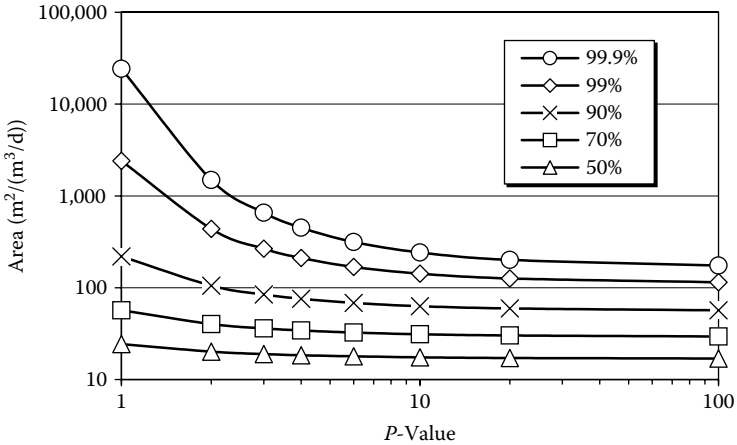

**FIGURE 17.2** The effect of the number of tanks on the area required for different degrees of removal. The calculations are for $k = 15$ m/yr and $C^* = 0$.

Chapter 7 and analyzed for rate coefficients. However, incoming TSS is often reduced rather quickly, and wetland-effluent TSS results from a balance of generation and resuspension in the FWS wetland. The removal rate coefficients that pertain to the inlet region of the wetland are often quite high, ≈10 m/d (3,650 m/yr), as shown in Figure 7.8. Colloidal materials are an exception to this generality. The design recommendation suggested here is the use of a high-rate coefficient for TSS (perhaps 200 m/yr), unless the design-limiting bottleneck happens to be TSS. In that event, it is strongly suggested that settling tests be conducted on the candidate wetland influent waters.

The frequency distributions of the reference tables are generally quite broad. It is up to the designer to narrow the selection for a given application, either by choosing the preferred degree of risk (blind to modifying factors), or by delving further into the details of existing wetland data sets, and to narrow the selection to wetlands closest to the intended application in terms of operating conditions. Regrettably, there is no modern, published, all-inclusive database to which to turn. The reader is cautioned that older databases such as the NADB (Knight *et al.*, 1993) and the 1994 Danish database (in Kadlec and Knight, 1996) have been superseded. Also, old databases are uneven in the quality and quantity of the data presented. There are numerous examples of misinterpretation in such databases, and it is concluded that their use as a sole source of narrowing the information field is dangerous. Because there are now so many treatment wetlands, it is not feasible to provide detailed data. In this book, the compromise is to provide analysis, references, and the generic list of sources used herein (see Appendix A).

## Design Sizing Goals: Load Reduction versus Concentration Reduction

A key feature of treatment wetlands is the ability to design or manage the system for either concentration reduction or for mass removal, but only one at the expense of the other (Trepel and Palmeri, 2002). Wetland performance, as modeled previously, follows the rule of mass action: the removal rate of a pollutant is greater at higher pollutant concentrations in the water. The first-order model assumes a (nearly) direct proportionality: doubling the concentration doubles the removal rate. As a result of this observed behavior, removal rates decrease as water passes through the treatment wetland, and pollutant concentrations are reduced (Figure 17.3). However, the actual mass of the pollutant that is removed increases with increasing hydraulic loading. Thus, increasing hydraulic loads result in more kilograms removed, but at the expense of higher effluent concentrations. This trade-off between removal efficiency and load reduction is a key feature of wetland design for nutrient control. These may be quantified via the first-order model. A simple version for $C^* = 0$ and no water loss is

$$\text{Concentration reduction} = \left(\frac{C_i - C_o}{C_i}\right) = 1 - \left(1 + \frac{k}{Pq}\right)^{-P} \tag{17.15}$$

$$\text{Load reduction} = \text{Input load} \times \text{Concentration reduction}$$

$$= qC_i \cdot \left(1 - \left(1 + \frac{k}{Pq}\right)^{-P}\right) \tag{17.16}$$

The maximum mass of pollutant that can be removed in a given footprint area results from a hydraulic load so high that little or no concentration reduction is achieved. Under these conditions, pollutant concentration is at a maximum everywhere in the wetland, thus maximizing the mass removal rate.

If the output load of a pollutant is to be held below some regulatory limit, then that has the same general effect as specifying an outlet concentration. However, because the load of a pollutant in the wetland outflow is usually taken to

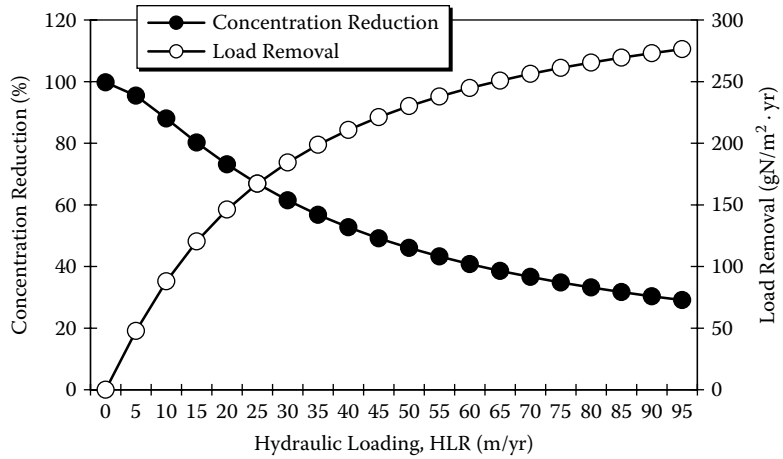

**FIGURE 17.3** Concentration reduction and load reduction as a function of hydraulic load for a hypothetical nitrate treatment wetland. Parameters: $C_i = 10$ mg/L, $k = 35$ m/yr, $C^* = 0$, $P = 4$.

be that in the surface water discharge, any reduction in flow through the wetland assists in providing lower output loads as well as higher load reductions.

All three of the potential design goals (concentration out, load out, load reduction) may be sensible, depending on the pollutant in question. These are marked as shaded cells in the example in Table 17.2. For instance, a low required outlet concentration can be of use in preventing ammonia toxicity in receiving waters. But if there is a load allocation, as might be the case for a discharge contributing to the total maximum daily load (TMDL) for an impaired water body, then the mass of the contaminant is of more direct interest. Lastly, if there is a desire to maximize the benefits of a given wetland footprint, then the goal should be to dissipate or retain the maximum amount of pollutant in the wetland.

Because it is easy to confuse these potentially conflicting goals, it is recommended that the designer clearly identify and state the purpose of the design.

## 17.2 AREA COMPUTATIONS

At this point in the development of constructed wetland technology, it would be disingenuous to provide overly simplistic design-calculation procedures. But it is also a mistake to think that adding more factors that may play a significant role in performance lends more accuracy or precision to design predictions.

### Goal Seeking: Determination of the Required Wetland Area

The fundamental and straightforward technique for determining the area is to adjust that area until the specified criterion is met. That is easy if the calculations have been set up on a spreadsheet; the area can then be sequentially and manually changed by the user until the criterion is met, or automatic searches may be invoked, such as the Solver™ routine in Microsoft Excel™. The hypothetical phosphorus example is continued to illustrate this process.

### Concentration Criterion

A common criterion for phosphorus in the United States is for monthly means to be less than 1.0 mg/L. Realistically, the project owner would not want to encounter exceedances very often. For the example, choose the compliance frequency to be 90%. From Table 10.13, the multiplier to contain exceedance at that frequency is 1.94. Therefore, the design target is adjusted downward to 1.00/1.94 = 0.52 mg/L, which becomes the value to be achieved as the wetland area is varied.

In just three manual iterations, the starting guess of 24 ha ($C_o = 0.62$ mg/L, Table 17.2) is changed to 27.6 ha ($C_o = 0.52$ mg/L). The same result may be obtained using Solver™, which provides the answer in an essentially instantaneous search from any plausible starting condition.

The exceedance containment multipliers for common constituents may be found as follows:

- $BOD_5$ Chapter 8, Table 8.6
- Organic N Chapter 9, Table 9.11
- Ammonia N Chapter 9, Table 9.21
- Oxidized N Chapter 9, Table 9.25
- Total N Chapter 9, Table 9.16
- Total P Chapter 10, Table 10.13
- Fecal coliforms Chapter 12, Table 12.4
- (TKN is not in this list because it is not normally regulated.)

### Maximum Load Criterion

The same philosophy of regulation might lead to an annual load limitation on the effluent from the system. An outlet concentration of 1.0 mg/L at a flow rate of 5,000 m$^3$/d (inflow rate) implies a maximum annual load of 1,825 kgP/yr leaving the wetland (50% load reduction). A search for the wetland area leads to a value of 10.1 ha. This is very much lower than that for the concentration goal for two reasons. First, the exceedance factor is not in play because of the annual character

of the load limit. Secondly, credit is built into the calculation for the loss of water to *ET* and for wetland infiltration.

### Minimum Load Reduction Criterion

A slightly different regulatory philosophy requires a minimum load reduction. For instance, some wetland systems in South Florida require a minimum of 75% phosphorus load reduction. A search for the wetland area leads to a value of 19.8 ha.

### Multiple Compounds of Concern

The projected outlet concentrations of all constituents of interest are calculated via the preceding Equation 17.7 (or Equations 17.12–17.14 in the case of nitrogen). All computed outgoing concentrations and loads vary with the selected wetland area. Area is adjusted until the most stringent criterion is met. Criteria often include outlet concentration specifications, each with an associated allowable frequency of exceedance. But in other cases, outlet pollutant loads may be specified (or load reduction). Loads are easily calculated using the outlet concentrations and flows from the last unit. If the contaminants are considered singly, then a last step remains: all performances are calculated on the controlling (maximum required) wetland area.

As an example of multiple contaminants, the previous phosphorus illustration, along with the additional requirements to also reduce BOD and total nitrogen, is continued. BOD enters the wetland at 30 mg/L, and total nitrogen, at 30 mg/L. The value of $C^*$ is chosen to be 2 mg/L for BOD, and $P = 1$. The value of $C^*$ is chosen to be 1.5 mg/L for TN, and $P = 3$. The rate coefficients are selected to be the medians shown for BOD and TN in FWS systems in Tables 8.2 and 9.14, i.e., $k_{BOD} = 33$ m/yr and $k_{TN} = 13$ m/yr. It is assumed that exceedances must be contained at the 90th percentile. The multipliers are 1.56 for $BOD_5$ (Table 8.6) and 1.55 for TN (Table 9.16).

The calculations of the required areas for each of the three contaminants are shown in Table 17.4. The largest area is needed for the reduction of total nitrogen—40 ha for the 5,000-$m^3$/d flow. When that area is applied to the calculation of performance for $BOD_5$ and TP, those pollutants are reduced more than necessary (Table 17.5).

**TABLE 17.4**
**Areas Needed for a Three-Parameter Wetland Sizing**

| | | $BOD_5$ | TN | TP |
|---|---|---|---|---|
| Inlet *C* | mg/L | 30 | 20 | 2.00 |
| Regulatory *C* | mg/L | 10.0 | 5.0 | 1.00 |
| Containment multiplier | mg/L | 1.56 | 1.55 | 1.94 |
| Target *C* | mg/L | 6.41 | 3.23 | 0.52 |
| Background $C^*$ | mg/L | 2.0 | 1.5 | 0.01 |
| *P*TIS | — | 1 | 3 | 3 |
| Annual *k* | m/yr | 33 | 13 | 10.0 |
| **Area** | **ha** | **30.3** | **40.0** | **27.6** |
| Hydraulic loading | cm/d | 1.65 | 1.25 | 1.76 |
| **Outlet *C*** | **mg/L** | **6.41** | **3.23** | **0.52** |

**TABLE 17.5**
**Performance for a Three-Parameter Wetland Sized for TN Reduction**

| | | $BOD_5$ | TN | TP |
|---|---|---|---|---|
| Inlet *C* | mg/L | 30 | 20 | 2.00 |
| Inlet loading | g/$m^2$·yr | 137 | 91 | 9.1 |
| Regulatory *C* | mg/L | 10.0 | 5.0 | 1.00 |
| Containment multiplier | mg/L | 1.56 | 1.55 | 2.00 |
| **Target *C*** | **mg/L** | **6.41** | **3.23** | **0.50** |
| Background $C^*$ | mg/L | 2.0 | 1.5 | 0.01 |
| *P*TIS | — | 1 | 3 | 3 |
| Annual *k* | m/yr | 33 | 13 | 10.0 |
| **Area** | **ha** | **40.0** | **40.0** | **40.0** |
| Hydraulic loading | cm/d | 1.25 | 1.25 | 1.25 |
| **Outlet *C*** | **mg/L** | **5.48** | **3.23** | **0.29** |

This concludes the preliminary calculation of the required wetland area. It may seem that there are no further steps needed, but in fact there is no guarantee that these preliminary calculations fit into reasonable, known patterns of wetland behavior. It is critical that the bounds of plausible biogeochemical cycles are not exceeded, that the required ancillary chemicals (oxygen, carbon) are present in ample supply, and that the forecasted results are reasonable compared to known performance data. Further, the seasonality of the system has yet to be investigated via forecasting.

## 17.3 CHECKING THE BIOGEOCHEMICAL CYCLES

In this phase of design, vegetation in the prospective wetland and its role in nutrient processing is brought into the picture. The rate coefficient-based analysis has provided first estimates of the quantities of materials entering and leaving the system, but there has been no allocation of the removals to the various processes that comprise the entire ecosystem function. It is not feasible to go too far in breaking down processes because the knowledge base does not support great detail. Here, the processing of carbon, nitrogen, and phosphorus are examined via the mass balances used in ecosystem analysis in Part I (see Chapter 9, Figure 9.14).

In the analysis that follows, two points are important. First, the analysis is based on estimates of what the ecosystem will be like. Such estimates cannot be precise, and, consequently, the analysis is "order-of-magnitude" only. The intent is to gain some insight into the relative importance of wetland processes that will likely be operating if the project is built. Second, the analysis is for an annual period, and hence there remains the issue of seasonality. Seasonal analysis proceeds more readily if we can first establish whether the wetland should be viewed as an agronomic system or a microbial system.

## C, N, and P Cycles

The pollutant removals simplistically described in the preceding section take no account of wetland functions; they are based on purely empirical *k*-values and outlet concentration data. It is therefore prudent to examine the empirical forecasts and to ascertain whether they comply with an estimated set of wetland processes. Of particular interest are the carbon, nitrogen, and phosphorus cycles.

The carbon cycle involves the growth, death, and decomposition of biological materials, including animals, plants, algae, and microbes. For many wetlands, the standing crop of these organic materials is relatively constant throughout the year, but the proportions of living and dead may vary considerably, as may the physical location (i.e., standing dead or litter). Further, the speed of cycling varies with the nature of the material and the time of the year (see Chapter 3). Fine detritus from microbes cycles rapidly, whereas the decomposition of some woody plant parts may take years. However, the important feature of the carbon cycle is the amount of material that does not decompose, for it is this residual that accretes in the ecosystem and forms storage for many pollutants, including phosphorus. This storage is relatively permanent under appropriate hydroperiod conditions.

An approximate assessment of the implied impacts of the carbon cycle can be made on the basis of two numerical characteristics: the speed of the cycle in grams of dry material per square meter per year, and the fraction of the cycled material that does not decompose. The speed of the cycle may also be characterized by the standing crop, in $g/m^2$, plus a turnover rate, in number of times per year. The recycled organic fraction contains carbon that is a source of support for denitrification and other heterotrophic processes. The burial fraction leads to sediment buildup and storage of nitrogen, phosphorus, and other trace contaminants that partition to organics. Typical values for the vegetative standing crop, turnover time, speed, and burial fraction are given in Table 17.6.

In general, the algal and microbial standing phytomass is small compared to the vegetative phytomass. However, turnover times are also small, so the annualized rate of uptake and burial for this component of the phytomass may be estimated to be 50–100% of the vegetative annual rates. Simply stated, the amounts of N and P processed by the big green biomass are not very much larger than those processed by the nearly invisible microbes and algae. This nondisparity has been characterized as the "buckets and teacups" analogy set forth by Richardson *et al.* (1986).

The term nutrient poor would reflect very low nutrient status, with TP < 20 µg/L and $NH_4$-N 0.2 mg/L. Nutrient-moderate wetlands would have TP < 200 µg/L, with $NH_4$-N < 1.0 mg/L. Nutrient-rich wetlands would have TP ≈ 1.0 mg/L, with $NH_4$-N ≈ 5.0 mg/L. Very-nutrient-rich systems would have TP > 5.0 mg/L, with $NH_4$-N > 10.0 mg/L. These definitions do not correspond to the equivalents for aquatic water bodies, where the dominant vegetation is plankton. In the treatment wetland context, bacterial and algal materials are of comparable importance with above- and belowground macrophytic vegetation.

The magnitude of the biogeochemical cycle increases with increasing nutrient availability—up to some presumptive limit enforced by availability of space and sunlight. This fertilizer response is not well-quantified for treatment wetlands and, therefore, cannot be used directly in design. However, rough estimates are of value in assessing the potential importance of the biogeochemical cycle—particularly to check that the empirical design calculations do not imply unreasonable ecosystem functions.

One technique for making such checks is to graphically link a presumed cycle to the mass balance calculations available from the preliminary sizing step. The biogeochemistry check, thus, is implemented via linked *ecosystem* mass balances, one each for C, N, and P. These do not replace, nor can they substitute, *the water column mass balances* used in *k*-rate removal calculations. In an annualized mass balance storage calculation, the following equations may be used:

$$G = D + B \tag{17.17}$$

$$GX_G = DX_D + BX_B \tag{17.18}$$

$$BX_B = \beta \cdot GX_G \tag{17.19}$$

where

$B$ = biomass burial, $g/m^2 \cdot d$
$D$ = biomass decomposition, $g/m^2 \cdot d$
$G$ = biomass growth, $g/m^2 \cdot d$
$X$ = fraction of the pollutant in each biomass compartment
$\beta$ = fraction of pollutant uptake that is stored

### The Carbon Cycle

The nomenclature for biomass processes in treatment wetlands is a bit confusing. The growth, death, and decomposition processes are referred to as part of the wetland carbon cycle, but more than carbon is involved. However, most vegetation and other wetland organisms are about 40% carbon; so, either dry biomass or carbon serves to track the amount of the material involved. Carbon itself is withdrawn from atmospheric sources as carbon dioxide for photosynthesis. Likewise, it is returned to the atmosphere as methane from anaerobic mechanisms, or carbon dioxide from oxidative processes (respiration included).

The ability to estimate nutrient cycling rests upon our knowledge of the biomass pools in the wetlands and their changes. Guidelines are shown in Table 17.6. According to Equations 17.17–17.19, on an annual basis, the important estimation quantities are

*Annual growth rate, $g/m^2 \cdot yr$* (standing crop phytomass = necromass + biomass times turnover per year)
*Annual burial fraction* (undecomposable residual fraction)

**TABLE 17.6**
**Estimates of Wetland Nutrient Cycling in Biomass**

| | | Nutrient Poor | Nutrient Moderate | Nutrient Rich | Very Nutrient Rich |
|---|---|---|---|---|---|
| **Organic matter** | | | | | |
| Standing crop | gDW/m$^2$ | 150 | 500 | 3,000 | 10,000 |
| Turnover time | times/year | 2 | 4 | 3 | 2 |
| Cycling rate ($G$) | gDW/m$^2$·yr | 300 | 2,000 | 9,000 | 20,000 |
| Burial fraction ($b$) | % | 2 | 10 | 20 | 25 |
| Accretion ($B$) | gDW/m$^2$·yr | 6 | 200 | 1,800 | 5,000 |
| **Phosphorus** | | | | | |
| Tissue content | mgP/kg | 1,000 | 2,000 | 3,000 | 4,000 |
| Uptake | gP/m$^2$·yr | 0.30 | 4.0 | 27.0 | 80 |
| Return | gP/m$^2$·yr | 0.29 | 3.6 | 21.6 | 60 |
| Accretion | gP/m$^2$·yr | 0.01 | 0.4 | 5.4 | 20 |
| **Nitrogen** | | | | | |
| Tissue content | %dw | 1.0 | 1.5 | 2.0 | 2.5 |
| Uptake | gN/m$^2$·yr | 3.00 | 30.0 | 180 | 500 |
| Return | gN/m$^2$·yr | 2.94 | 27.0 | 144 | 375 |
| Accretion | gN/m$^2$·yr | 0.06 | 3.0 | 36 | 125 |

*Note:* Bacterial and algal cycling are included in these values.

*Source:* For first two categories, data from Davis (1994) In *Everglades: The Ecosystem and Its Restoration*. Davis and Ogden (Eds.), St. Lucie Press, Delray Beach, Florida, pp. 357–378. For the second two, data from Kadlec (1997a) *Ecological Engineering* 8(2): 145–172.

An assumption is made that the nutrients taken up, but not buried as accretion, are returned to the water column of the FWS wetland. For nitrogen, this is the maximum estimate, as microbial processes in abovewater tissues can transfer nitrogen to the atmosphere without entering the water. These phytomass quantities, together with phytomass nutrient content (percentage or mg/kg), allow checks on the empirical removal calculations.

For purposes of design, for order-of-magnitude checks on the calculated nutrient removals, the total growth rate and burial fraction are assumed based on the strength of the water to be treated. This provides a rough annual estimate of the biomass cycle (Figure 17.4). Note that the magnitude of this cycle and the nutrient contents are a function of the degree of fertilization of the wetland (see Chapter 3).

The wetland carbon cycle is also critical to observe performance as it relates to sediment oxygen demand and to the carbon supply for denitrification. The implied supply constraints of this carbon cycle are examined in the constraint check section of this chapter.

## The Phosphorus Cycle

For phosphorus, the calculated removal is represented as a large uptake ($GX_G$)—in major part balanced by the return of soluble phosphorus from tissue decomposition ($DX_D$). For

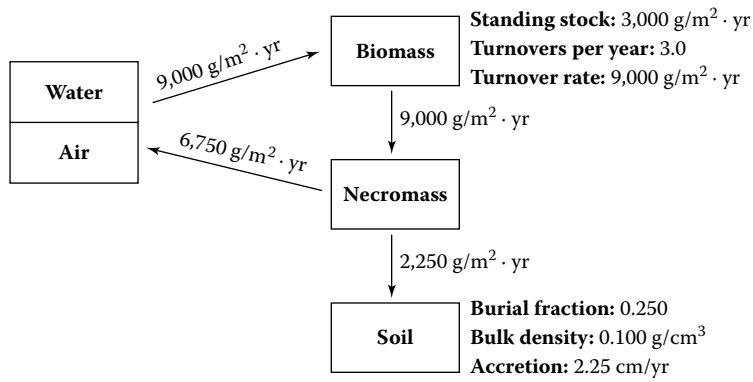

**FIGURE 17.4** Estimated annual biomass cycle in a FWS treatment wetland for a rich nutrient condition. Note that the standing stock and turnover refers to above- and belowground material, and to macrophytes, algae, invertebrates, and microbes.

a stable ecosystem past startup, the net phosphorus removal associated with the *k*-rate calculation is assigned to accretion. Sorption and the building of additional biomass are no longer sinks for phosphorus (Kadlec, 1997a). Because the *k*-rate calculation is independent of the biomass cycle calculation, there is one degree of freedom, which is taken to be the computed accretion fraction. It is known through extensive data from treatment wetlands that this percentage ranges from ≈500 to 5,000 mgP/dry kg, or from 0.05–0.5% dry weight. A somewhat narrower range is shown in Table 17.6 because extremely nutrient-poor wetlands are uncommon in treatment applications. It is unlikely that higher removals can be sustained via accretion. The corresponding accretion rates are 0.01–20 gP/m$^2$·yr. The values in Table 17.6 are provided as an order-of-magnitude check point. If a design is forecast to exceed these approximate cycling, removal, and storage values, then more detailed mass balances should be invoked. If it appears that the phosphorus removal calculated by a *k*-rate exceeds the ecosystem capacity to store, then the *k*-value should be adjusted downward.

As a graphic illustration, the design example is carried forward (Figure 17.5). Because the nutrient concentrations are high (2 mg/L P and 20 mg/L TN), it is anticipated that the nutrient-rich condition will prevail, as illustrated in Figure 17.4. The biogeochemical cycle removes 27 gP/m$^2$·yr from the water column (9,000 gdw/m$^2$·yr × 0.3% P), far more than the loading to the wetland of 9.1 gP/m$^2$·yr. The *k*-rate calculations indicate that 7.4 gP/m$^2$·yr are removed, and, hence, it is deduced that (27 − 7.4) = 19.6 gP/m$^2$·yr are returned to the water from decomposition and leaching of the biomass. The removal to accretion is thus 7.4/27 = 28% of the biomass uptake. These uptakes and returns involve aboveground plant parts (≈50%), belowground plant parts (≈15%), and microbes and algae (≈35%). The 28% burial rate for phosphorus is somewhat higher than the comparison value in Table 17.6 of 20%. If phosphorus were the controlling substance for sizing, it would be advisable to adjust the rate coefficient downward from the value of 10 m/yr used in the design forecast. But, the wetland is overdesigned for phosphorus reduction, and, hence, it is probably not necessary to revise the *k*-rate calculation.

## The Nitrogen Cycle

For nitrogen, a more complex situation occurs as a result of the multiple speciation of water column nitrogen. The details of nitrogen mass balancing have been presented in Part I, Chapter 9. The water column contains organic, ammonium, and nitrate nitrogen. Their interconversions are computed from the empirical *k*-rates. The biogeochemical cycle is linked in a manner analogous to phosphorus, but with abstraction from both the ammonium and nitrate pools in the water, and return from both the ammonium and organic pools in the water. This allocation recognizes a split of plant uptake between ammonium and nitrate (Martin and Reddy, 1997) and the fact that decomposition processes produce organic nitrogen. The nitrogen content in accreting sediments is known from extensive data from treatment wetlands to range from ≈1.0–2.5% dry weight (Table 17.6). A lower value would be associated with nutrient-poor wetlands, a higher with nutrient-rich systems. Again, because the *k*-rate calculations are independent of the cycle calculation, there is one degree of freedom, which for nitrogen is taken to be an assumed percentage of the cycled nitrogen that is buried in accreting sediments. A nitrogen deficit may be assumed to be supplied by fixation, a process known to occur in nitrogen-deficient wetland environments.

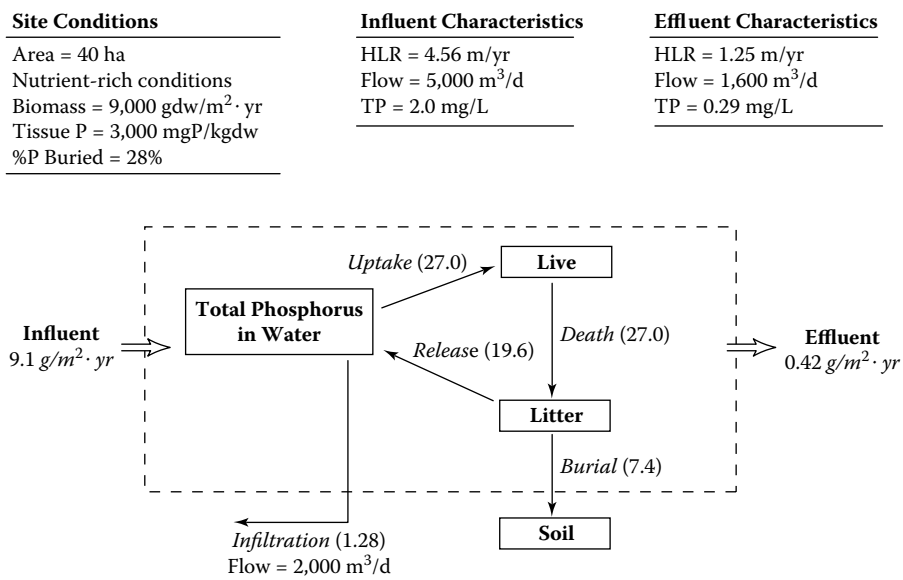

**FIGURE 17.5** Estimated annual phosphorus cycle in a FWS treatment wetland for a nutrient-rich condition. Flows, concentrations, and loadings leaving the wetland are from *k*-rate forecasts. The cycle turnover and tissue-phosphorus concentrations are presumptive. The fraction of phosphorus buried as accretion is calculated by mass balance.

| Site Conditions | Influent Characteristics | Effluent Characteristics |
|---|---|---|
| Area = 40 ha | HLR = 4.56 m/yr | HLR = 3.29 m/yr |
| Nutrient-rich conditions | Org N = 9.0 mg/L | Org N = 1.84 mg/L |
| Biomass = 9,000 gdw/$m^2 \cdot$ yr | $NH_4$–N = 10.0 mg/L | $NH_4$–N = 0.15 mg/L |
| Tissue N = 2% dw | $NO_x$–N = 1.0 mg/L | $NO_x$–N = 1.37 mg/L |
| Fraction $NH_4$–N Uptake = 0.81 | TN = 20.0 mg/L | TN = 3.23 mg/L |
| N Buried = 25% | TKN = 19.0 mg/L | TKN = 1.87 mg/L |

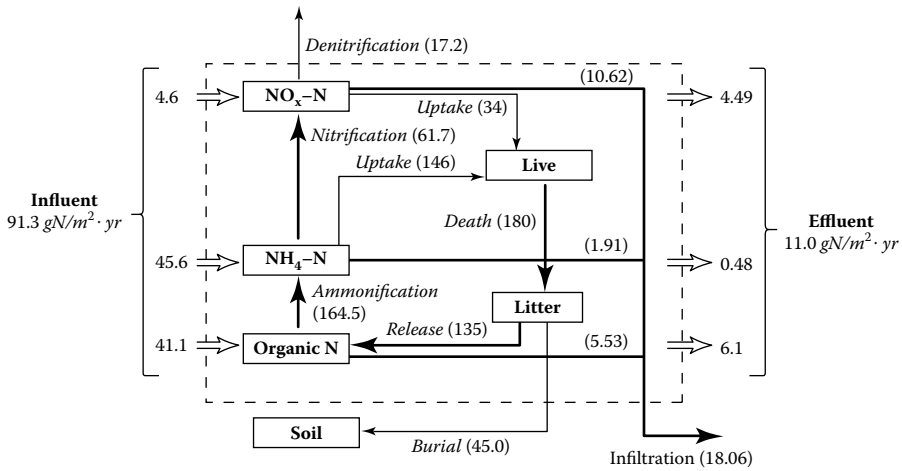

**FIGURE 17.6** Estimated annual nitrogen cycle in a FWS treatment wetland for a nutrient-rich condition. Flows, concentrations, and loadings leaving the wetland are from *k*-rate forecasts. The cycle turnover and tissue–N concentrations are presumptive. The fraction of biomass nitrogen buried as accretion is assumed to be 25%.

An illustration of the use of the nitrogen cycle and interconversions to confirm the design *k*-rate calculations is shown in Figure 17.6. The previous illustrative example is continued, but for simplicity, the details of the *k*-rate calculations for the various nitrogen species are not shown here. As indicated in Figure 17.6, the incoming nitrogen is presumed to be mostly organic (9 mg/L) and ammonia (10 mg/L), comprising nearly all of the 20 mg/L of TN. The nitrogen loading to the wetland is 91 gN/$m^2$·yr, which is a low loading that places the system in the category of an agronomic system (see Chapter 9). It is therefore expected that the biogeochemical cycling of nitrogen will play an important role in the overall reduction, but not to the exclusion of microbial processes.

Once the size of the biomass cycle has been selected, together with the phytomass nutrient content, mass balances fix all the nitrogen fluxes for the specified inflows and outflows. For this proposed design example, the cycling of biomass nitrogen is very important. The required nitrogen to build the annually cycled biomass is 180 gN/$m^2$·yr, which is just about double the amount of nitrogen supplied in the wastewater (Figure 17.6). However, there is no concern that the plants will starve, because there is a correspondingly large return flux of nitrogen from leaching and decomposition of necromass. It is again necessary to keep in mind that these uptakes and returns involve aboveground and belowground plant parts as well as microbes and algae.

The ultimate fate of removed nitrogen in the example is apportioned to accretion (56%), denitrification (21%), and seepage (23%). Interestingly, this does not mean that there are only small amounts of nitrification occurring, because about two thirds of the incoming nitrogen load winds up being nitrified (61.7 out of 91.3 gN/$m^2$ yr, Figure 17.6) because of leakage and a small amount of biomass uptake. The question then arises as to whether there is sufficient oxygen supply to support the nitrification implied by this mass balance. This implied supply is evaluated in the next section.

## 17.4 CHEMICAL SUPPLY CONSTRAINTS

Traditional chemistry assumptions indicate a requirement for carbon to support heterotrophic denitrification and oxygen to support nitrification.

Table 17.7 lists some of the more important chemical and biological constraints on wetland processes. The top block of information shows that the carbon balance, and, hence, the implied biochemical oxygen demand (BOD), is due to removal of incoming BOD and to the carbon formed by the biogeochemical cycle. Denitrification requires 4.0 g of chemical oxygen demand (COD) to reduce 1 g of nitrate nitrogen (U.S. EPA, 1993b; Crites and Tchobanoglous, 1998). Decomposing biomass is far more important than added BOD in the water in many instances. However, some moderate fraction of the biomass decomposition takes place in air, thus reducing the available carbon for denitrification.

The second block concerns nitrification, for which there are associated oxygen and alkalinity requirements. An oxygen equivalent is retrieved as the result of denitrification (third block, Table 17.7), as well as some of the required

**TABLE 17.7**
**Supply and Demand Constraints**

| Process | Units | Basis |
|---|---|---|
| BOD removed | $gO/m^2 \cdot d$ | *k*-rate load reduction |
| Nitrate-N equivalent of BOD removed | $gN/m^2 \cdot d$ | 0.25 Mass ratio to COD (BOD) |
| SOD equivalent of decomposing biomass | $gO/m^2 \cdot d$ | 0.1–0.5 Mass ratio |
| Max oxygen required for BOD and SOD | $gO/m^2 \cdot d$ | Sum of BOD and SOD |
| Reaeration | $gO/m^2 \cdot d$ | 0–4 |
| Oxygen required for traditional nitrification | $gO/m^2 \cdot d$ | 4.57 Mass ratio to N |
| Oxygen required for anammox | $gO/m^2 \cdot d$ | 1.72 Mass ratio to N |
| Alkalinity required for nitrification | $g/m^2 \cdot d$ | 7 Mass ratio to N |
| Oxygen from denitrification | $gO/m^2 \cdot d$ | 2.86 Mass ratio to N |
| Carbon required for denitrification | $gC/m^2 \cdot d$ | 1.1 Mass ratio to N |
| Alkalinity produced by denitrification | $g/m^2 \cdot d$ | 3 Mass ratio to N |
| Biomass produced | $g/m^2 \cdot d$ | 2–50 |
| Biomass accreted | $g/m^2 \cdot d$ | 2–25% of production |
| Usable carbon generated | $gC/m^2 \cdot d$ | 10% of biomass |
| Carbon accreted | $gC/m^2 \cdot d$ | 2–25% of production |
| Carbon burned | $gC/m^2 \cdot d$ | 75–98% of production |
| Sediment generated | cm/yr | 0.05–0.2 bulk density |
| Sulfur for denitrification | $gS/m^2 \cdot d$ | 1.69 Mass ratio to N |

alkalinity for nitrification. The carbon produced in the wetland supplies some or all that is necessary for denitrification (fourth block, Table 17.7). The accretion process implies a rate of sediment buildup determined from the sediment bulk density. Finally, the possibility of sulfur-driven denitrification carries a demand for sulfide-sulfur.

These constraints are critical to design because wetland chemical processes cannot proceed without the necessary ancillary compounds. Nowhere is this more apparent than in the need for oxygen to drive ammonia removal routes. Therefore, if inadequate supplies of ancillary chemicals are forecast, rate constants and loadings must be reduced until the constraints are met. Alternatively, additional supplies may be introduced into the wetland. This may require costly supplements, such as the addition of methanol to fuel denitrification (Gersberg *et al*., 1984). However, sometimes rearrangements of flows can resolve the supply problem, such as the feedforward of high BOD unpretreated influent for a carbon supplement for denitrification (Burgoon, 2001).

## Oxygen Supply

The various oxygen requirements for the example design are calculated (estimated) in Table 17.8. Removal of BOD (0.35 $gO/m^2 \cdot d$) and nitrification (0.73 $gO/m^2 \cdot d$) appears to exert only a small demand, which should easily be supplied by atmospheric reaeration. The decomposition of the generated necromass would consume something like 10 $gO/m^2 \cdot d$, but that decomposition is in part due to anaerobic processes and, in part, occurs above the water as standing dead materials oxidize. Another part of oxidation may involve root respiration, which comprises plant oxygen transfer. Therefore, it is difficult to attach great significance to the apparent need for large amounts of oxygen for necromass oxidation.

## Carbon Supply

The carbon produced by biomass in the example wetland (4.93 $gC/m^2 \cdot d$) far exceeds that necessary for denitrification (0.05 $gC/m^2 \cdot d$), and in fact could be supplied easily by the reduction of BOD (0.13 $gC/m^2 \cdot d$). Thus, despite the fact that only a fraction of the biomass-produced carbon is available in the water, there is no apparent shortage of carbon for denitrification in this example.

Because there is a large phytomass cycle, the accretion of solid residuals is an important factor. The implied rate of sediment buildup is 2.3 cm/yr, which is comparable to the rates observed in operating wetlands (Kadlec, 1997a).

## Intersystem Performance Checks

The question addressed next is, how does the proposed design compare with results from existing wetlands for which there is operating data? The annual performance period is retained for this phase of investigation.

The intersystem loading chart for phosphorus (Figure 17.7) shows that the overall scatter follows an increasing trend of outlet concentrations with increasing loading. However, in design, the loading variable is usually restricted to a fixed inlet concentration, whereas the hydraulic loading is variable in response to different choices of the wetland area. Therefore, in any particular design, only a subset of the larger loading group is relevant. For phosphorus and most common pollutants, a particular inlet concentration subset shows a more modest increasing trend than that of the whole set.

A generic loading chart looks similar to the conceptual "cloud" indicated in Figure 17.8. The larger data group encompasses all systems for all inlet concentrations, whereas each subgroup at a specific range of inlet concentrations occupies a smaller group. The left side of either data cloud represents less efficient systems, and hence these are prototypes of low risk for the design. The right side represents more efficient systems, a riskier assumption. Any performance calculation is represented by a single point on this plot and, therefore, may be compared to the intersystem data scatter on this chart.

The loading graphs that allow intersystem comparisons for common constituents may be found as follows:

- TSS — Chapter 7, Figure 7.19
- $BOD_5$ — Chapter 8, Figure 8.9
- Organic N — Chapter 9, Figure 9.17
- Ammonia N — Chapter 9, Figure 9.37
- TKN — Chapter 9, Figure 9.23
- Oxidized N — Chapter 9, Figure 9.51
- Total N — Chapter 9, Figure 9.29
- Total P — Chapter 10, Figure 10.17
- Fecal coliforms — Chapter 12, Figure 12.11

**TABLE 17.8**
**Supply and Demand Constraints for the Example**

| | Annual Flux | | Daily Flux | | Basis | |
|---|---|---|---|---|---|---|
| BOD removed | 129 | gO/m²·yr | 0.35 | gO/m²·d | — | |
| SOD equivalent of decomposed biomass | 3,600 | gO/m²·yr | 9.9 | gO/m²·d | 32/12 | Mass ratio |
| Max oxygen required for BOD and SOD | 3,729 | gO/m²·yr | 10.2 | gO/m²·d | — | |
| Oxygen required for nitrification | 265 | gO/m²·yr | 0.73 | gO/m²·d | — | |
| Alkalinity required for nitrification | 120 | g/m²·yr | 0.33 | g/m²·d | 7 | Mass ratio |
| Oxygen from denitrification | 59 | gO/m²·yr | 0.16 | gO/m²·d | 48/14 | Mass ratio |
| Carbon required for denitrification | 19 | gO/m²·yr | 0.05 | gC/m²·d | 1.1 | Mass ratio |
| Carbon equivalent of BOD removed | 48 | gO/m²·yr | 0.13 | gC/m²·d | 12/32 | Mass ratio |
| Alkalinity produced by denitrification | 51 | g/m²·yr | 0.14 | g/m²·d | 3 | Mass ratio |
| Biomass produced | 9,000 | g/m²·yr | 24.7 | g/m²·d | — | |
| Biomass accreted | 2,250 | g/m²·yr | 6.16 | g/m²·d | 25% | of Production |
| Carbon generated | 1,800 | gC/m²·yr | 4.93 | gC/m²·d | 20% | Content |
| Carbon accreted | 450 | gC/m²·yr | 1.23 | gC/m²·d | 25% | of Production |
| Carbon burned | 1,350 | gC/m²·yr | 3.70 | gC/m²·d | 75% | of Production |
| Sediment generated | 2.3 | cm/yr | — | | 0.1 | g/cc Bulk density |

After the necessary wetland area has been calculated based on the limiting pollutant and the performance for the other contaminants of concern recalculated for that area, the position of the design may be plotted on each loading chart of concern. For the example design that has been carried forward, these are shown in Figures 17.9 (BOD), 17.10 (TN), and 17.11 (TP). It is seen that in all cases, the design point is close to the central tendency of the intersystem data. That is not an accident, because the rate coefficients used in the example were selected to be at the 50th percentile of the intersystem values. In general, there is no design requirement to choose that percentile, and the loading charts can assist in interpretation of the consequences of picking higher- or lower-rate coefficients.

As should be expected, the wetland area is sensitive to the choice of rate coefficients. The two modes of design calculations are the area search and performance forecast that follows once the limiting (largest) area has been found. Figure 17.12 shows the effect of changing rate coefficients for phosphorus during the area-seeking phase of design. Recall that the goal was to achieve an outlet concentration of 0.52 mg/L. For a rate coefficient of 10 m/yr, this required 27.5 ha. Picking a lower rate coefficient (2.8 m/yr) results in a higher area (67 ha) and, thus, in a lower phosphorus loading (5.4 gP/m²·yr) (Figure 17.12). Picking a higher rate coefficient (25 m/yr) results in a lower area (12 ha) and, thus, in a higher phosphorus loading (30.4 gP/m²·yr). It is seen that the effect of changing the estimate of the *k*-value moves the design point from the left to the right on the loading chart. Note that at low *k*-values for phosphorus, the area exceeds that needed for nitrogen reduction, and, thus, the limiting constituent would change from nitrogen to phosphorus.

In the forecast mode, the effect of changing the estimate of the *k*-value moves the design point up and down on

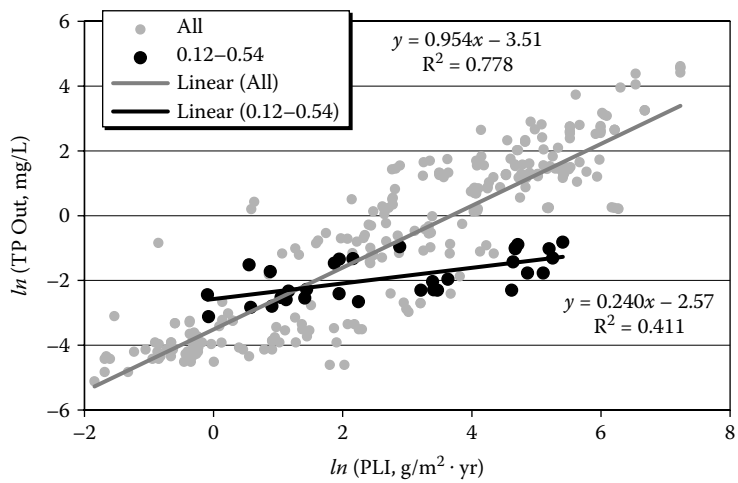

**FIGURE 17.7** The phosphorus loading chart for FWS wetlands replotted from Figure 10.17. Log-linear regressions are shown for the entire data set and for the inlet concentration range 0.12–0.54 mg/L.

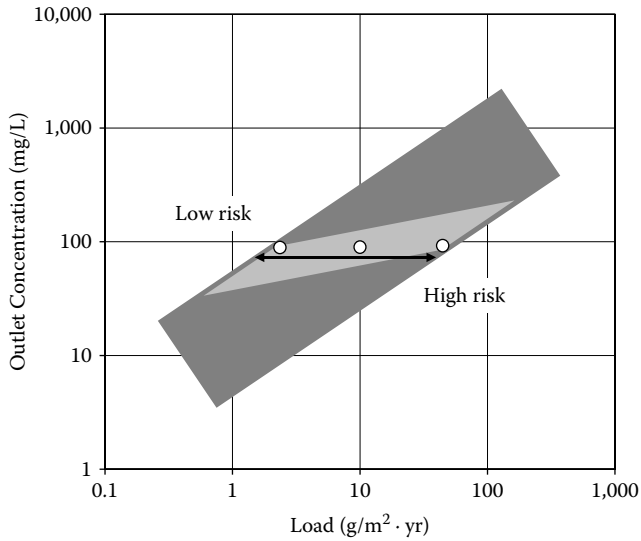

**FIGURE 17.8** Concepts of risk on the pollutant-loading chart. The overall data set of comparison systems occupies a band of increasing concentrations with increasing load. However, the data set for a particular inlet concentration occupies a smaller band, oriented at a lesser slope.

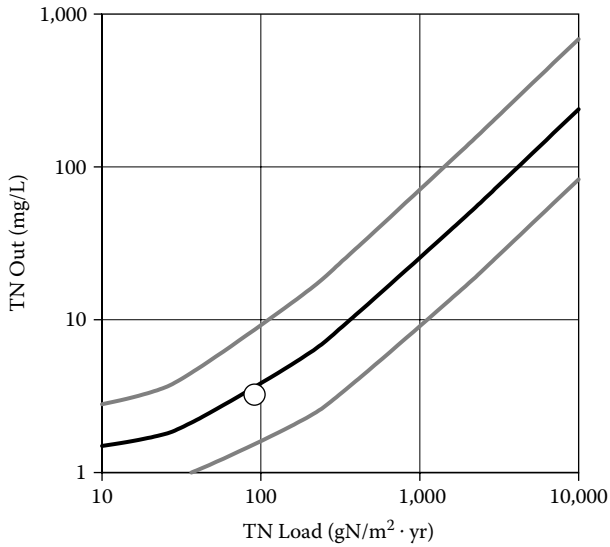

**FIGURE 17.10** Location of the example design on the TN-loading graph. The upper and lower lines are the approximate bounds of data shown in Figure 9.29. The central line represents the central tendency of annual data.

the loading chart. The system area is fixed at that needed for nitrogen reduction, 40 ha in the example. As seen in Figure 17.13, if the phosphorus *k*-value is too low, the outlet phosphorus concentration exceeds the maximum allowable design value of 0.52 mg/L, and, thus, the limiting constituent would change from nitrogen to phosphorus.

Clearly, there are a number of choices open to the designer for selection of wetland performance. The procedure set forth here advocates the use of rate coefficients, complemented by the use of loading charts as a cross-check on intersystem performance.

## 17.5 ADJUSTMENTS FOR SEASONALITY

The methods of analysis, up to this point, have utilized annual average performance measures. However, some wastewater constituents display seasonal removal behavior in FWS treatment wetlands, as has been discussed on a case-by-case basis in Part I. Seasonal patterns are particularly evident for nitrogen species, driven either by temperature effects on microbial processes or seasonal plant growth patterns, or both. Consequently, the magnitudes of seasonal swings in pollutant reduction are

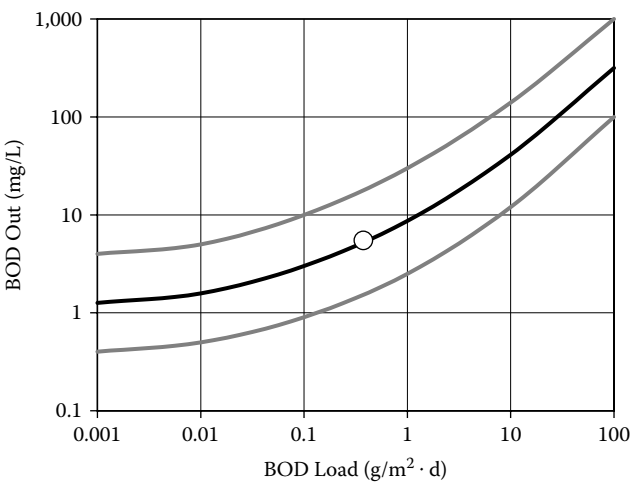

**FIGURE 17.9** Location of the example design on the BOD-loading graph. The upper and lower lines are the approximate bounds of data shown in Figure 8.9. The central line represents the central tendency of annual data.

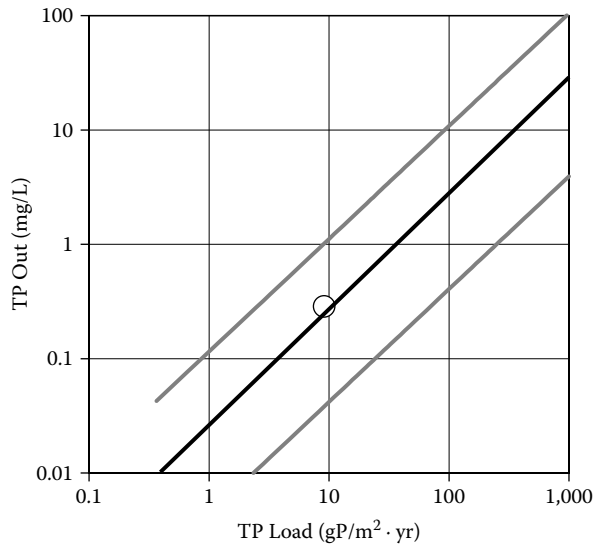

**FIGURE 17.11** Location of the example design on the TP-loading graph. The upper and lower lines are the approximate bounds of data shown in Figure 10.17. The central line represents the central tendency of annual data.

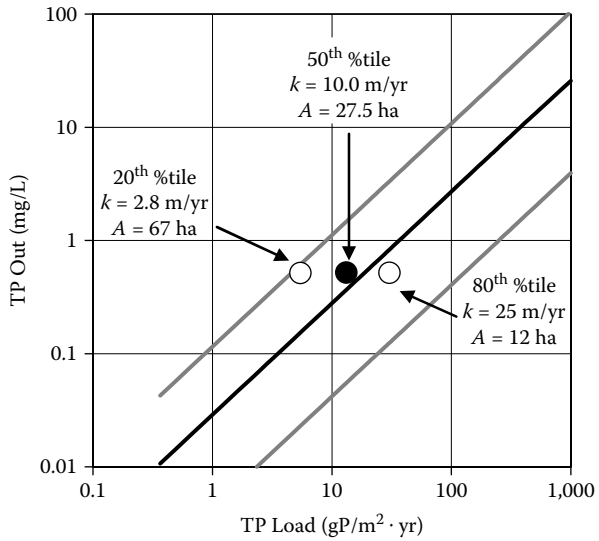

**FIGURE 17.12** Location of the example design on the TP-loading graph. The upper and lower lines are the approximate bounds of data shown in Figure 10.17. The central line represents the central tendency of annual data.

sensitive to the magnitude of the annual temperature cycle or the growth-senescence patterns of a particular climatic region. There are three fundamentally different ways of dealing with these effects: temperature coefficients (theta factors), monthly rate coefficients, and outlet trend amplitudes. If theta factors are appropriate, then the water temperature must be forecast.

### Wetland Water Temperature

A first approximation for long detention wetlands has been shown to be the mean daily air temperature during the unfrozen season (see Part I, Chapter 4). The next level of approximation involves estimating longitudinal profiles of wetland water temperature via the use of accommodation coefficients. The water temperature may depend on wetland size due to lack of time to reach the balance condition. In that case, design iteration may become necessary. The prediction of wetland water temperatures is briefly summarized here.

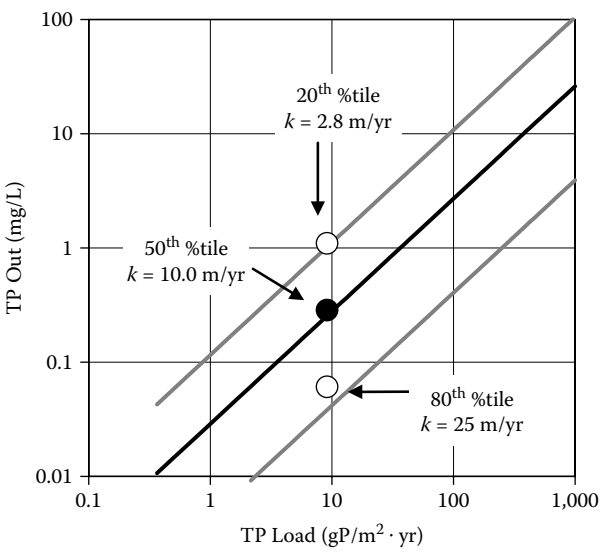

**FIGURE 17.13** Location of the example design on the TP-loading graph. The upper and lower lines are the approximate bounds of data shown in Figure 10.17. The central line represents the central tendency of annual data.

### Balance-Point Temperature

A treatment wetland may contain one or two thermal regions, depending on water loading (detention time). For long detention times, there is an inlet region in which water temperatures adjust to the prevailing meteorological conditions and an outlet region in which that adjustment is complete. The value reached is determined by the balance of energy flows and is termed the *balance temperature*. For short detention times, near the wetland inlet, the adjustment may not be completed. To a rough approximation, wetland water balance temperatures are equal to air temperatures during the unfrozen season. More accurate forecasts are possible utilizing the energy balance, as described in Chapter 4.

### Wetland Water Temperature Cycles

The annual cycle of wetland water temperatures in mild to warm climates follows a sinusoidal pattern, with a summer maximum and a winter minimum. In northern climates, the onset of frozen conditions typically is accompanied by under-ice water temperatures of 1–2°C. The sinusoidal model, truncated for frozen conditions, is as follows:

For the unfrozen season ($t_1 < t < t_2$),

$$T_w = T_{avg}\left(1 + A \cdot \cos\left[\omega(t - t_{max})\right]\right) \tag{4.27}$$

For the frozen season ($t_2 < t < t_1$),

$$T_w = T_o \tag{4.28}$$

where

$A$ = fractional amplitude of the sinusoid, dimensionless
$\omega$ = yearly cycle frequency = $2\pi/365 = 0.0172\ d^{-1}$
$t$ = time, Julian day
$t_1$ = ice-out time, Julian day
$t_2$ = freeze-up time, Julian day
$t_{max}$ = time of annual maximum temperature, Julian day
$T_w$ = water temperature, °C
$T_{avg}$ = annual average water temperature, °C
$T_o$ = under-ice water temperature, °C

Table 4.6 lists the parameters for this sinusoidal model for a variety of FWS wetlands at different latitudes. The deterministic trend represents the central tendency of water temperatures, but there are also stochastic variations. For instance, the standard deviation of the monthly means for Columbia, Missouri, is 1.6°C.

*The Accommodation Zone*

The inlet zone of a treatment wetland exhibits temperature changes as the water approaches the balance temperature. For short detention times (typically less than three days for FWS), the adjustment may not be completed, and the balance temperature is not reached (Kadlec, 2006c).

An empirical exponential model may be easily calibrated and used to describe the approach to the balance temperature:

$$T_w = T_b + (T_{wi} - T_b)\exp\left(-\frac{\eta t}{\rho c_p h}\right) = T_b + (T_{wi} - T_b)\exp\left(-\frac{t}{\tau_A}\right) \tag{4.40}$$

where

$c_p$ = heat capacity of water, $4.182 \times 10^6$ J/kg·°C
$h$ = water depth, m
$T_w$ = wetland water temperature, °C
$T_b$ = wetland balance temperature, °C
$T_{wi}$ = inlet water temperature, °C
$\eta$ = accommodation coefficient, MJ/m²·d·°C
$\rho c_p$ = volumetric heat capacity of water, MJ/m³·°C
$t$ = nominal detention time to an internal point, d

The quantity $\tau_A = \rho c_p h/\eta$ represents characteristic accommodation time for the wetland water on its travel through the system, during which 63.2% of the change from inlet to balance temperature is achieved. At $3\tau_A$, 95.0% of the change is accomplished. Data for free water surface wetlands indicate that adaptation takes a detention time on the order of one to three days (see Table 4.9).

## Temperature Coefficients

Temperature effects on $k$ are usually summarized using the modified Arrhenius equation

$$k_T = k_{20}\theta^{(T-20)} \tag{17.20}$$

where $k_T$ is the rate constant at temperature $T = T$°C and $k_{20}$ is the rate constant at 20°C. Values of the temperature correction factor ($\theta$) have been estimated for data sets with adequate operational temperature data.

Frequency distributions for theta factors and corresponding $k_{20}$ values for common constituents may be found as follows:

- $BOD_5$ Chapter 8, Table 8.4
- Ammonia N Chapter 9, Table 9.29

## Rate-Constant Adjustment

The goal of design calculation is the selection of the wetland area that will provide the necessary treatment in all seasons of the year. The annualized calculations that have gone before are presumed to represent conditions roughly corresponding to the average annual water temperature. However, it is now necessary to adjust these rate coefficients downward to winter conditions, which range downward to about 2°C.

The controlling pollutant in the example is total nitrogen. It is also shown that this is an agronomic wetland, with considerable influence of the biomass cycle. It is probably not appropriate to use theta-factor corrections under these conditions, but, nonetheless, it shall be done here for illustration purposes. From Table 9.20, the median $k_{20}$ = 21.5 m/yr and the median $\theta$ = 1.056. Suppose it is forecast that the low winter water temperature is going to be 4°C. (This would apply to the midsection of the eastern United States, e.g., Kentucky/Tennessee). The corresponding $k_4$ = 9.0 m/yr. The annual calculation used is $k$ = 13 m/yr, so a larger wetland area is needed, which is found to be 52 ha—up from 40 ha.

Note that if the temperature coefficient is large and the winter temperature is low, e.g., 1–2°C, then the area may become quite large, and winter storage may be warranted.

The median theta factors for some pollutants are very close to, or even less than, 1.000, implying very little temperature dependence. BOD removal in FWS wetlands has a median of $\theta$ = 0.985 (Table 8.4), and fecal coliform reduction has a median of $\theta$ = 0.963 (Table 12.5). Of course, sustainable, postsorption phosphorus removal mechanisms rely heavily on the balance of vegetative uptake over return, and, therefore, agronomic models should apply. That is reflected in median $\theta$ = 1.005 (Table 10.12). It is various nitrogen species that exhibit theta factors, which implies a need for temperature correction in design.

## Monthly Rate Coefficients

As discussed in Chapter 9, temperature coefficients apply to microbial controlled systems but not necessarily to agronomic systems. It would be desirable to have monthly rate coefficients for the various sequential nitrogen conversions under agronomic conditions, but these are generally not available at this time. What is clear is that agronomic wetlands display a peak of ammonia removal during the spring growth period and that this does not correspond to the maximum of water temperature (see Chapter 9, Figure 9.28).

The mean ammonia behavior of 11 cold-climate wetlands under partial or total agronomic control is shown in Table 17.9. Note that the rate coefficient is highest in May, which is typically the maximum growth month. Summer is, in general, a time of greater ammonia reduction, perhaps reflecting microbial activity as well as growth in some instances. The average total nitrogen loading to these wetlands was 130 gN/m²·yr, just over the putative limit of 120 for agronomic wetlands; the ammonia loading was a bit lower at 90 gN/m²·yr. It is noteworthy that January remains the "bottleneck" month, with a rate coefficient that is about

**TABLE 17.9**
**Apparent First-Order Rate Constants for Ammonia Removal in FWS Treatment Systems in Cold Climates**

| Month | Rate Coefficient (m/yr) |
|---|---|
| January | 2.4 |
| February | 4.1 |
| March | 7.1 |
| April | 14.7 |
| May | 20.3 |
| June | 13.1 |
| July | 11.5 |
| August | 12.4 |

| November | 5.8 |
| December | 3.0 |
| **Annual Average** | **9.5** |

*Note:* Model parameters are $P = 3$ and $C^* = 0$; data from 11 wetlands; the mean nitrogen loading was 130 gN/m$^2$·yr (N = 11).

four times lower than the annual average and about ten times lower than the growing season maximum.

### Trend Amplitudes

When contaminant concentrations are well above wetland background levels, the seasonal variations in wetland effluent concentrations may be described equally well by a *P-k-C** model or an empirical sinusoidal model. Both employ the three constants with which the data is fit. Under such conditions, either may form the trend basis from which the exceedance frequencies are determined. The absence of a significant temperature coefficient for the rate coefficient (different from unity) does not necessarily imply the absence of an annual cycle in wetland effluent concentrations. If the wetland is large enough to reach approximately background concentrations, then there may be a seasonal pattern to the outlet concentration resulting from a seasonal pattern in *C**.

However, when the wetland effluent concentration is close to background, the value of *C** prevails and the rate constant, whether agronomic or microbial, does not control behavior. This situation is known to occur with fair frequency for TSS and BOD. Performance forecasting then depends on understanding the seasonality of *C**.

It is possible to use an Arrhenius factor for *C** (Kadlec and Knight, 1996; Stein *et al*., 2006b). Values ranging from $0.935 < \theta < 1.029$ were reported for COD, depending upon vegetation type (Stein *et al*., 2006b). In general, *C** for COD was found to decrease with increasing temperature ($\theta < 1.000$). A central tendency for a TSS of $\theta = 1.065$ was reported by Kadlec and Knight (1996), which reflects an increase in *C** with increasing temperature.

The parameters for seasonal trends in TSS for several FWS wetlands are shown in Table 7.7, with an example cycle shown in Figure 7.16. On an average, the magnitude of the cycle is 39% of the mean, with a maximum in midsummer on yearday 166. The parameters for seasonal trends in BOD for several FWS wetlands are shown in Table 8.5, with example cycles shown in Figure 8.15. On average, the magnitude of the cycle is 27% of the mean, with a maximum in midsummer on yearday 129.

A hypothetical annual TSS *C** cycle is illustrated in Figure 17.14. If the winter to summer temperature swing is 15°C, the corresponding swing $\theta = 1.056$ for *C**. But note that the TSS is highest in summer, and, therefore, it is the summer peak and the associated scatter that are of concern in design. There is no design control over the TSS background.

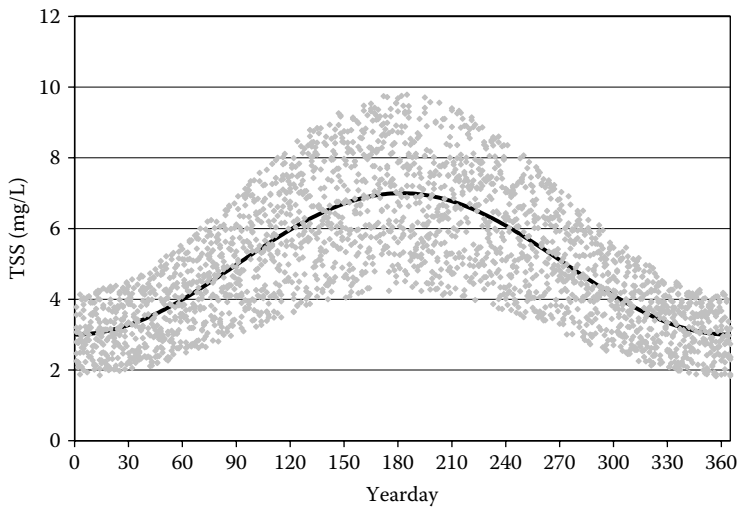

**FIGURE 17.14** Hypothetical scatter of TSS around a seasonal trendline. The annual mean is set at 5 mg/L, and a ± 40% scatter is indicated. The peak TSS occurs in midsummer.

The annual values of BOD and TSS may not reach as low as $C^*$, in which case the annual cycle parameters are used to adjust the design target. The amplitude of the sinusoidal trend can serve to show what "extra" concentrations may occur seasonally. A procedure for accounting the seasonality is to add the seasonal effect to the scatter effect. The trend multipliers tabulated for use with the *P-k-C** model can be extended to include the seasonality. For instance, the scatter in Figure 17.14 is 40%, and can be contained in a design using a trend multiplier of 1.40. However, the summer peak in the trend, 7 mg/L, is also 40% higher than the annual mean of 5 mg/L. The overall multiplier is thereby increased to 1.96, which is used to contain both the random scatter about the mean trend and the seasonal trend. This is the procedure recommended in Kadlec and Knight (1996), who reported a 100th percentile total containment (trend plus scatter) multiplier of 1.9 based on data for 49 wetlands.

### Winter Storage versus Winter Operation

TSS and BOD reductions in treatment wetlands are approximately independent of season, and the decision for winter storage involves only hydraulic concerns with freezing conditions. But, winter rate constants are about one third and one tenth the summer values for phosphorus and ammonia, respectively (Kadlec and Reddy, 2001). Thus, for nutrient removal, the winter removal-process slow-down adds to the hydraulic concerns. There are several options for dealing with winter slow-down, including the following:

1. Provide no winter storage, and increase the wetland size to meet desired winter performance.
2. Provide winter storage by adding storage lagoon volume, but operate the wetland year-round and at a reduced (bleed) flow in winter.
3. Provide winter storage by adding storage lagoon volume, do not attempt to operate the wetland in winter, and control the warm-season releases according to water-temperature patterns.
4. Provide winter storage by adding storage lagoon volume, do not attempt to operate the wetland in winter, and release water from the pond and wetland at a uniform rate throughout the warmest season.

Options 3 and 4 are the choices for climates so severe that the hydraulic operation is questionable because of freezing. In more moderate climates, where ice formation is absent, or hydraulic operation of the wetland can continue with minor ice formation, all options may be considered.

Winter operation is hydraulically possible for lagoons, even for fairly severe cold, where ice thicknesses may range up to a meter (Heaven and Banks, 2005). Indeed, most lagoon systems receive water year-round. Winter operation is also possible for FWS wetlands, even in moderately cold conditions, because water can be managed to flow under ice. Complete freeze-up leads to over-ice water flows and ice buildup. Cold water temperatures lead to large reductions in microbial processes, and the vegetation cycle is dormant in frozen conditions. Oxygen transfer to under-ice water is blocked by ice and snow. These individual process effects combine in complex ways to produce the overall observed slow-down of treatment.

Performance modeling may be used to resolve the requirements of the four options for pond volumes and wetland areas. Typically, the storage options will require the least land (smallest footprint) and the most earthmoving, whereas Option 1 (no winter storage) will require the most land and the least earthmoving. Controlled discharge (Option 3) is operationally the least convenient, because it requires operator attention to set the flows on a periodic schedule throughout most of the year. For North American conditions, although Option 3 often leads to capital investment economics that favor controlled discharge, operational considerations almost invariably lead to a uniform warm season release (Option 2).

### An Illustration

A hypothetical example of some of the design and performance factors for a large-scale system is given in Table 17.10. The flow to the system is 4,000 $m^3$/d in all seasons, and the effects of seepage, rain, and *ET* are assumed negligible for simplicity. The design target for this example is to meet a monthly ammonia effluent concentration of 3 mg/L on an average during all the months of the year, and this value includes the allowance for random variability. The degree of storage pond treatment is as predicted by procedures in the lagoon literature (U.S. EPA, 1983c; Crites *et al*., 2006), and the treatment in the wetland is computed using the *P-k-C** model with $P = 3$, $C^* = 0$, and a temperature dependent $k$ value, and with $k_{20} = 0.05$ m/d and $\theta = 1.09$. The pretreatment facilities, upstream of wetlands and storage lagoons, are presumed to produce 20 mg/L. Under these conditions, the design bottleneck is winter for the no-storage operation. Storage moves the bottleneck to early spring and late autumn, which are the times of lowest temperature during the unfrozen discharge season. Option 2, employing a winter bleed flow through the wetland, has a dual requirement: neither winter nor summer effluent concentrations must exceed the target. Therefore, the wetland area is determined by the spring and fall bottlenecks, and the winter bleed flow is set to meet the target in winter. Option 1, year-round wetland operation, uses a wetland size that meets winter requirements. The flow and storage time series for the various options are shown in Figures 17.15 and 17.16. Associated effluent ammonia concentrations are summarized in Figure 17.17.

The ranking of alternatives indicates an increasing footprint (total area) as storage alternatives move from Options 2 to 3 to 4 (Table 17.10). Option 2, use of a winter bleed flow, has the smallest footprint, 58 ha, just a little more than half the year-round operation footprint of 100 ha. This system includes 87 days of lagoon storage. If the choice is to avoid winter discharges altogether, then the best option is to utilize a controlled release strategy. Small releases are used in early

spring and late autumn, and maximum release takes place in midsummer, the time of warmest water temperature. An area of 67 ha, containing 138 days of storage, is forecast to achieve the required ammonia standard. However, the convenience of a steady summer discharge might lead to the choice of the 89 ha system, which has 184 days of storage. The extra two months of storage are needed to avoid the (high) uniform flows during early spring and late autumn, or else the wetland will become nearly as large as that for no storage. Land acquisition, and perhaps liners, are area-specific costs, which form a large proportion of the total system capital cost and, hence, Options 2 and 3 are favored for lowering those costs.

Earth moving is another major cost in natural systems, and there are large differences among the three alternatives in the illustration. Year-round wetlands require the least earth moving, and a complete winter shutdown requires the most. Table 17.10 shows that total basin volumes (lagoon plus wetland) of the alternatives vary widely for the example, with the winter operation of the wetland needing only 25% of the earth moving that a uniform summer discharge system would require. Thus, the presence or absence of liner requirements, or the type and cost thereof, can shift the economic advantage from one option to another. This example suggests that wetlands should be used in winter if hydraulically practical, because land and liner costs typically will not outweigh earth-moving costs.

### Wetland Systems with Storage

There are considerable numbers of treatment wetlands that operate seasonally, with off-season storage (Table 17.11). Many of these are preexisting lagoon systems with wetlands added, so storage was already available. A common mode of operation of lagoons and facultative ponds is pulse discharge during spring or autumn, thus taking advantage of the maximum dilution potential while receiving surface waters. Some or all of the needed storage capacity may, in fact, be present prior to wetland add-ons.

## 17.6 STORMWATER WETLANDS

Stormwater wetlands are nearly always FWS systems because of the need to hydraulically accommodate large-event flows and because there is no perceived health hazard associated with the water. Design follows one of the four following tracks:

1. Percentage of the contributing watershed
2. Design storm detention
3. Annual average performance
4. Detailed dynamic modeling

The first two of these are technology-based because they provide prescriptions that imply a general level of treatment rather than specific numerical concentration or loading goals. Technology-based volume or area specifications are attractively simple because they do not require any information about the incoming water chemistry. They suffer from an inability to be adjusted for removal targets other than the original presumptions. The second two are performance-based methods, which depend on forecasts of wetland reductions of target pollutants. Performance-based sizing calculations may be either on an average basis, usually annual, or on a short time scale to capture the full dynamics, usually daily. For example, annualized performance can be related to hydraulic loading and inlet TSS by using Equation 14.8 as a design prediction tool. Exploration of this formulation shows that it is consistent with the technology-based procedures in the 75–80% removal range.

All of the methods require knowledge of the runoff volume characteristics of the contributing watershed; the performance-based methods also require the incoming contaminant concentrations.

Associated with stormwater wetlands is the concept of bypassing. Bypassing is necessitated when site constraints prevent the treatment of all imaginable flows. The constraint may occur because of limited land availability, which creates

a hydraulic conveyance constraint on how much water can be passed through the system. For instance, the intense rains of subtropical regions can occasionally create runoff flows that simply cannot be routed through a reasonably sized wetland. The second constraint arises owing to the availability of maintenance water. If the wetland is sized large enough to accommodate major events, then the demand for maintenance water during interevent periods may be too large.

Agricultural stormwater systems might differ somewhat from urban stormwater systems because the target may be sediment or nutrient control and load or concentration reduction.

Chapter 14 has provided the experience base for the design of stormwater wetlands. Here, the design sizing procedures are outlined. These rely on source characterization, just as for the continuous flow wetlands discussed in Chapters 14 and 16.

### Inflow Estimation

The amounts of water to be expected to reach the wetland depend on the size and character of the watershed. Rainfall records provide an accessible and useful means to determine the amount of water received by the watershed, and runoff fractions provide the resultant flows to the wetland. Runoff coefficients vary with land use; they are typically high (80–90%) for impervious surfaces but lower (20–30%) for more absorbent conditions in the watershed (Table 14.1). An example of the determination of the runoff coefficient for particular applications is the New York calculation (Center for Watershed Protection, 2001):

$$\text{Runoff coefficient} = R_V = 0.05 + 0.009I \qquad R_V \geq 0.20 \tag{17.21}$$

where

$I$ = percent impervious

However, regional considerations can easily preempt generic information such as the impervious cover estimates summarized in Table 17.12. For instance, runoff coefficients for the Everglades agricultural area are about 50%, not because of imperviousness but because of extremely high water tables

**TABLE 17.12**
**Imperviousness of Various Land Uses**

| Land Use Category | Mean Impervious Cover |
|---|---|
| Agriculture | 2% |
| Open urban land (parks, golf courses, cemeteries) | 9% |
| One-acre lot residential | 14% |
| Quarter-acre lot residential | 28% |
| Multifamily residential | 44% |
| Institutional (schools, churches) | 28–41% |
| Light industrial | 48–59% |
| Commercial | 68–76% |

*Source:* Data from Center for Watershed Protection (2001) *New York State Stormwater Management Design Manual*. Report by the Center for Watershed Protection (CWP) for the New York State Department of Environmental Conservation, Albany, New York.

and high rainfall. Accordingly, runoff should be considered highly site specific.

A design storm is specified according to regulatory or negotiated considerations. For instance, the 90th percentile of the event number distribution is used in New York (90% of all rain events are less than this event). The rainfall amount varies with geographical location but is approximately 3 cm in the northeastern United States. Given the area of the watershed and the runoff coefficient, the volume of water that the design event delivers to the wetland, $V_{design}$, may be determined. This amount may then be converted to the annual volume reaching the wetland, via the ratio of the annual total rainfall to the amount of the 90th percentile. More detailed estimates may be made on the basis of the variation of $R_V$ with the rainfall amount, whereby very small rains are assumed to produce no runoff. Further, by implication, larger events are bypassed, either in total or partially.

## Hydraulic Considerations

Interpretation of performance for event-driven wetlands depends on the amount of a given event that is retained in the system and by the length of the interevent period, rather than by detention time or the average hydraulic loading. Detention and loading may, nonetheless, be computed if desired. As an example, consider a wetland of volume $V$ m$^3$ that quickly receives the same volume of water as an inflow. If the wetland were in plug flow, then the new water would just displace the antecedent wetland water. That effluent water would have been subjected to batch treatment over the period since the preceding event. Thus, the effluent concentration would be determined by the concentration that entered with the preceding event and by the detention during the interevent period, and would have nothing to do with the concentration of the water that displaced it.

Stormwater wetlands receive pulses of widely varying volume and frequency and are not usually anywhere close to plug flow. The TIS model may be used to explore how much of the water of events of different sizes will stay within the wetland (see Chapter 6 for details of the TIS model). In general, the fraction of the event that remains in the wetland increases as the number of tanks increases, to the limit of plug flow (see Figures 14.5 and 14.6). Some existing design methods specify the particular return frequency event for which the runoff is to be nominally contained in the wetland (Schueler, 1992). This design event is characterized by the value 1.0 in Figure 14.5. At this event size, the actual fraction of the event that is retained is strongly dependent on $N$, the number of TIS. It is therefore desirable to maximize this number in the design. Walker (1998) suggested that computational fluid mechanics could be used to investigate the geometrical design factors that contribute to the retention that is to be expected. This procedure utilizes a dispersion coefficient to explore deviations from plug flow, and it leads to Figure 14.6.

## Percentage of the Contributing Watershed

The amount of water and pollutants that reach stormwater treatment wetlands from contributing watersheds are not typically known in advance. The number and duration of the events that produce the input, together with the interevent spacing, are thought to affect the efficiency of the stormwater wetland. Because of this variability of actual flow rates, detention time and hydraulic loading are difficult to define, and other single-number sizing rules have evolved. One such method of presumptive sizing is a specification of the wetland-to-watershed area ratio (WWAR). This rule of thumb states that the wetland size should be a specified fraction of the contributing watershed, usually in the range of 1.0–5.0%. A little arithmetic shows that this is equivalent to the range of hydraulic loading rates cited earlier for continuous flow treatment wetlands. In a moderate climate,

Annual rainfall = 60 cm
Average annual rain rate = 60/365 = 0.164 cm/d
Watershed runoff coefficient = 0.75
Runoff = 0.75 × 0.164 = 0.123 cm/d
Watershed/wetland area ratio:
WWAR = 1/.025 = 40 (for 2.5% of the watershed)
Average annual wetland HLR = 40 × 0.123 = 4.9 cm/d

Because this average annual HLR is close to the median of the distribution of HLRs for FWS wetlands (e.g., 4.0 cm/d for TSS systems and 4.8 cm/d for TP systems), it is reasonable to expect that stormwater wetlands designed in this way would perform somewhere near the average for the emergent marsh database set. For instance, the mean reduction for phosphorus in 284 FWS wetlands was 38% at a median HLR = 4.8 cm/d; the mean reduction for several constructed stormwater marshes with an average WWAR = 4.3% was also 57% (Strecker *et al*., 1992).

Ratios of 2% for marshes alone and 1% for pond–marsh combinations have been advanced (Schueler, 1992), but some authorities require more. Ontario and Alberta target 5%. However, such generalizations are dangerous as they do not extend to other event-driven wetland applications. For example, Braskerud (2001a) found 50–60% TSS removal in four wetlands over a six-year period, with WWAR between 0.03 and 0.07%.

## Design Storm Detention

A stormwater wetland may also be sized to contain a specific volume of water, usually the volume associated with a rain event of a specified return frequency or probability of occurrence. For instance, Schueler (1992) suggests that wetlands have sufficient volume to fully contain any rain event up to the 90th percentile of the rainstorm quantity distribution. Again, this may be shown to match the loading and detention design ranges used for point-source wetland systems.

In the vicinity of Washington, D.C., there is 104 cm annual rainfall, and the 90th percentile storm is 3.18 cm:

Watershed area = 40 ha = 400,000 $m^2$
Watershed runoff coefficient = 0.75
Design storm runoff volume = 0.75 × 0.0318·400,000 = 9,540 $m^3$
Wetland area @ 0.3 m depth = 9,540/.3 = 31,800 $m^2$ = 3.18 ha
WWAR = 100 × (3.18/40) = 8%
Annual flow = 0.75 × 1.04 × 400,000 = 312,000 $m^3$
Average annual detention time = 9,540/312,000 = 0.03 years = 11 days
Average annual wetland HLR = 312,000/31,800 = 9.8 m/yr = 2.7 cm/d

This single-number design technique has the advantage of allowing a variable percentage of watershed, depending on the annual rainfall pattern and annual rainfall total. As in the case of WWAR design, the loading and detention times correspond to the median values for point-source treatment wetlands. It is, therefore, not surprising that Schueler (1992) lists pollutant reductions that are in the mid-range for other treatment wetlands. For instance, the total phosphorus removal is projected to be 45%, compared to the 38% mean for FWS systems in general.

The selection of volume or area also corresponds to a projected level of TSS removal. For example, Schueler (1992) suggests that 75% TSS reduction can be reliably achieved by stormwater wetlands that capture the 90th percentile of rain events. Although confirmation of that assumption remains elusive, the criterion has been adopted in New York (Center for Watershed Protection, 2001). Other states, such as Wisconsin, have adopted similar criteria, which recommends a design rain of 3.8 cm and suggests that this corresponds to an 80% reduction (Prey *et al.*, 1995).

## Annual Average Performance

Another level of detail may be added via annual average performance calculations. The average hydraulic loading is computed from individual events of the year, utilizing precipitation records and the definition of the maximum event to be treated. Incoming concentrations are determined from the watershed data or from estimates. The flow-weighted concentrations are used. Both regression equations and rate coefficient formulations have been proposed.

### Regression Equations

Duncan (1998), as referenced and reported by Wong *et al.* (1999), suggested the use of regression equations for purposes of sizing. He presents relations based on the analysis of 76 stormwater wetland systems, presumably including pumped systems. The proposed relations are

$$\text{TSS percent remaining} = 78q^{0.33}C_i^{-0.49} \quad R^2 = 0.80 \tag{14.8}$$

$$\text{TP percent remaining} = 12q^{0.44} \quad R^2 = 0.71 \tag{14.9}$$

$$\text{TN percent remaining} = 14q^{0.43} \quad R^2 = 0.78 \tag{14.10}$$

where
$C_i$ = inlet concentration, $g/m^3$
$q$ = hydraulic loading rate, m/yr

Carleton *et al.* (2001) also suggest that the WWAR may be used as a predictor of performance. Their regression equations are developed for small data sets, including natural wetland systems, and have low correlation coefficients ($R^2 \approx$ 0.15–0.45). Within the range 0 < WWAR < 0.1, the data scatter was particularly large. Regressions of the data for TSS, TP, and nitrogen compounds in Tables 14.5–14.10 are generally unsatisfactory. For TSS, for example, the remaining fractions increase slightly with WWAR.

### Annualized Rate Coefficients

It has been suggested that the design techniques from continuous flow wetland performance may be transferred to event-driven systems by using rate coefficients to forecast average performance (Wong and Geiger, 1997; Carleton et al., 2001). However, the rate coefficients are not necessarily the same as those found for the continuous flow systems. Stormwater data sets analyzed by Strecker *et al.* (1992) and extended by Carleton *et al.* (2001) include about half of the natural wetland systems. Strecker *et al.*, in fact, found that natural wetlands performed somewhat better than constructed wetlands, but the use of natural wetlands is not encouraged owing to real and perceived negative impacts (U.S. EPA, 1993e).

The median annual areal rate constants reported by Carleton *et al.* (2001) for FWS-constructed gravity systems (N = 9) are as follows:

| | |
|---|---|
| Total phosphorus: | 8.3 m/yr |
| Ammonia: | 5.0 m/yr |
| Nitrate: | 6.7 m/yr |

These are very low compared to the *k*-values reported for continuous flow systems in Part I. Analysis of the few detailed data sets that exist indicates that higher rate coefficients than these apply to individual events. For instance, Kadlec (2001a) reported $k = 100$ m/yr for phosphorus, and Werner and Kadlec (2000b) measured 125 m/yr for nitrate, both based on pumped event dynamics.

The designs of the 16,000 ha of constructed stormwater treatment areas (STA wetlands) of South Florida, which target phosphorus removal, were essentially based on annualized rate coefficients. The prototype was an event-driven natural wetland that produced $k = 10$ m/yr for $C^* = 2$ μg/L and $P = \infty$ (Walker, 1995). Subsequent analyses have shown that the constructed systems have annualized *k*-values of the same general magnitude. However, the dynamic *k*-values are higher (Walker and Kadlec, 2005). Further, the *k*-values are sensitive to the characteristics of the event sequences. It is likely that more accuracy can be gained only by dynamic simulations.

## Detailed Dynamic Simulations

The most detailed design calculations involve dynamic simulations of wetland performance, accounting for nonideal flow patterns and the time series of flows and concentrations that enter the wetland. This procedure has been calibrated for some few wetlands (Wong *et al*., 2006), but the input parameters are of unknown transferability to other wetlands and sediment types. For instance, data from stormwater wetlands at Elbow Valley, Alberta (Amell, 2004), indicate a first-order removal rate coefficient for TSS on the order of 0.6–0.9 m/d, whereas the rate coefficient found by Wong *et al*. (2006) were 16–21 m/d. The magnitude of this difference is not surprising, given the extreme variability in the TSS settling rates, shown in Figure 7.8. There are some suggested procedures that account for the size distribution of the incoming TSS (Lawrence and Breen, 1998), but such measurements require significant data acquisition for the source water. In terms of model nomenclature, the parameters *k*, *C**, and *N* are not known in advance. Wong *et al*. (2006) found it necessary to calibrate the dynamic TIS model for the number of TISs. Treatment wetland technology is not yet capable of determining that number *a priori* from design and layout details. Computational fluid mechanics would offer a way to do this (Walker, 1998), but there is not yet a verification of the accuracy of this procedure using wetland field data.

At present, the only generally available dynamic simulation tool developed solely for the design of event-driven wetlands is for phosphorus removal in warm climates. The dynamic model for stormwater treatment areas (DMSTA) computer routine is given at Web site http://www.wwwalker.net/dmsta/. This model has seen extensive use in the design of constructed wetlands in South Florida, including eight large systems of the order of 1,000 ha each. There are numerous other computer codes that have varying capabilities to deal with time-variable stormwater flows and concentrations, together with some form of constituent tracking. Some of these have been listed in Chapters 9 and 10. However, calibrations to wetland data are typically lacking, except for DMSTA, which has been calibrated to more than 100 wetland data sets, ranging from mesocosms to large full-scale systems.

A key feature of the dynamic simulation of event-driven wetlands is the inclusion of the storage of contaminants. Nutrients are stored in vegetation and sediments and cycled on a preset time scale. Movements of pollutants into and out of storage have important effects on the long-term reductions in these pollutants.

Detailed dynamic simulations are very data hungry. Rather extensive time series of inflows, concentrations, and meteorology are needed. The probable rainfall sequence may be constructed from historical records, but the inflows and concentrations will typically have to be estimated. As a consequence, full dynamic simulations are likely to be restricted to situations involving large and expensive wetlands.

## Flow Equalization versus Pulse Operation

Event flows create large instantaneous loads on a treatment wetlands that, if not contained, will be the cause of low degrees of treatment. The peaking factor (PF) may be defined in a manner similar to that used to describe the fluctuations in continuous flows, namely, as the ratio of the peak flow to the mean flow. To illustrate the effect of flow equalization, consider a highly idealized example in which an average of 2,000 $m^3$/d at 100 mg/L is to be treated in 8 ha. The *P-k-C** values are selected to be $P = 3$, $k = 10$ m/yr, and $C^* = 0$. For continuous, uniform flow, the calculated exit concentration is 39 mg/L. Suppose the peaking factor is 10, i.e., the flow all occurs at 20,000 $m^3$/d, but only for 10% of the time. The calculated exit concentration is then 90 mg/L. The reduction has dropped from 61% to 10%. This example is unrealistic for several reasons; for example, there are changes in storage in the water body, which have not been accounted.

Next, we broaden this illustration to include storage and (batch) treatment during the interevent periods. The event sequences will be limited to a time series of ten-day events, separated by periods that increase as the peaking factor increases. The average flow is maintained at 1,000 $m^3$/d. Treatment continues during the interevent period, but there is no flow. Water from the next flow event mixes with the antecedent water and displaces it.

It is supposed that the design should achieve 50% reduction; two alternatives are to be compared: a wetland only, and a storage pond plus wetland. The pond is sized to fully equalize the flow sequence and thus generate a uniform continuous flow. The pond performs no treatment.

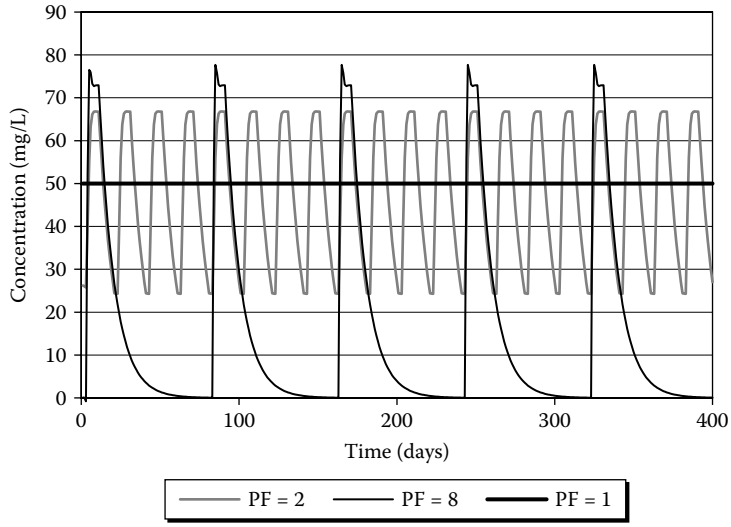

**FIGURE 17.18** Outlet concentration time series of equalized and non-equalized flow scenarios for event train treatment in a hypothetical example. See text for assumptions and conditions.

First, consider the alternative of allowing the pulses to pass through the wetland with no equalization. The concentration time series for the three peaking factors for non-equalized flow are shown in Figure 17.18. The case of PF = 1 corresponds to the continuous uniform flow and produces a uniform outlet concentration of 50 mg/L. When the PF = 2, the flow occurs only 50% of the time, and the wetland acts as a batch reactor the other 50% of the time. Concentrations swing from 25 mg/L at the end of the batch time to 65 mg/L at the end of the flow time, but the flow-weighted outlet concentration remains at 50 mg/L. When the PF = 8, the flow occurs only 12.5% of the time, and the wetland acts as a batch reactor the other 87.5% of the time. Concentrations swing from 0 mg/L at the end of the batch time to 75 mg/L at the end of the flow time, but the flow-weighted outlet concentration remains at 50 mg/L. Clearly, in the hypothetical example, event flows lead to large swings in outlet concentrations; and, indeed, this is expected and observed for real systems as well (see Figure 14.9 for example).

The wetland sizes to accomplish a flow-weighted outlet concentration in the hypothetical example range from 2.85 ha for continuous flow to 24.4 ha for a peaking factor of 16. High peaking factors are in fact observed; for instance, they range up to 13 for STA6 in South Florida (see Figure 14.9). The question thus arises as to the desirability of adding flow equalization to the treatment train. In the hypothetical example, it is supposed that a storage pond would operate in a working depth range of 0.0–2.5 m, exclusive of freeboard and minimum depth requirements. It is then possible to compute the pond volume and area necessary for providing full equalization. Under the equalized scenario, the wetland continues to be sized at 2.85 ha. Figure 17.19 shows, for the

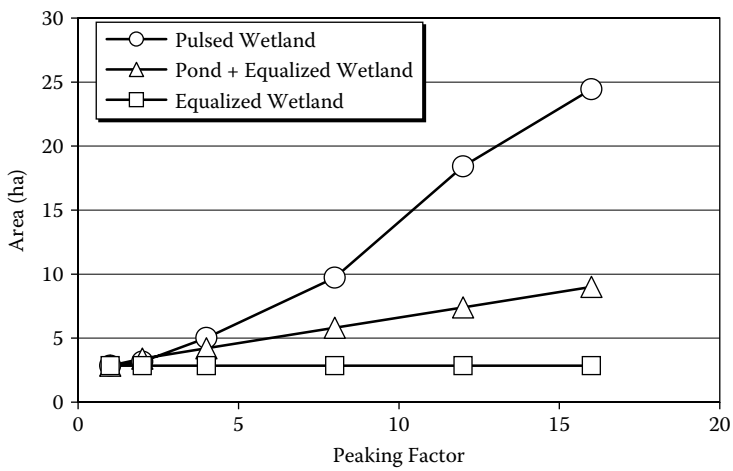

**FIGURE 17.19** Total working footprint area of equalized and non-equalized flow scenarios for event train treatment in a hypothetical example. See text for assumptions and conditions.

conditions of the hypothetical example, that the area requirement for the equalized flow alternative is always less than that for a pulsed wetland with no equalization and, at PF = 16, the combined storage plus wetland is only 37% as large as the pulsed wetland, to achieve the design goal of 50 mg/L. However, rough estimates suggest that earth moving would not vary much between alternatives (not shown). As a result, the decision to equalize would normally be made on the basis of land cost and availability.

Of course, the results of this hypothetical example should not be used in an actual design decision, because it is highly unlikely that all the conditions would be met. Nevertheless, the example provides an illustration of the concepts that would be exercised in a real design situation. As will be seen, most urban stormwater systems would contain a small forebay for solids collection, and thus provide some small measure of equalization, in any case.

## SUMMARY

This chapter has integrated the analytical elements of preceding chapters into a sequential approach to designing and evaluating a FWS treatment wetland system. Sizing is the first step in design, for which complementary techniques have been integrated. First-order removal equations are used first. The rate coefficients are selected from the percentile tables of Part I. Hydraulic efficiency is chosen via the selection of the number of TIS. Calculations include the possibility of a nonzero background concentration, corresponding to a return flux from the ecosystem. Rate constants and background concentrations vary with season or temperature in some instances. Goals may include concentration reduction and/or load reduction, which are conflicting objectives. Excursions may need to be contained, for which the exceedance frequency data of Part I is used. The model equations are solved on spreadsheets, with a tank-to-tank calculation procedure. Nitrogen compounds further require linked species computations. Wetland area is adjusted to meet the project objectives.

There is nothing about the rate-constant approach that acknowledges the limitations of the wetland biology or ancillary chemistry. Therefore, the cycling of carbon, nitrogen, and phosphorus is checked to ensure that there are no unreasonable requirements for the ecology, oxygen, and carbon supplies. Rate coefficients may need adjustment if the presumed capacities of the ecosystem are exceeded. Loading charts are a method of understanding the behavior of existing systems. Designs that fall outside the range of the existing data scatter would require further justification.

For some pollutants, adjustments to the design may be required to account for seasonal or temperature-driven behavior. Nitrogen reduction is the primary situation in which either seasonality can occur for agronomic systems or temperature-driven rates can occur for microbially-driven wetlands. If the winter season creates too much of a constraint, leading to very large wetlands, then the possibility of winter storage requires consideration.

Stormwater wetland design may follow a similar path, but technology-based design strategies are also available. The time-variable nature of event-driven systems can lead to a requirement for dynamic simulation in design.

# 18 Implementation of FWS Wetlands

The purpose of this chapter is to provide information that will increase chances for successful wetland establishment and to help with understanding and overcoming difficulties that may arise during construction and start-up of wetland treatment systems.

Wetland treatment system establishment can be subdivided into three topics: (1) physical design, (2) construction, and (3) vegetation establishment. Physical design encompasses all the choices of how the wetland basin is built, and how the water is conveyed to and through the system. With the exception of urban stormwater wetlands (Schueler, 1992), there is no single comprehensive literature source that explains options for layout and configuration of the wetland cells that typically comprise a treatment wetland.

Site civil construction is a broad discipline of engineering and has been refined through centuries of experience. This chapter does not attempt to discuss all aspects of this engineering practice but rather describes the highlights of site civil construction that are most relevant to wetland treatment system construction. A brief general discussion of wetland site civil construction is provided by Tomljanovich and Perez (1989). All aspects of wetland construction are discussed in detail in the *Wetlands Engineering Handbook* (U.S. Army Corps of Engineers, 2000). This handbook discusses engineering procedures for establishing necessary hydrologic conditions, geotechnical design and soils handling for site modification, selecting appropriate vegetation and planting schemes, and establishing substrate conditions conducive to the desired functions. It also discusses baseline assessments of existing site conditions, monitoring strategies to determine long-term success, and contracting considerations. However, the objective of this handbook is the construction of mitigation/habitat wetlands, not treatment wetlands.

Establishment of wetland vegetation seems deceptively simple, but is not, and is frequently outside of the experience of many site civil contractors. Therefore, this important aspect of treatment wetland establishment should generally be subcontracted to specialists, nursery owner/operators, or wetland builders.

## 18.1 PHYSICAL DESIGN

The size of the wetland has been determined, at least initially, by the procedures of the preceding Chapter 17. The general characteristics of the site have been investigated in Chapter 16. There remain a number of design decisions on arrangement, vertical and horizontal placement, and methods of moving and controlling water.

### Siting

General conditions of the potential site will have been considered during the establishment of the basis of design. In general, there will remain a number of possibilities for the location of the system within the overall site confines. Conditions that should be evaluated during physical design of a wetland treatment system include geography, soils and geology, runoff water volume and chemistry, ecological and socioeconomic factors, and ancillary regulations. The importance of each of these conditions may vary, but all should be investigated to some extent. Detailed studies may be needed to determine the importance of those site conditions that affect technical feasibility.

### Floodplains and Floodways

A hypothetical siting situation is shown in Figure 18.1, which indicates that the regional waterways, a river and its tributary, are geographic features to be reckoned with. Constructed wetlands located in floodplains with extreme flood conditions, such as along major rivers, must have dikes that are designed to allow the passage of floods and/or that are sized to exclude flood waters. Constructed treatment wetlands have typically been allowed in floodplains under constrained conditions. Designs should avoid damage due to high-frequency recurrence events, and therefore would usually be built to withstand the 25-year flood event without impairment of function. Similarly, wetland facilities would usually be designed to withstand the 100-year flood event without severe damage. However, floodplains may be jurisdictional wetlands, thus creating regulatory questions. Nevertheless, many FWS wetland systems have been constructed in floodplains such as those at Columbia, Missouri; Brawley and Imperial, California; and Tres Rios, Arizona.

If a wetland is built in a floodplain, it is necessary to demonstrate that its presence will not back up floodwaters upstream of the project. In other words, the project should not block the floodway of the river. For most major rivers of the United States, there exist published maps showing the boundaries of the 100-year floodplain and the floodway.

### Other Regulatory Concerns

Wastewater treatment and disposal are regulated by an ever increasing number of federal, state, and local laws, rules, ordinances, and standards. In some cases, the most challenging part of implementing a wetland treatment project is complying with regulations through the permitting process. In fact, regulations may hinder innovative project design

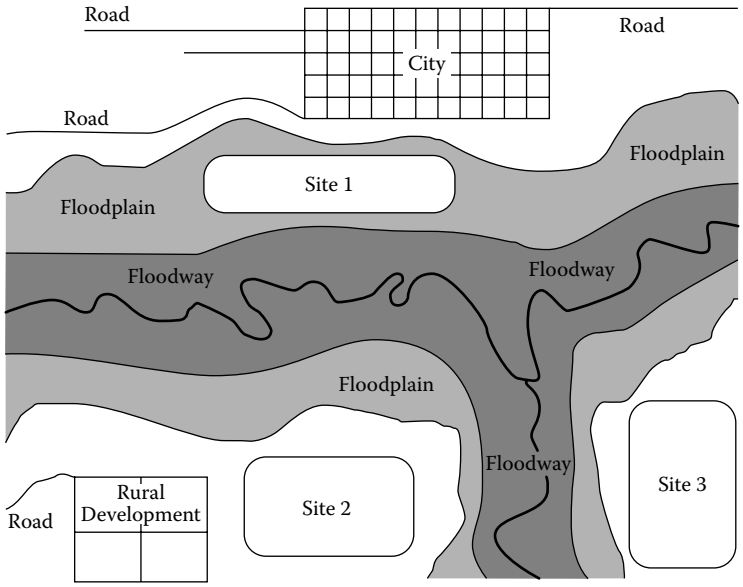

**FIGURE 18.1** Siting and flood concerns for a hypothetical treatment wetlands project. Communities are adjacent to a river and its tributary. The floodway occupies the central valley corridors and is bounded by the floodplain. Three potential constructed wetland sites are indicated, one in the floodplain.

for wetland treatment systems, even when the new design improves upon existing technology. Permitting an innovative project may delay implementation and increase cost with no incremental benefit for environmental protection. As a result of regulatory constraints, designers may opt for conventional technology with well-known deficiencies instead of technology that is perceived to have a greater risk—but with potentially high environmental benefits.

A detailed knowledge of pertinent regulations is essential to evaluate the feasibility of a wetland treatment project. This section provides an overview of the regulations that affect the use of wetlands for wastewater treatment in the United States as well as examples of some specific state situations. An updated and more detailed survey of federal, state, and local ordinances should be conducted to determine those that might be relevant to specific projects.

## Endangered Species

Under the Endangered Species Act, the U.S. Fish and Wildlife Service is mandated to identify and list plant and animal species that are threatened or endangered by extinction or that are considered likely to be threatened in the future. Threatened and endangered species cannot be harmed, killed, or otherwise negatively affected by human activities. The U.S. Fish and Wildlife Service reviews potential impacts to federally listed species and can veto Clean Water Act permits (such as a Section 404 wetland fill permit or an NPDES permit) by issuing a "jeopardy" opinion.

The potential for occurrence of threatened or endangered species inhabiting a project site should be considered during project planning. Typically, a list of threatened and endangered species that could occur at a project location is compiled from federal and state natural resource agency records. Potential project impacts on any of these species are assessed. If negative impacts on a species are anticipated during this review, it may be prudent to conduct a field survey to ascertain whether that species actually occurs at the proposed site. This confirmation step is important in eliminating the chance of finding a "fatal flaw" after considerable planning, design, or construction monies have been spent.

Experience indicates that the presence of federally protected species does not always necessitate substantial changes to wetland treatment project siting or design. In a number of cases, the discharge of treated wastewater effluents to constructed wetlands has enhanced the population of listed wetland-dependent species by creating additional habitat and food resources. For example, populations of bald eagles, wood storks, and snail kites, all federally protected bird species, have been increased in and around the 485-ha Orlando Easterly constructed wetland treatment system in Florida. Thus, the potential impacts of a project on protected species must be evaluated on a species-by-species basis. As a further illustration, the operation of the 2,400-ha STA1E treatment wetland in south Florida was prevented for a period of weeks because of the nesting activities of burrowing owls (*Athene cunicularin floridana*) and stilts (*Himantopus mexicanus*) (Figure 18.2).

## Cultural Resources

The U.S. National Historic Preservation Act requires that sites of significance for the early peoples of America be preserved. That normally involves avoidance of construction activities that might disrupt ancient village sites and burial grounds. For example, a historic archaeological site was excluded from the Coyote Hills, California, urban stormwater wetland (Figure 18.3). The Musselwhite, Ontario, mine-water treatment

**FIGURE 18.2** Nesting black-necked stilts (*Himantopus mexicanus*) caused brief stoppage of the STA1E project in Florida.

wetland was sited with due recognition of the line-of-sight from the regional First Nations burial ground.

### Layout and Configuration

The area determined to achieve the project treatment goals may typically be arranged in a number of ways. The principal decisions are

1. How many independent flow paths?
2. How many cells in each?
3. What aspect ratio for the cells or flow path?

There is a need to set the compartmentalization of the system. The number of flow paths in the design of surface flow wetlands is based on considerations of redundancy, maintenance, and topography. All constructed wetland treatment systems should have at least two cells that can operate in parallel to allow for operational flexibility (cell resting, rotation of flows, or maintenance). The ability to take cells out of service is usually viewed as very desirable. Maintenance activities do not normally require frequent shutdowns, but it is usually a good idea to allow at least two flow paths so that complete system bypass is not needed. Having at least two parallel cells is especially important because of unexpected events such as vegetation die-off, pretreatment failures and subsequent wetland contamination, and berm and other structural failures. Multiple flow paths allow the loading rate to be manipulated to meet varying inflow water quality. Also, parallel flow paths allow cells to be drained for replanting, rodent control, harvesting, burning, leak patching, or other possible operational controls. In the extreme long term, replacement of structures and piping become necessary. Some of the older FWS treatment wetlands are now reaching this point in their service life. Large systems may profitably incorporate more than two flow paths for purposes of internal flow control and to accommodate the site boundaries, site

**FIGURE 18.3** This archaeological site was excluded from the Coyote Hills urban stormwater wetland.

topography, and desired aspect ratios. However, multiplicity of inlet and outlet control structures can add significant cost to the overall project.

## Compartmentalization

Compartmentalization interacts with the design-area calculation because more cells and higher aspect ratios lead to higher tanks-in-series (*N*TIS) numbers, and hence to higher *P*TIS numbers. As seen in the previous chapters, higher *P*TIS does not help much for low desired-removal percentages but is a necessity if very high percentages are required. Aspect ratio is also a determinant of *N*TIS, with fewer for low length-to-width ratios. A single FWS wetland cell of modest aspect ratio ($1 < L/W < 5$) is likely to behave as three or four *N*TIS in tracer testing. When compounded with the weathering factor that influences most wastewater parameter reductions, it is likely that a *P*-value for the *P-k-C** model will be two or three. That may be perfectly adequate if the treatment does not attempt to achieve outlet concentrations close to *C**, but as the effluent target approaches *C**, the value of *P* becomes more and more important. If the computation is sensitive to *P*, then it becomes desirable to use cells in series. Use of three cells in series will lead to *P*-values between six and nine, beyond which is a region of diminishing returns.

Site constraints of steeply sloped ground may mandate terraced, multicell design. Because it is not possible to maintain uniform level and shallow depths on steep slopes, the change in elevation is accomplished via drop structures between cells in series. Inman *et al*. (2001; 2003) reported that site slopes of up to 25% called for 22 cells arranged on three separate flow paths at the Clayton County, Georgia, wastewater-polishing wetland facility. That project required the movement of 420,000 $m^3$ of earth over the 22 ha of wetlands or close to 2 m of cut and fill over the site area.

Costs increase as the number of cells increases. The number of cells required in each flow path must be determined by balancing the cost of more cells with the need for high-hydraulic efficiency. The ratio of berm area to wetland surface area increases with more cells. Figure 18.4 shows the design variables associated with increasing cells in series for a hypothetical fixed rectangular project footprint. Compartmentalization increases the *N*TIS for the footprint. The number of transfer structures increases with the number of cells, but the vegetated area becomes smaller due to more berm area and more water distribution zone areas. If the total area were not fixed, the total footprint would increase with compartmentalization. For an extreme example of dual-flow paths and multiple cells, see Figure B.24 in Appendix B for the Orlando Easterly project, which contains 34 structures for 17 cells on two flow paths.

## Internal Cell Arrangement

The arrangements of internal features of a single wetland cell have very large implications for the efficiency of the cell. Both the volumetric efficiency, $e_V$, and the detention time distribution efficiency, $e_{DTD}$, are very sensitive to the vegetation patterns within the cell. It is probably these factors that give rise to the majority of the intersystem scatter in performance data.

Each individual wetland cell may be contoured in a number of different ways. The goals of internal physical design are to provide efficiency of treatment, adequate conveyance of water, and perhaps habitat values. Wetlands have a tendency to channelize from points of inlet to points of outlet. If permitted, this operational feature reduces the gross areal efficiency of the wetland. Control of the bottom elevation and

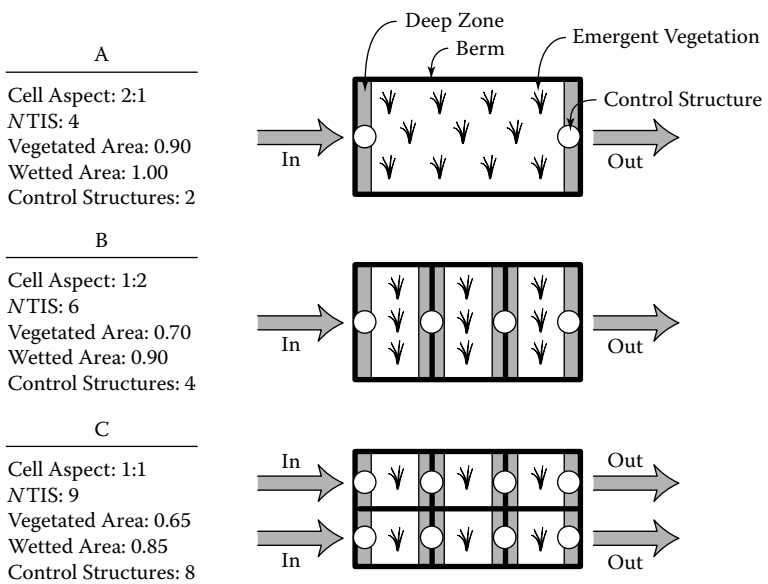

**FIGURE 18.4** Options for cells in series and parallel. *N*TIS are rough estimates. Areas are examples only; actual numbers are size-dependent.

vegetation density can, in principle, prevent poor flow distribution. But in practice, the bottom of the wetland can neither be constructed nor maintained at tolerances that promote full areal contacting. Nevertheless, care must be taken to degrade any preexisting ditches, roads, or berms on the site, because these will exert possibly undesirable flow control in the FWS wetland.

There are no hard and fast rules for design for high-areal efficiency for an individual wetland cell. Some general recommendations are

1. Avoid very small length-to-width ratios.
2. Avoid blind spots in corners.
3. Avoid unvegetated short-circuit paths.
4. Reestablish flow distribution at intermediate points in a flow path.
5. Maintain good bottom uniformity during construction and start-up: minimize the formation of topographic channels parallel to flow.

Figure 18.5 illustrates some of these ideas.

## Aspect Ratio

The length-to-width (aspect) ratio is important in basin design because of its effect on flow distribution and hydraulic short circuiting. Theoretically, a constructed wetland with a high-aspect ratio is not better for treatment than one with a lower aspect ratio, as long as flow is distributed effectively. It has been speculated that long, narrow flow paths are closer to plug flow than short, wide flow paths. But the interior microchannels of a uniform depth, uniformly vegetated FWS wetland have small dimensions; recirculation eddies are limited by depth (on the order of 0.3 m for a FWS wetland) or by the lateral spacing of plant stems or clumps of stems (also a fraction of a meter). Thus, the effective length-to-width ratio is predetermined and widening the wetland only adds more parallel channels.

There is a large literature dealing with the effects of aspect ratio (length-to-width, L:W) on the behavior of inert tracers and on the performance of ponds and wetlands for pollutant reduction as a function of aspect ratio. Thackson *et al*. (1987) presented data that illustrate the importance of L:W on the effective volume ($e_V$) of unvegetated ponds, showing an increase with L:W. Since that time, computational capabilities have permitted theoretical exploration of the values of $e_V$ and $e_{DTD}$ for basins of different shapes and inlet configurations (see Chapter 2 for a discussion of these efficiencies). For instance, Persson *et al*. (1999) investigated the effect of L:W using the two-dimensional, depth-integrated code of MIKE-21 (Warren and Bach, 1992). Jenkins and Greenway (2005) also investigated empty ponds using the two-dimensional, depth-integrated code of TDFLOW (Jenkins and Keller, 1990). Both numerical studies utilized point inlets and point outlets, and found a theoretical increase in $e_{DTD}$ (increase in *N*TIS) with increasing L:W, up to 10–30 TIS for L:W = 15. However, both studies neglect wind mixing, which may be the dominant driving force in open water systems.

Just as importantly, increasing aspect ratio will decrease the inefficiency of utilizing a point inlet or outlet, but there are other steps that may be taken to minimize poor inlet or outlet distribution of flows. A large aspect ratio tends to improve volumetric efficiency, quantified by the ratio of actual to theoretical detention time. In other words, it is not possible to get closer to the plug-flow model, but it is possible to utilize the entire wetland area. For empty ponds, a L:W of over 10 may be needed to minimize the effect of jet flow short-circuiting and corner dead zones (Figure 18.6).

FWS treatment wetland data show that "longer and narrower" does not necessarily mean less effect of mixing, and hence a closer approximation to plug flow. For example, the tracer studies at Richmond, Australia, showed *N*TIS = 4.6 for an open water unit of L:W = 25 and *N*TIS = 5.0 for a *Myriophyllum* FWS wetland of the same aspect (Bavor *et al*., 1988). A number of tracer tests of the wetland cells

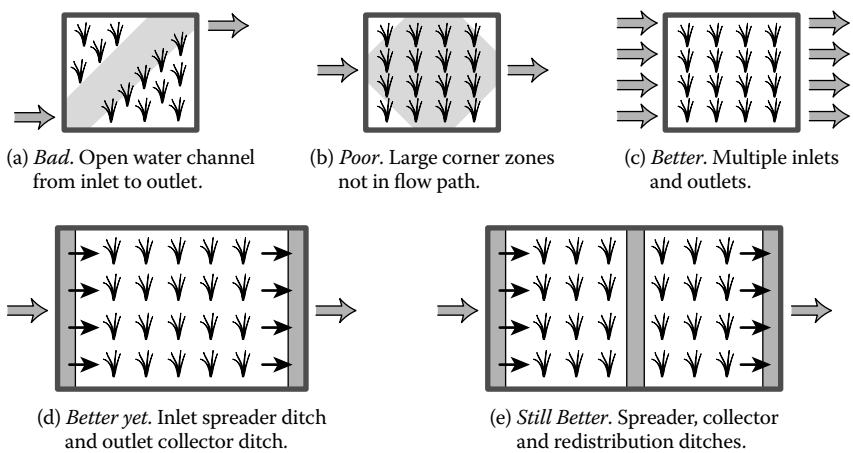

**FIGURE 18.5** Concepts of cell internals: inlet distribution, outlet collection, and internal redistribution. (From Kadlec and Knight (1996) *Treatment Wetlands*. First Edition, CRC Press, Boca Raton, Florida.)

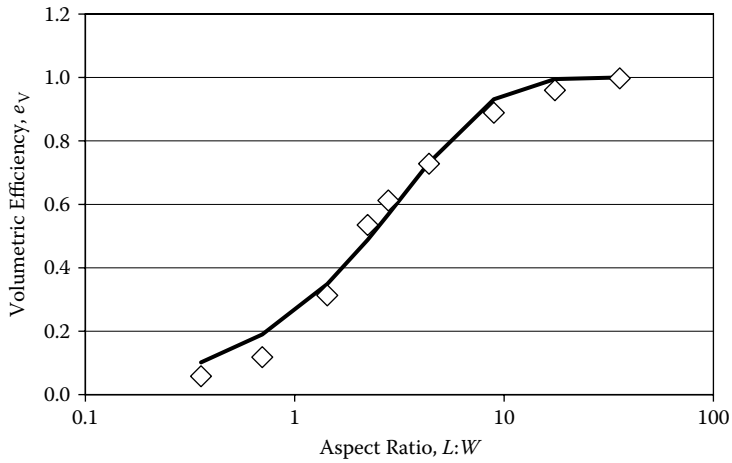

**FIGURE 18.6** The effect of aspect ratio on the volumetric efficiency of unvegetated ponds with point inlets and point outlets. (Simulation data from Jenkins and Greenway (2005) *Ecological Engineering* 25(1): 61–72.)

7B and 9B, both with L:W = 12.5, at the Sacramento, California, project found *N*TIS = 4.7 ± 0.8 and 5.0 ± 1.4, respectively (Nolte and Associates, 1998b). On the other hand, the data from the Champion, Florida, project show *N*TIS = 11 for a FWS wetland with L:W = 10 (Knight *et al*., 1994). Likewise, the South Florida Water Management District (SFWMD) periphyton treatment wetland project found *N*TIS = 9 for L:W = 5 and *N*TIS = 25 for L:W = 45 (CH2M Hill, 2003a). The effect of aspect ratio in these studies is confused by issues of wind, vegetation patterns, and deep zones. Thus, it is dangerous to assume that aspect ratio alone can provide the desired improvements in efficiency.

The literature contains a few "recommendations" for L:W ratios to be used in design. For instance, Crites *et al*. (2006) recommend 2:1 < L:W < 4:1. U.S. EPA (2000a) comments that, in general, FWS wetlands are built with L:W > 1:1. These appear to be reasonable suggestions that go with the recognition that lower *system* aspect ratios may be used provided cells in parallel are used. However, there is not much quantifiable treatment performance motivation to prefer one aspect ratio over another, as long as the design stays in a reasonable range, such as 2 < L:W < 10. However, there are sometimes limitations on aspect ratio due to the hydraulic profile (see Chapter 2 and subsequent sections of this chapter).

If one looks beyond the volumetric improvements, data from FWS wetland studies indicate somewhat better performance for higher length-to-width ratios (Herskowitz, 1986; Knight *et al*., 1994; CH2M Hill, 2003a), but the margin is not large when the pollutant reductions are low-to-moderate (0–50%).

Higher aspect ratios increase the area of external berms that must be constructed to enclose a given wetland area. Therefore, economics may argue for low L:W ratios (Knight, 1987). Other methods for maintaining effective flow distribution, such as deep zones, should be considered as alternatives to reduce the need for higher length-to-width ratios.

## Sinuousity

One of those alternatives is to use smaller internal divider berms to create a sinuous flow path of high-aspect ratio (Figure 18.7). An extreme example of this design is the Tucush, Peru, wetland with 14 cross-passes in each of two flow paths (see Figure 16.1). The interior berms create longer flow paths at the expense of cost and area. Not only do the berms subtract from the wetted area but the frequent flow reversals invite dead zones in the corners of the switchbacks. These corner zones may be minimized by orienting the flow in the long dimension of the cell.

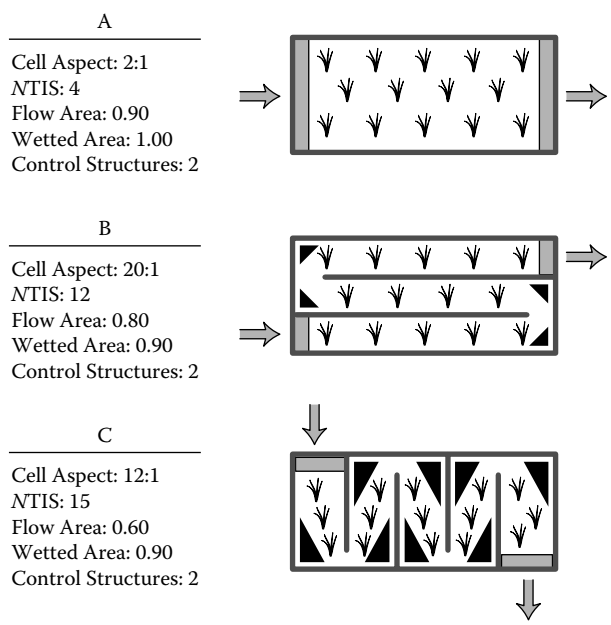

**FIGURE 18.7** Options for interior berms creating sinuosity. *N*TIS are rough estimates. Areas are examples only; actual numbers are size-dependent.

Computational fluid mechanics, in conjunction with first-order reaction rate kinetics, was used by Abbas *et al*. (2006) to simulate the effect of baffles creating sinuosity in ponds of different aspect ratios. These calculations were vertically averaged, and thus might be considered representative of unvegetated wetlands as well. Higher length-to-width was effective in promoting biochemical oxygen demand (BOD) reduction, but more internal baffles were yet more effective. Ratios 1:1 < L:W < 100:1 were investigated for point inlets and outlets. The swing in BOD reductions was from 10 to 95%.

Field testing of pathogen reduction was done in a side-by-side test at Lidsey, United Kingdom, utilizing baffled and unbaffled ponds, 1 m deep, with point inlets and outlets (Bracho *et al*., 2006). The unbaffled pond had L:W = 9:1; the adjacent pond of the same shape and size had three longitudinal baffles, creating L:W = 79:1. Tracer testing indicated $N$TIS = 2.1 and $e_V = 0.33$ for the unbaffled pond, and $N$TIS = 7.3 and $e_V = 0.38$ for the baffled pond. The low efficiencies were attributed to "jet flow short-circuiting." The reduction of fecal coliforms was 82.1% in the unbaffled pond and 99.4% in the baffled pond.

Interestingly, the use of divider berms to create back-and-forth sinuous flow paths has been found to provide low-volumetric efficiency while showing moderate-to-high $N$TIS values in some systems. Tracer tests at the sinuous Hillsdale, Michigan, site showed $N$TIS = 4.3 and 7.4, and $e_V = 0.33$ and 0.51, and for the east cell of L:W ≈ 16 (four cross-passes in a 1:1 footprint); and $N$TIS = 37, and $e_V = 0.34$, and for the west cell of L:W ≈ 18 (five cross-passes in a 1.6:1 footprint). The reason was found to be the fact that the flow path became channelized (deeper) in the center portion of the sinuous path, leaving excluded sides and corners.

A side-by-side comparison of sinuous and nonsinuous cells for phosphorus removal was conducted by the SFWMD (Figure 18.8) (CH2M Hill, 2003a). The hydraulics of the sinuous cell were superior with $N$TIS = 25 versus $N$TIS = 9 for the nonsinuous cell. However, the volumetric efficiency was only 58% versus 88% for the nonsinuous cell. The phosphorus performance of the sinuous cell was superior to that of the nonsinuous cell with higher $k$-values.

Divider berms are very prone to cross-berm leakage, which may create bad short-circuits. This was the case at the SFWMD project. Also, the divider berms occupy some measurable fraction of the total footprint, which detracts from overall areal effectiveness. Results to date indicate that internal sinuosity may have little net effect.

## Flow Distribution

Both field results and computational studies have shown that point inlets and point outlets are not a good idea. Pond studies are not a good model in this regard, because inlets to ponds are very frequently point inlets. The corner zones of the pond are often not easily accessed by the incoming water. However, the presence of vegetation in FWS wetlands can lead to even more difficulties for water to reach corner zones. Computational fluid mechanics suggests that if the water is distributed uniformly from side-to-side of the wetland inlet, rather than at a point, there will be a significant improvement of the hydraulics (Persson *et al*., 1999). The changed distribution is forecast to increase $N$TIS from 1.5 to 6.7, and $e_V$ from 79 to 89% for a basin of L:W = 2:1. Wörman and Kronnäs (2005) computed that as the width of the water inlet increases relative to the wetland width, both $e_V$ and $N$TIS should increase.

Stairs (1993) experimentally determined the effect of inlet cross-spreading by performing tracer tests both before and after the removal of a perforated pipe spreader. With the spreader, $N$TIS = 4.47 and $e_V = 83.6\%$. Without the spreader, for a point inlet, $N$TIS = 3.27 and $e_V = 66.5\%$. Thus, the theoretical results of simulations have been verified in the field.

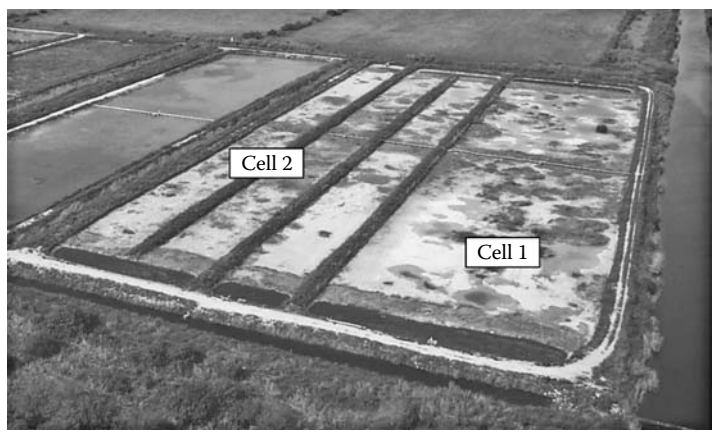

**FIGURE 18.8** Cells 1 and 2 of the South Florida Water Management District periphyton treatment wetland project. Cell 1 had an aspect ratio of 5:1, whereas Cell 2 had L:W = 45:1, because of a three-pass sinuous design. Both were two hectares in size and are shown empty in this photo. Cell 1 tracer tested at $N$TIS = 9, whereas Cell 2 tested at $N$TIS = 25. (Photo courtesy CH2M Hill.)

The collection of the water at the wetland outlet poses the same problems of corner dead zones. Therefore, collection across the wetland width is advantageous.

### *Bathymetry: Deep Zones and Speed Bumps*

Wetlands have a tendency to channelize from points of inlet to points of outlet. If permitted, this operational feature reduces the gross areal efficiency of the wetland (see Figure 4.21, for instance). Control of the bottom elevation and vegetation density can, in principle, prevent poor flow distribution. But in practice, the bottom of the wetland can neither be constructed nor maintained at tolerances that promote full areal contacting. Bottoms do not start completely level, and a number of processes contribute to the formation of local highs and lows such as soil heaving and sediment deposition. Nevertheless, care must be taken to degrade any preexisting ditches, roads, or berms on the site because these will exert possibly undesirable flow control in the FWS wetland. Dierberg *et al*. (2005) demonstrated the poorer treatment that occurs along such channelized short circuits.

Compartmentalization involves emergent berms with transfer structures, but such cross-berms may also be constructed so as to be always or occasionally under water. For example, the treatment wetland at Bulwer Island, Australia, was constructed with a repeated pattern of $0.4 \rightarrow 0.2 \rightarrow 1.0$ m depths along the flow path (Simi and Mitchell, 1999). The intent of this design was to break up longitudinal channeling and to promote different microenvironments. Underwater cross berms have also been placed in some of the stormwater treatment areas in South Florida. It is not known if these have positive effects on treatment. The use of cross-benches was forecasted to promote good hydraulics, *N*TIS = 23 and $e_V$ = 0.80, by Persson *et al*. (1999).

Deep zones in surface flow constructed wetlands are supposed to serve several purposes (Knight and Iverson, 1990). These deeper areas extend below the bottom of the vegetated basin areas by at least 1 m to exclude the development of rooted macrophytes (Figures 18.9 and 18.10). Such unvegetated cross ditches provide a low-resistance path for water to move laterally and provide a nearly constant head across the wetland. They also provide for extra detention time, but in a deep water zone. Such ditches often become covered with duckweed (*Lemna* spp.) and can be used by wetland birds and fish as reliable habitat. These redistribution ditches change the potential for short-circuiting within the wetland, because high-speed rivulets are intercepted and mixed with quiescent water in the deep zone. However, the redistribution ditch adds a potential for wind mixing that compensates the reduced short circuiting. But water is more effectively distributed over the wetland, improving the gross areal efficiency to some extent. Lightbody *et al*. (2007) provided evidence from laboratory models and computations that indicated improvement due to deep zones at high degrees of removal. However, that improvement was contingent on the assumption that serious short-circuiting occurred in the vegetated sections of the system.

Knight *et al*. (1994) operated a set of six treatment wetlands receiving treated paper-pulp mill effluent for two years. Two pairs of these received the same influent water, one of each pair containing two internal deep zones comprising 25% and 45% of the area (Table 18.1). There was variability in flow (different HLRs) and aspect ratios (2.5 and 10) between the pairs. Tracer data from that project were here reanalyzed and characterized by a tanks-in-series (TIS) detention time distribution. The effect of deep zones was to decrease the number of TIS (Table 18.1). And, for the larger cell pair (A and B), the volumetric efficiency was improved by deep-zone addition. The load reductions for all contaminants were increased by the inclusion of deep zones but by only a very small margin for the higher aspect ratio pair (E and F). One

interpretation of these results is that the net effect of better efficiency and worse *N*TIS results from interception of short circuits in the wide cell but that these are less important for the high-aspect cells. Thus, wide cells profit from deep zones but narrow cells do not. Another important feature of these results was the fact that the added volume provided by deep zones resulted in smaller volumetric rate constants, an observation in agreement with similar results detailed in Part I.

The artifact of L:W was not present in a study of 12 research wetlands operated under varying conditions at a site west of the city of Phoenix, Arizona (Kadlec, 2006a). These were constructed as a triplicated design with zero, one, two, and three internal deep zones, all containing an inlet distribution and an outlet collection deep zone, together comprising 12.5–35% of the wetland areas. There were no differences in the internal hydraulics with deep-zone numbers. Deep-zone numbers in the wetlands did not affect nitrogen treatment performance. No differences with deep-zone numbers were found for temperature, dissolved oxygen, pH, or nitrogen removals or rate constants. In this study, there was no large treatment benefit or detriment of incorporating internal deep zones in free water surface wetlands.

Moore and Niswander (1997) operated a set of six treatment wetlands receiving diluted dairy wastewater for two years. Two wetlands had a central internal deep zone comprising 45% of the area, whereas the other four had no internal deep zone. The authors concluded that deep-center sections did not show any significant impact on treatment efficiency. Data for the second year, past the startup period, are shown in Table 18.2, as reported in NADB v.2 (NADB database, 1998). None of the outlet concentrations are different at the 5% level. The wetland areas were all identical and, hence, the hydraulic loading to all six wetlands was uniform at 3.95 cm/d. For a presumed 4 TIS hydraulic pattern, the areal *k*-values do not differ at the 5% level. For instance, for total Kjeldahl nitrogen (TKN), $k = 10.1 \pm 1.1$ m/yr compared to

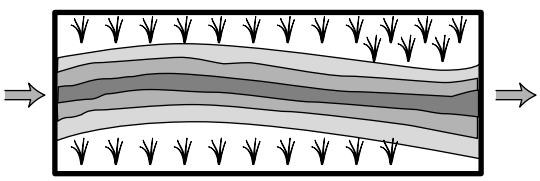
$k$ = 11.0 ± 1.1 m/yr for the two cells with deep zones. However, the inclusion of the deep zone added to the water volume, and increased the average depth from 30 to 75 cm, and consequently increasing the nominal detention time from 7.6 to 19 days. As a consequence, the $k_V$ values for TKN were different at the 5% level, 0.093 ± 0.01 $d^{-1}$ for no deep zones versus 0.040 ± 0.004 $d^{-1}$ for deep zones. As for the Champion study, these Oregon State University results suggest that the extra depth added by deep zones carries a penalty in volumetric performance.

Importantly, all three studies demonstrate a penalty for deep zones in terms of lower *volumetric* rate constants for systems with deep zones. The presumption of constant $k_V$, which is reiterated in much of the treatment wetland literature (Crites and Tchobanoglous, 1998; U.S. EPA, 1999; U.S. EPA, 2000a; Water Environment Federation, 2001), is, therefore, inappropriate for design of FWS wetlands with deep zones. This further substantiates the growing body of knowledge that wetland areal models are to be preferred over volumetric models for FWS wetlands, in general. For deep zones, the added water volume and its attendant-added detention time do not contribute proportionately to pollutant removal.

Taken together, these studies do not demonstrate a clear advantage or a clear disadvantage for deep zones. Other wetland attributes, such as aspect ratio, vegetation community type, and compartmentalization, may be equally or more important for water quality improvement. Nevertheless, deep zones may be important for habitat value, may provide for increased reaeration, and may provide opportunity for pathogen reduction via UV radiation. The amount of open water that may be included in a cell remains a controversial issue. Based upon anecdotal evidence, U.S. EPA (2000a) contends that the central part of a flow path must be open water/SAV to provide oxygenation for ammonia reduction. However, Kadlec (2005e) found no particular support for that view in an examination of data from many systems, including ponds as the open water extreme. Open water sections in a cell provide better habitat value than does a uniform dense stand of emergent plants (Weller, 1978). However, habitat values must be balanced by the potential for wildlife to interfere with treatment. Excessive waterfowl use can add pathogens to the water. Muskrats, nutria, and beavers want the deep water for refuge and can seriously impair the vegetation, hydraulics, and possibly treatment (Kadlec *et al*., 2007).

An important function of an inlet deep zone is the settling of particulate matter that might otherwise create difficulties in the inlets of vegetated sections. This has been discussed in Chapter 7 but deserves consideration here as part of the process of developing a layout for the treatment wetland. It is useful to remove large sediment loads before they reach the vegetation, so that the eventual cleanout is from a pond rather than from vegetation. The Imperial, California, system employs a 3.9-ha, two-cell sedimentation basin before wetlands (Figure 18.11). Over a four-year operating period, the basins trapped 3,820 tons of sediments, amounting to approximately 10 cm of accretion. Those solids would have been detrimental to the inlet zone of the 4.7-ha follow-on wetlands. Table 7.8 indicates that it is easily possible to settle river-borne solids in just a few days detention in a presettling basin with removals of over 90%. The sizing of this inlet element of the treatment train is dependent upon the settling characteristics of the specific solids in question, as well as the accumulation rate of the solids. An inlet deep zone built for flow distribution may fill up quickly and require emptying at frequent intervals (see Figure 7.13). A simple mass balance suffices for the sizing of sedimentation basin storage for the desired loading and emptying frequency, whereas a settling calculation determines the area needed for a given basin-operating depth.

### *Fringing, Banded, and Clumped Vegetation*



Many natural wetlands are riverine, meaning that the wetland contains a central stream channel, which may meander through a zone of emergent vegetation. Indeed, this wetland form is so common that it is mistakenly presumed to be a good prototype for a treatment wetland. Nothing could be further from the truth. A central channel will convey most of the water, and the fringing vegetation will effectively receive flow only on rising flood conditions and discharge it on the ebbing stage. Therefore, configurations similar to Figure 18.12A are usually to be avoided. Simply stated, if the water needs to go through the plants, do not plant them off to the side of the flow path. Jenkins and Greenway (2005)

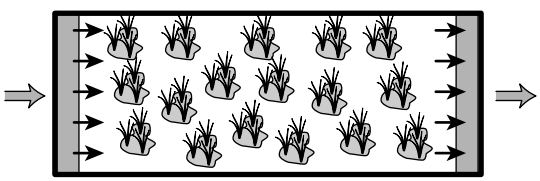


**FIGURE 18.11** Aerial view of the Imperial, California, treatment wetland. Two sedimentation basins, in parallel, precede the four wetland cells. The first cell is built sinuous with fringing vegetation. The second is built with cross-banded vegetation. The final two cells are out of the view to the upper right.

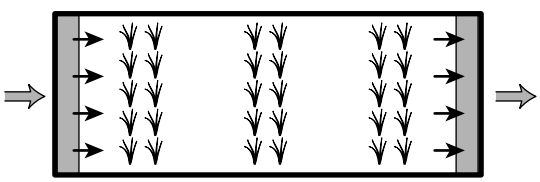
provide numerical calculation results for several aspect ratios and cover percentages, which show that hydraulic efficiencies are low for fringing vegetation.



The Jenkins and Greenway (2005) computational research also demonstrated that cross-banded vegetation is a better option for hydraulic efficiency than fringing vegetation. Therefore, any open water that may be included in the cell should be oriented across the flow direction, whether or not it is deeper than the average. However, as will be discussed in the following text, adequate conveyance may be difficult to maintain if large aspect ratios are combined with significant banded or uniform vegetation.

(a) *Bad*. Bench and channel design provides fringing vegetation, dead zones and a short circuit due to topography.

(b) *Better*. Inlet distribution, outlet collection, and hummocks.

(c) *Still Better*. Inlet distribution, outlet collection, and banded vegetation.

**FIGURE 18.12** Concepts of cell internal vegetation patterns. Fringing, patterned, and banded vegetation may be used.

These concepts were utilized in the Brawley, California, treatment wetland (Figure 18.13). The first cell was built with a sinuous path and fringing vegetation; the second cell was built with banded vegetation. Only overall system data were taken, thus no information on relative efficiencies is available.

A third concept for the vegetation pattern is the use of small islands or hummocks, either emergent or submerged (Thullen *et al*., 2005). At the present time, there is no information on the hydraulic efficiency of this alternative or any pollutant removal comparison.

## Fitting the Wetlands to the Site

Given the total required wetland area and the concepts of system configuration, there still remains the placement of the wetland on the site. The principal considerations are adaptation to the boundaries and contours of the site, minimization of intercell conveyance, and minimization of earthmoving.

Site boundaries often determine the external shape of the overall system, because there is often no extra land or the ability to choose the shape of the available land. In that event, the various pieces of the overall system must conform to the space available. The topology of the conceptual layout is retained, but shapes and perhaps areas are sacrificed. A good example is the initial layout of the Columbia, Missouri, treatment wetlands (Brunner *et al*., 1992; Brunner and Kadlec, 1993). The conceptual configuration was selected to be three banks of cells in parallel. The available lands were bounded by streams, roads, towns, railroads, and the floodway of the Missouri River. As a consequence, the actual

**FIGURE 18.13** Aerial view of the Brawley, California, treatment wetland. The first cell of two in series is built in a hairpin, sinuous with fringing vegetation. The second is also a hairpin but with cross-banded vegetation.

layout was not completely rectangular nor were the cells all in close proximity (Figure 18.14). Despite the long-transfer distances, this complex of cells is gravity driven. A transfer pump is provided at the system outlet, to supply the treated water to the Eagle Bluffs wildlife wetlands, where it is used to foster habitat. A fourth bank of wetland cells was added to the system in 2003.

## 18.2 HYDRAULICS

Linear velocity can become a consideration in design for very large wetlands. For instance, total suspended solids (TSS) removal depends on sedimentation and trapping within the wetland. Excessive linear velocities lead to large values of shear stress on deposited solids, and therefore can lead to

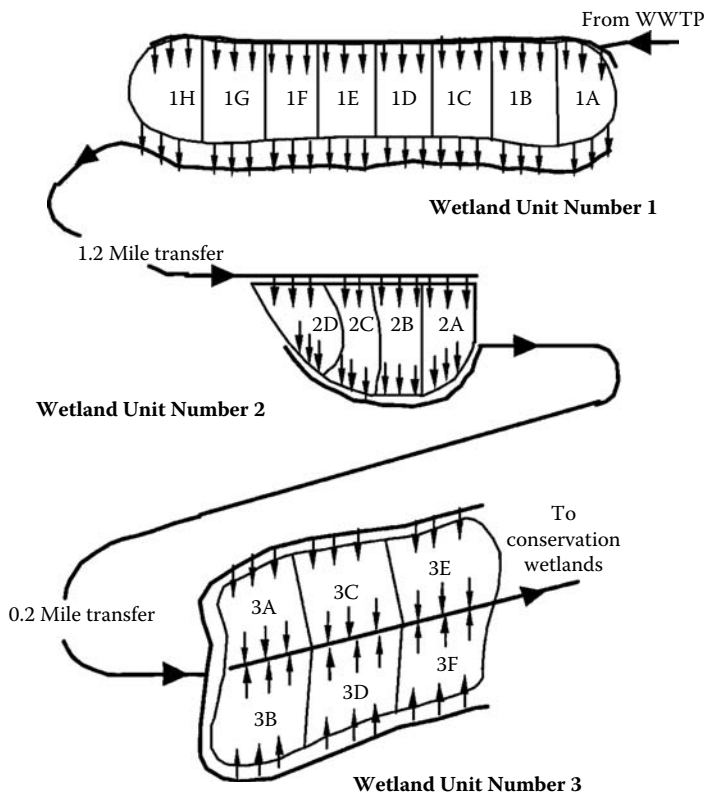


**FIGURE 18.14** Arrangement of cells within the initial configuration of the Columbia, Missouri, wetland treatment units. All cells receive water via submerged, gated distribution pipes along the inlet edge; each cell has three outlet structures. (From Kadlec and Knight (1996) *Treatment Wetlands.* First Edition, CRC Press, Boca Raton, Florida.)

the potential for resuspension of those solids. The critical shear stress for resuspension has not been determined for any treatment wetland, as discussed in Chapter 7. As conservative interim design criteria, it is recommended that linear velocity be kept below a value which would resuspend fine particles. The minimum velocity for resuspension has been suggested to be about 20 cm/s (U.S. Army Corps of Engineers, 2000) (Figure 18.15). However, it is well to bear in mind that existing FWS wetlands operate at velocities lower than this, mostly below 100 m/d, and, hence, there is no field test of the criterion. The large Florida phosphorus control wetlands have all been subjected to a maximum velocity criterion of 3.0 cm/s (2,600 m/d).

Theory indicates that higher water linear velocities may favor improved pollutant removal because of improved mass transfer (Kadlec and Walker, 2004). In stagnant water, pollutant transport to removal sites is by molecular diffusion, whereas in turbulent flow, eddies carry materials to solid surfaces.

As the length-to-width ratio is increased, both the linear velocity and the head loss increase. At some point, the head loss will produce an inlet water depth that is unacceptably large, as detailed in Chapter 2. A hydraulic analysis would usually be used to check whether an aspect ratio, set from site considerations and constraints, produces an acceptable hydraulic profile.

## Hydraulic Profiles

The primary purpose of calculating the expected hydraulic profile is to determine if the proposed wetland can pass the design flow without an excessive "pile-up" of water at the inlet. The water depths for any particular cell configuration and flow may be calculated using known procedures of varying complexity. Complicated, two-dimensional calculations may be required for complex wetland geometries. Examples of readily obtainable computer codes include the suite of Hydraulic Engineering Center (HEC) models (Feldman, 1981). However, simpler one-dimensional spreadsheet calculations often suffice to determine the approximate shape of the water surface profile through a FWS wetland cell along the flow direction. The water balance and friction equations combine to give the equation for depth (see Chapter 2; also Kadlec, 2003b):

$$aWh^b\left(-\frac{d(h+B)}{dx}\right)^c = Q \tag{2.23}$$

$$H_{\text{at } x=L} = \mathrm{H}_L \tag{2.24}$$

where

$a, b, c$ = constants
$B$ = elevation of the bed bottom above datum, m
$h$ = water depth, m
$H$ = water depth, m
$L$ = wetland length, m
$Q$ = volumetric flow rate, $m^3/d$
$x$ = distance from wetland inlet, m
$W$ = wetland width, m

Here it is assumed that the bottom is uniform across the flow direction, but possibly sloped, and a power law describes vegetative resistance to flow. The coefficients $a$, $b$, and $c$ are selected to be representative of the type and density of the vegetation (see Chapter 2). The usual specification for the outlet depth is determined as a weir setting plus the height over that weir, but other devices may also result in an outlet depth specification. Because the depth is known (set) at the outlet, the integration of Equation 2.24 proceeds from the outlet upstream to the inlet, thus resulting in the designation as a backwater calculation.

The wetland-sizing procedure will have determined a hydraulic loading for the design, $q = Q/LW$, where $Q$ is the design flow. The wetland width is set from the selected aspect

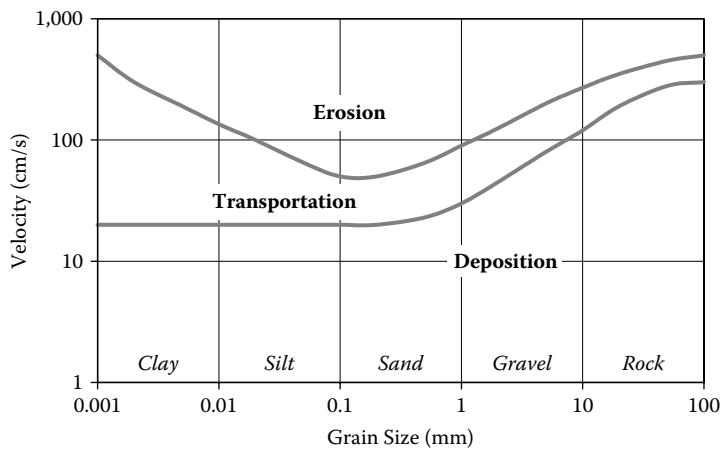

**FIGURE 18.15** Relationship between grain size, velocity, and sediment movement. At low velocities, deposition is dominant, whereas at higher velocities, resuspension and transport may occur. (From Hayes *et al*. (2000) *Wetlands Engineering Handbook*. ERDC/EL TP-WRP-RE21, U.S. Army Corps of Engineers: Washington, D.C.)

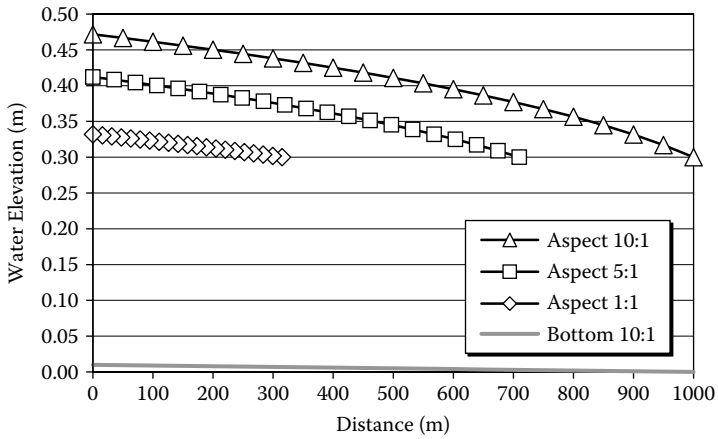

**FIGURE 18.16** Wetland hydraulic profiles for aspect ratios of L/W = 1:1, 5:1, and 10:1. The height over the weir is set at 0.3 m (left-hand side). Bottom has been set as nearly level. The design hydraulic loading is 10 cm/d. Note that water surface is not a level pool nor is it parallel to the bottom.

ratio and the design area. The backwater calculation then determines the hydraulic profile, $h(x)$.

As an illustration, consider a wetland designed for a hydraulic loading of 10 cm/d (10,000 $m^3$/d on 10 ha). Different aspect ratios may be chosen in recognition of site constraints and the desire for high-hydraulic efficiency provided by high-aspect ratio. For this illustration, three ratios are selected: 1:1 (316 m × 316 m), 5:1 (710 m × 142 m), and 10:1 (1,000 m × 100 m). The exit weir is set for a depth of 30 cm. For the three cases, the inlet depths for dense vegetation are 33, 41, and 46 cm, respectively (Figure 18.16). These are all probably acceptable hydraulic profiles.

A field example of an unacceptable head loss situation occurred for the Imperial, California, wetland (see Figure 18.11). This system is comprised of four cells with a combined aspect ratio of 30:1 (TTI and WMS, 2006). In 2003, the hydraulic-loading rate to the Imperial wetland was increased to determine the impact it would have on wetland performance. However, during this period, the water overtopped the inlet levees, and thus loading had to be reduced. However, the reduced hydraulic-loading rates used after the overtopping event were still well above the original design flow rate at which the wetland was operated throughout 2001 and most of 2002. The levees overtopped because physical constraints made it impossible for water to pass through the wetland at the rate it was being applied. This demonstrates that when considering different wetland designs, it is important to take into account the fact that the physical characteristics of the wetland may constrain the hydraulic-loading rate.

## 18.3 EARTHMOVING: DIKES, BERMS, AND LEVEES

### Berm Design

Berms are designed based on hydraulic and geotechnical considerations. The purpose of berms is to regulate and contain water within specific flow paths. Figures 18.17 and 18.18 show typical design features of constructed wetland berms for lined and unlined systems. Exterior wetland berms are kept as small as possible while still providing adequate containment and freeboard to prevent unauthorized flow releases. Interior berms may be used to augment flow distribution but do not have to be designed to control offsite water releases.

Exterior berm freeboard should be adequate to prevent overtopping during sudden storm events (based on a storm event frequency of 10, 25, or more years) and allow overflow of less frequent storm events through controlled and protected emergency overflow points. Berm freeboard should also consider that the wetland will gradually fill with vegetation and with mineral and organic sediments that increase flow resistance and decrease freeboard during system life. Berm height should equal the sum of the maximum desired normal water level (for example, 45 cm), the return storm rainfall amount (for example, 20 cm for a 25-year storm event), and the lifetime loss of freeboard due to sediment and plant accumulation (approximately 1 cm/yr in some wetlands receiving municipal wastewaters). For a 20-year life, this hypothetical wetland should have an emergency spillway height of at least 85 cm with an additional 20 cm or so of berm above that level. Any additional berm height provides additional system life and insures against unauthorized discharges. In the event that an open water system is contemplated, the freeboard should also be adequate to contain wind setup and wave action. The foregoing example provides 1 m of freeboard, which would be sufficient to control wind set and waves for an unobstructed fetch of about 1 km (U.S. Army Corps of Engineers, 2000).

Berms should be constructed on the basis of standard geotechnical considerations. The materials that are available dictate how berms will be designed and constructed. Surface liners or internal clay plugs may be required to minimize berm seepage if sandy or other permeable materials are used for berm construction. External seepage collection channels may be necessary if soils are unconsolidated. An exterior slurry

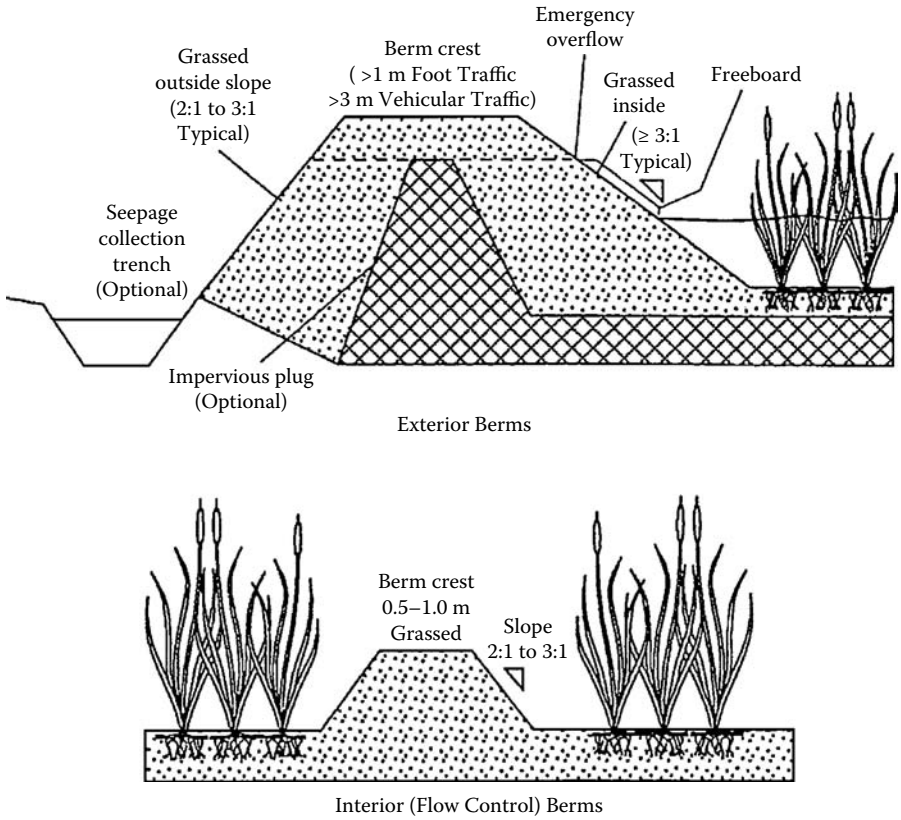

**FIGURE 18.17** Design considerations for constructed wetland berms. (From Kadlec and Knight (1996) *Treatment Wetlands*. First Edition, CRC Press, Boca Raton, Florida.)

wall tied into deeper, low-permeability sediments can be used to limit offsite infiltration.

Berm slope is dictated by geotechnical considerations and a slope-stability analysis. Minimum berm slopes typically used in constructed wetlands are 2:1 (horizontal:vertical), and slopes up to 10:1 or 20:1 are used when a shallow littoral shelf is desired to create habitat diversity. Berm width should be adequate for the intended use. For example, if the berm will be used for vehicular traffic, it should be more than 3 m in width.

Dikes are used for access by walking or driving. A vehicle access dike needs to be more than 3 m wide at the top; interior divider berms designed for pedestrian access may be as narrow as 1 m. Dikes greater than about 5 m in width are less likely to be fully penetrated by muskrats. The side slopes of these are typically at a three-to-one slope and may be rip-rapped with stone to prevent erosion or rodent burrowing (Figure 18.19). The interior of a containment dike usually is designed to contain a compacted core and a layer of sealant, which extends above water level. Water containment dikes are subject to local dam safety regulations.

## Basin Bottom Contouring: Cut and Fill

The constructed wetland complex of cells and dikes requires earthmoving. The cost for this activity consists of two distinct

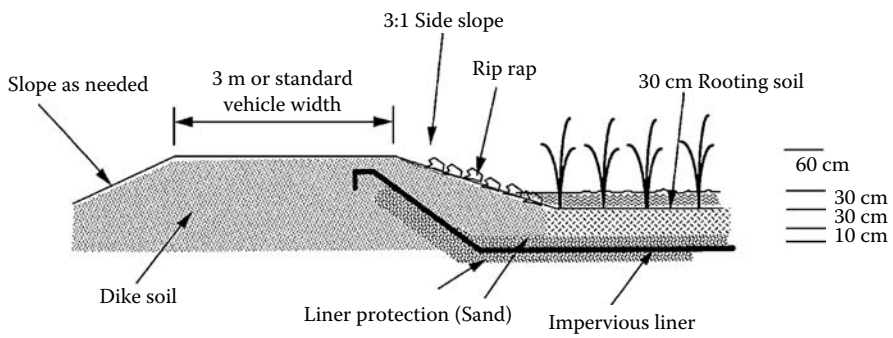

**FIGURE 18.18** Typical constructed wetland exterior berm with a liner.

**FIGURE 18.19** Wetland berm protection using stone riprap at the Lake Nebagamon, Wisconsin, treatment wetland. This divider berm is not drivable. Photo shows wetland just after planting.

components: the cost for moving soils within the site boundaries (cut and fill) and the costs for importing or exporting material from the site, from external borrow sources or to spoil disposal sites. Equal cut and fill is the preferred option because it avoids import/export costs. Selection of the bottom elevation of the cells, together with proper positioning on the site with respect to its topography, generally allows balancing of cut and fill.

Rough estimates of the internal volume of a wetland cell may be made based upon the intended geometry. For the common rectangular geometry, the excavated volume may be calculated from:

$$V_B = \frac{h_E}{6}\left[LW + (L - 2sh_E)(W - 2sh_E) + 4(L - sh_E)(W - sh_E)\right] \quad (18.1)$$

where

$h_E$ = excavated depth, m
$L$ = wetland length at grade, m
$s$ = side slope, m/m
$V_B$ = excavated volume, $m^3$
$W$ = wetland width at grade, m

The volume of earth needed for the levees for one cell, neglecting the corners, is

$$V_L \approx \left[2(L + W_T + 2sh_L) + 2(W + W_T + 2sh_L)\right](W_T h_L + sh_L^2) \quad (18.2)$$

where

$h_L$ = height of levee above grade, m
$V_L$ = levee volume, $m^3$
$W_T$ = levee top width, m

The overall depth of the created basin is

$$h = h_L + h_E \quad (18.3)$$

This overall depth of basin is required to meet the freeboard and water depth requirements of the design. As an example, suppose that the length and width at grade are 100 and 50 m, respectively, and the total depth is to be 1.5 m. The levee is set at a top width of 3 m and side slopes of 3:1. Equations 18.2 and 18.3 balance at a cut depth of 0.45 m with 1.05 m of levee above grade. For many projects, there is enough importance of earthmoving to warrant the use of one of the several available software packages that allow very accurate balancing of cut and fill over variable topography.

### Liners and Rooting Media

The bottom of the wetland, as well as the core of containment dikes, may be formed of compacted clays or bentonite. Locally available clays are preferred from the standpoint of cost reduction. Plastic liners may be feasible for smaller size wetlands. This clay layer or other sealant should not be penetrated by plant roots, so that it retains its integrity. The topsoil from the site should be stockpiled and replaced within the wetland to form a rooting medium. The roots and rhizomes of emergent macrophytes now in use—cattails, bulrushes, and *Phragmites*—usually occupy the top 30–40 cm of the soil column. Therefore, a layer of that thickness should be used. The original topsoil from the site may be useable; and if so, it should be stockpiled separately from the other soils during construction. This topsoil will contain seeds of the wetland plants of the region, which may assist in vegetating the wetland. If acceptable topsoil is not available at the site, it may need to be imported or soil amendments used to optimize plant survival and growth. Final grading to tolerances of about +3 cm is necessary to maintain sheet flow conditions in shallow marsh areas.

For some treatment wetland applications involving hazardous substances, double liners may be required. For example, landfill leachate wetlands may need to be double lined. Liner costs are the key factor in design decisions and are addressed in Chapter 23.

### Synthetic Liners

Wetland cells may need to be lined with clay or plastic if regulatory requirements prohibit mixing with groundwater or if natural infiltration rates will make it difficult to maintain surface water wetland conditions. The decision to install a liner in a wetland system and which type of liner to use depends on the project goals and regulatory requirements. Some wetlands are unlined, either because the *in situ* native soils are deemed to have sufficient sealing properties or because groundwater recharge is a function of the system. If the wetland must be lined, there are a variety of liner materials available. The two most common liner materials used are 30-mil (0.76 mm) polyvinyl chloride (PVC) and 40-mil (1.0 mm) high-density polyethylene (HDPE). PVC liners are generally factory-seamed, one-piece liners used on small projects less than 0.1 ha in size. HDPE liners generally come in rolls and are field seamed for larger projects.

Liner materials include: polyvinyl chloride (PVC), polyethylene (high-density HDPE, and linear low-density LLDPE), polypropylene (PPE), and compacted clay. Some liners can include a scrim, that is, a woven net of nylon or polypropylene embedded in the plastic material or encloses the clay (Interstate Technology and Regulatory Council, 2003). Scrims provide extra strength and resistance to tears in the material, and liners with scrims will cost more.

For a given thickness, PVC is generally the least expensive material and the easiest to work with in the field. PVC has the best puncture resistance of all the materials (except those with scrims). It has the most flexibility but also has the least resistance to ultraviolet degradation, and therefore must be covered to protect it from degradation. Because the wetland construction process generally covers the liner with soil or gravel, PVC is a good first choice. A minimum thickness is generally considered to be 0.76 mm (30 mil).

Polyethylene (PE) comes in two forms for liners: linear low-density polyethylene (LLDPE) and high-density PE (HDPE). HDPE is harder to work with in the field than LLDPE, especially in cool weather. The thickness should be 1.00 mm (40 mil) to be equivalent to 0.76 mm PVC for puncture resistance. UV resistance is good for both PE materials. Field repairs are easy. Seaming with tape should provide good waterproof characteristics and is easily performed in the field, at though welds are usually required to affect a more permanent seal at the seams. It is usually 10% more expensive than PVC. On large projects, this cost differential can be offset by the ease of field seaming. Polypropylene (PPE) has good installation properties because field seaming and repairs are easy. It has the best puncture resistance of all three plastics. A major disadvantage is that it is the most expensive of the three materials.

### Reinforced Plastics

Some plastics can include a scrim, that is, a woven net of nylon or PPE embedded in the plastic material. If the project can afford them, liners with scrims such as 1.5 mm (60 mil) Hypalon, 1.5 mm (60 mil) XR-5, or 1.1 mm (45 mil) PPE are the toughest, most resistant to puncture and tears, and UV radiation (U.S. EPA, 2000a; Interstate Technology and Regulatory Council, 2003). Vehicles such as front-end loaders and trucks can drive on them. This presents certain advantages in placing the gravel media (subsurface flow wetlands) or soil (surface flow wetlands). The contractor's savings in placing the gravel media or soil may offset the difference in cost of liner materials. Hypalon is a chloro-sulfonated PE with a nylon scrim. It has excellent UV properties and puncture resistance. It is expensive, and repair is difficult after ageing. Hypalon may be less palatable to nutria, muskrats, and beavers than other synthetic liners based on anecdotal evidence.

XR-5 is a PVC material with a scrim, which has very high strength and excellent puncture resistance, and is easy to repair. XR-5 is the most expensive of all synthetic liners and requires specialized equipment for installation. Reinforced 1.1 mm (45 mil) PPE has all of the advantages of PPE but with higher strength and puncture resistance.

### Clay Liners

Natural materials, such as clays or bentonite, may also be used as liners. Some are composed of a layer of clay between two scrims of finely woven PPE or PE. These have a distinct advantage for irregular-shaped cells because of difficulties of installation of plastic materials in nonrectangular geometries. Bentonite may be considered, but costs depend on the *in situ* soil and the distance from the bentonite supply, which in North America is in the western United States (Wyoming). However, source location is also a key issue for native clays because a nearby source may not be available. In most cases, clay with permeability less than $10^{-6}$–$10^{-7}$ cm/s would be required. The installed thickness would usually be on the order of 30 cm with compaction. These factors combine to make the use of clay a costly alternative, requiring economic comparison with synthetic materials.

## Erosion and Flood Protection

A treatment wetland site may be unavoidably in the floodplain of a river. The question of protection of the wetland from flooding then arises. There are two aspects to potential flooding: maintaining the physical integrity of the system and the effect on treatment during flood events.

Physical damage to dikes and structures is not likely to be serious if the system is not placed in the floodway of the river. The main flood currents should not impinge upon the wetlands. Several treatment wetlands have easily survived gentle inundation without any significant damage, for example, Des Plaines, Illinois; Jackson Bottoms, Oregon; Tarrant County, Texas; and Columbia, Missouri. Care must be taken to allow uniform flooding to prevent uplift of a sealed bottom by hydrostatic forces. In some cases, it may be necessary to install underdrains beneath a wetland liner to relieve hydrostatic pressure in the event of rising regional groundwater. Outlet structures should be designed to allow backflooding (not through-flooding) of wetland cells.

**FIGURE 18.20** Wetland dike erosion occurring due to wave action at Stormwater Treatment Area 1W in Florida. Winds at the site have a long fetch across this large wetland cell. Hurricane-force winds caused this damage.

Damage to the wetland vegetation is not likely for inundation up to a week or two. However, prolonged submergence, such as the midwestern U.S. floods of 1993, which lasted for many weeks, will drown the wetland plants.

The treatment efficiency of the wetland will obviously be reduced under flood conditions. Generally, the dilution effect of the flood flow is so great that reduced efficiency can easily be tolerated for the brief duration of the flood. And, some of the floodwater will receive beneficial detention in the wetland after the flood recedes.

The sides of the dikes must be protected from runoff and wave action, and the attendant erosion during a period of wetland vegetation establishment. Emergent vegetation will prevent the wind fetch necessary to cause wave erosion, but those plants are absent during start-up and in wetlands with intentional patches of open water that abut the dike. Rainfall runoff can erode newly constructed dikes as well. In such circumstances, it is important to stabilize the bank with an appropriate cover crop (Figure 18.20).

## 18.4 WATER CONTROL STRUCTURES

Structures are needed to bring water into the wetland, maintain a desired water level, and to collect the discharge from the wetland. A very large number of options are available, and the choice will depend upon the magnitude of the flow to be managed. Wastewater may be conveyed to a wetland treatment system site by use of a pressurized forcemain, by a gravity pipeline, or by an open channel. Construction of pump stations, pipelines, and open channels are not described in this chapter, and the reader should consult general references on hydraulic design and construction for more information. Once the wastewater is brought to the wetland site, it is typically distributed into the wetland via some distribution system consisting of pipes, channels, or coarse rock beds. Inlet control devices may be used to split the flow between parallel FWS treatment trains. Adjustable weirs are preferred for splitter structures, as this allows the flow split to be adjusted between the treatment trains. Proportional flow splits can be achieved by using weirs of different widths.

### Controlling Inflow

Water flows entering the wetland complex may require flow balancing among flow paths, or complete shutoff of a cell or flow path for maintenance. The wetland inflow may be subjected to flow measurement and water quality monitoring. Therefore, inflow structures may be needed. The complexity of inlet structures depends upon their intended use. A simple upturned pipe may suffice for small flows (Figure 18.21), or complex remote-controlled gates might be needed for large flows (Figure 18.22).

### Spreading the Water

The inlet device initiates the flow of wastewater into the constructed wetland. Because water quality treatment is the primary objective, the inlet device initiates a sheet flow of wastewater in the wetland by broadly and evenly distributing the influent. Multiple inlet devices may be used to distribute flows to large wetlands. The inlet device must be able to shut off during maintenance or resting of the constructed wetland. In some cases, the device is used to monitor flow and water quality. Given the strong impetus to spread the entering water across the wetland width, there remains the subject of how to accomplish that objective. The alternatives include:

- Point inlet
- Sprinklers and dribblers (Figure 18.23)
- Spreader canal
- Gated pipe (Figure 18.24)

**FIGURE 18.21** Inlet structures include point discharges, perhaps with pre-aeration at the Olentangy Wetlands in Ohio.

- Multiple tees
- Perforated pipe
- Large rock zone
- Spreader swale
- Castellated weir

Figure 18.25 shows several approaches that have been used to distribute inflows and create sheet flow conditions in constructed wetlands. These often involve gated distribution pipes or spreader canals, but multiple inlet points have also been successfully used. A single inlet point is usually not an appropriate design based on hydraulic efficiency considerations. However, in very small systems, point inlets may be acceptable. For instance, they may be configured to provide aeration of the incoming water (Figure 16.21 and Figure 18.21). Selection of one of these alternative inlet configurations is based on wastewater characteristics, cost, and engineer preference. In cold climates, inlet water distribution and its associated plumbing must be kept below the ice layer.

The key to successful water spreading is to provide both side-to-side introduction and head equalization from side to side. The latter is accomplished by the use of an inlet spreader canal or deep zone. This provides a low resistance flow path across the flow direction, and thus equalizes the water stage across the inlet. This spreader canal may be filled with coarse rock if desired for animal control. Only if the cross width is very great will it be necessary to consider the side-to-side head loss.

Inflow can be distributed by gravity flow or by pressurized flow. Gravity flow is desirable because it conserves energy and reduces operation and maintenance costs. Gravity flow distribution systems may require larger pipe sizes to reduce head loss to acceptable levels. Pressurized inflows may result in high orifice velocities that can cause sediment erosion or physical damage to emergent wetland plants. By providing a greater number of individual outlets and greater cross-sectional area, erosion is less likely to result.

Gated distribution pipes have been used at a number of constructed surface flow wetland treatment systems. The header pipe material is selected on the basis of required system life and cost. Inlet pipes have been made from a variety of materials, including irrigation gauge aluminum pipe, PVC water pipe, and ductile iron. Because the header pipe is exposed to temperature extremes and UV radiation, PVC will have a limited life expectancy and may break. Aluminum pipe may dent. Ductile iron is strong and has a long life, but it corrodes and generally costs more. The pipe must be sized to control head loss so that flow is distributed evenly over the distribution pipelines. A clean-out should be provided at the end of distribution pipes so that accumulated solids can be removed periodically. Pressure relief valves should be installed in pipes where air blocks might occur.

**FIGURE 18.22** Wetland inlet structure at Stormwater Treatment Area 1 East in Florida. This automated structure, remotely controlled by telemetry, is one of 13 that bring water into the 2,080-ha constructed wetland. Its capacity is 730,000 $m^3/d$.

**FIGURE 18.23** Sprinkler and rock bed system used to distribute the inlet flows to the FWS wetland at Mandeville, Louisiana.

Gated distribution pipes use a variety of outlet configurations, depending on specific goals. Simple, plastic, sliding outlet gates may be used on aluminum irrigation pipe to regulate flow volume (from off to wide open). PVC fittings or simple orifices are commonly used in PVC distribution systems. If flow distribution is a concern because of the length of the distribution pipe (potentially a problem when the distribution pipe is more than about 20 m long), swivel outlet pipes can be used to more precisely control the elevation of individual outlets. Swivel outlets also can be used with ductile iron pipe, although they may be more difficult to regulate after they begin to corrode. Perforated pipes can be used successfully on short, gravity-fed, distribution pipes. Orifices should be at least 5 cm in diameter to minimize plugging by wastewater solids and to reduce the need for frequent maintenance.

Level spreader swales and castellated weirs also provide, in theory, a gravity-fed distribution system. Outlets are hard structures that are precisely leveled during construction. These are difficult to install, because a very high degree of vertical control on positioning is required. Because these typically provide no adjustment, they are not recommended for treatment wetlands.

Inlet selection is partly based on the need for fail-safe operation under the prevailing climatic conditions. The need for uniform transverse distribution was discussed in the preceding text. Problems to be avoided include freeze-up in

**FIGURE 18.24** The inlet to the New Hanover County treatment wetland near Wilmington, North Carolina. This warm climate system utilizes gated pipe distribution onto a concrete mat slope into an inlet deep zone. The liner underneath may be seen exposed in the background, as the divider between the two flow paths.

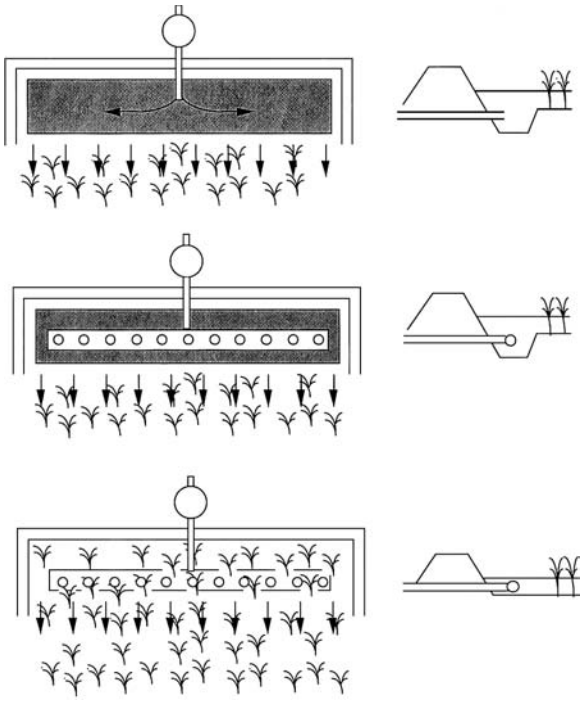

**FIGURE 18.25** Inlet distribution options include point discharges, spreader deep zones, and gated or perforated pipes, or combinations.

northern climates and clogging by debris or animals. Freezing can be prevented by use of buried feeder mains followed by point discharge structures or submerged distribution headers. Allowance must be made for ice formation on the surface of the wetland waters. Incoming waters that originate in lagoons can often contain leaves, sticks, and other debris. These can block small orifices in a distribution system. The collection well in the lagoon system is frequently a favorite habitat for turtles, which can block flow. Screens or other appropriate prevention measures should be considered.

If the inlet distribution system should fail, the route of the incoming water should be acceptable for continued treatment and unimpaired system integrity. This is accomplished by the incorporation of an emergency overflow at the inlet.

### Outlets

Wetland outlet design is important for maintaining sheet flow distribution, for controlling water level, and for monitoring flow and water quality. Many outlet designs have been used in successfully constructed wetlands, ranging in complexity from a corrugated metal pipe embedded in a berm to remote-controlled motor-actuated gates.

### Water Collection

As shown in Figure 18.5B, flow distribution in a rectangular wetland basin with a single outlet point is compromised and effective hydraulic retention time is decreased. This situation can be improved by adding outlet weirs along the downstream berm of the wetland or by using a perpendicular deep zone to collect and route flows to a single outlet weir. If a terminal deep zone is used to accomplish this flow control goal, it should be kept as small as possible to discourage a long residence time and subsequent algal growth.

### Level Control

Outlet structures are designed to be the primary control on water level within the wetland. Selection of a particular device should include ease of operation as well as ability to set the desired water level. The water level within the FWS wetland cell is controlled at the downstream end of the wetland through the use of a hydraulic control structure. Having a separate control structure in each FWS cell allows the water level in the cells to be adjusted independently. This operational flexibility is very important for managing water levels during plant establishment, allowing access for maintenance, and planning for winter operations.

The hydraulic control structure should have enough vertical adjustment to accommodate the full range of water levels that will be expected to occur over the life of the facility. The outlet structure should have enough weir capacity to pass the peak storm events within the designed freeboard range. A conceptual example of a good outlet control structure for a FWS wetland is shown in Figure 18.26.

For small wetlands, common outlet control structures utilize stacked stoplogs (flashboards) or adjustable weir gates (Figure 18.27). Stoplog designs made from channel iron and dimensioned lumber are not suitable for small-scale projects because their high leakage rates can interfere with maintaining a stable water level. Manufactured stoplog systems have much lower leakage rates and are better suited to wetland projects. Water level adjustment is performed through the addition or removal of stoplogs. With stoplog systems, adjustment increments are limited to the height of the stoplog. Adjustable weir gates offer the significant advantage of being continuously adjustable. A deep-water zone at the outlet provides a sump that allows for greater height adjustment, which is useful in the event that the cell must be drained.

An outlet control device with a fixed elevation should not be used for a FWS wetland, as these do not provide the degree of operator control necessary for successful system operation.

Outlet weirs or pipes do not need to be sized to handle peak wastewater inflow rates because of the amplitude dampening effect of volumetric storage in the wetland cell. However, weirs should be designed to pass maximum average daily or weekly flows plus the volume of rainwater that might fall on the wetland surface from a storm event, while not compromising the design depth range. Weirs can be designed to pass these storm flows quickly (broad-crested horizontal weir) or slowly (v-notch or vertical notch weirs). Weir design is also important in quantifying wetland outflow rates. Integrating flow meters can be designed to work with almost any weir configuration.

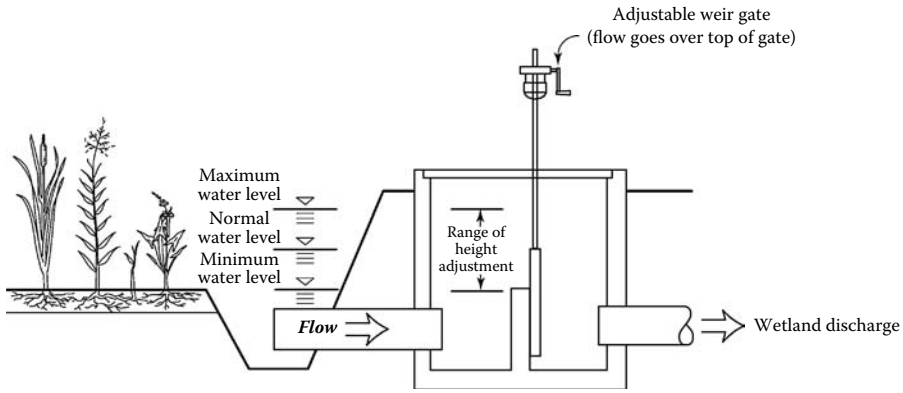

**FIGURE 18.26** Typical outlet level control structure for a FWS wetland. (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

One of the most important functions of outlet devices is to provide convenient control of wetland water levels. The required water level is based on requirements for plant growth, hydraulic residence time, and cell maintenance. In most constructed surface-flow wetland treatment systems, water levels should be controllable between 0 (the cell bottom) and 60 cm. If water level adjustments will be frequent, making the use of stoplogs impractical, then variable control weir gates can be designed. For large applications, these weir designs can become quite sophisticated and may rely on

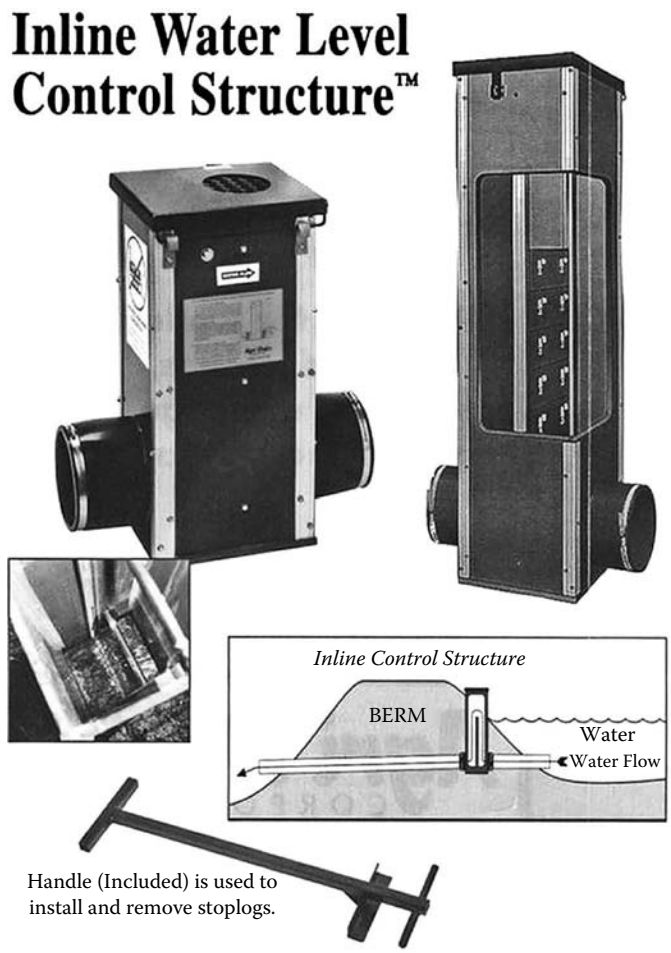

**FIGURE 18.27** Prefabricated stoplog structures are available in pipe sizes to 60 cm with capacities up to 3,500 $m^3$/d. The one pictured is manufactured by the Agri Drain Corporation, Adair, Iowa. (Photo from company literature. Reprinted with permission.)

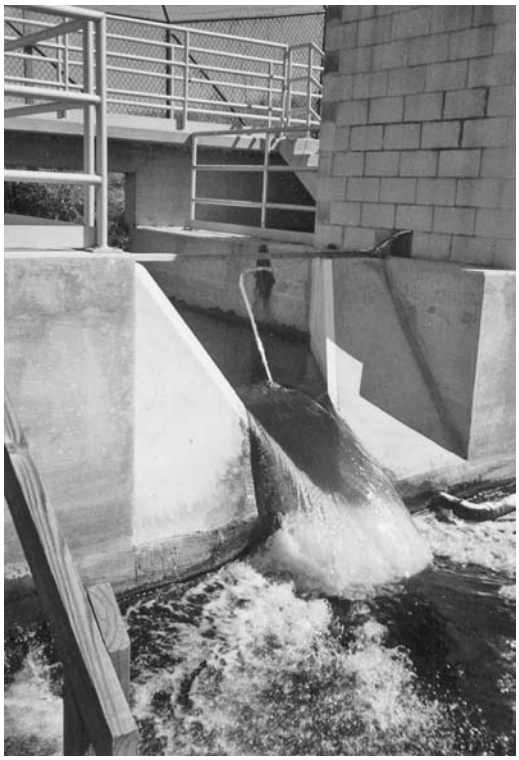

**FIGURE 18.28** The effluent structure at the 500-ha Lakeland, Florida, FWS treatment wetland. The average flow is approximately 35,000 $m^3$/d. A sampling pipe is positioned in the center of the flow.

electric power and remote control, and be combined with other flow measurement elements such as flumes (Figure 18.28).

Flows at the wetland outlet device are usually calibrated to stage and can be monitored with a staff gauge or water level recorder. For a variable outlet configuration or for a hybrid weir design, a stage-discharge curve can be prepared by using periodic volumetric flow measurements at various stage values.

### Trash Racks

Outlet structures are prone to accumulation of debris. The combination of water direction and the litter production of the wetland ensures the potential for an accumulation at outlets (Figure 18.29). A large-mesh debris fence, placed a meter or two from the structure, can alleviate this problem, but it will become clogged and form a barrier to flow upstream of the discharge structure. The use of floating skimmer boards can keep floating debris from the outlet. Its use is coupled with water withdrawal at a subsurface location. In very large systems, automated cleaning devices have been used to good advantage.

### Emergency Overflows

If flood conditions are anticipated, there should be appropriate provisions, possibly including emergency overflow spillways and back-flood gates. Emergency spillways are simply armored low sections in the containment levees with a preset elevation of their bottom (Figure 18.30).

### Pumps

Pumps are required for one of four reasons: supplying water to the wetland for treatment, removing water from the wetland to downstream uses, recycling water back to the inlet, and returning groundwater leakage to the wetland. Some systems have none of these; no North American system presently has more than three. Pumping incurs a capital cost, which is repeated on a time scale shorter than the life span of the ecosystem. Further, the operations and maintenance costs add to the capitalized total cost of the facility.

In very flat terrain, a low-head inlet pump may be needed to transfer water from the source to the wetlands at an elevation sufficient to move the water cross-country to the outlet. For the same reason, it may be necessary to utilize pumping to lower the water level at the system outlet (see Figure 14.2).

**FIGURE 18.29** Both live and dead plant material can collect at wetland outlets. Photo from the Imperial, California, treatment wetland.

**FIGURE 18.30** An emergency spillway at the Onaway, Michigan, treatment wetland. This low spot in the levee has been armored with coarse riprap.

Redundancy is usually built into these pumping facilities so that a portion of the capacity is normally out of service and accessible for maintenance.

If the wetland leaks an appreciable amount of water, it is a common practice to surround the wetland with a perimeter ditch to collect lateral seepage. Seepage water is then pumped back to the wetlands. This is the case in South Florida, where water conservation wetlands and stormwater treatment areas are so configured.

Recycle inevitably requires pumping. Treatment advantages that may be gained by this procedure are, therefore, expensive and sometimes are more economically accomplished by increasing the size of the wetland.

## 18.5 STORMWATER WETLANDS

The physical design of event-driven wetlands differs in some respects from continuous flow wetlands because they are focused on capture rather than efficient flow hydraulics. Nonetheless, it should be apparent that the general concepts of continuous flow wetlands mostly carry over to event-driven systems. However, the desire for ancillary benefits seems stronger among those who design, build, and permit stormwater wetlands. Therefore, these systems rarely are depicted as having regular geometry, and the configuration is more likely to reflect habitat than optimization of treatment.

### Bathymetry

Because runoff water is usually contaminated by TSS, most treatment wetland systems contain a wet pond or forebay at the inlet (Figure 18.31). This process element serves as a repository for settled solids, preventing them from clogging the vegetation in the remainder of the system. This deep-water area also provides storage for captured events and is typically sized as a fraction of the overall footprint. For instance, Schueler (1992) shows options with 10–45% of the area allocated to the deep inlet pool. The balance of the footprint is usually devoted to shallow and deep emergent marsh, and possibly to deep cross-zones (Figure 18.31). This patterning of the bathymetry is completely in agreement with the principles elucidated for good hydraulic efficiency for continuous flow systems. However, some literature goes on to add channelization of the marsh from inlet to outlet, presumably in an effort to emulate natural riverine wetlands (Schueler, 1992; Interstate Technology and Regulatory Council, 2003). That addition is detrimental to treatment and can only be justified by a need to avoid head loss during extreme high flows. However, those extreme flows would normally be bypassed.

Because it is not reasonable to expect to treat those extreme flows, there is an implied need to provide an alternate routing for those low-return frequency events.

### Control Structures

Because of the erratic arrival of water to the wetland, it is usually not feasible to consider operation at a fixed depth. The outlet structure for the system is designed to provide a workable hydropattern for the treatment system. A fixed weir or orifice is normally not a good choice (Somes and Wong, 1997), but there are simple passive alternatives that do work well. A siphon can act to regulate the water level between two limits with a well-modulated discharge during interim level conditions (Figure 18.32). In fact, an outlet siphon has also functioned well for the continuous flow wetland at Lake Nebagamon, Wisconsin (see Figures 3.23 and 18.19). The lower limit reflects a volume of water termed the *permanent pool*, whereas the upper limit is *extended storage*. A second alternative utilizes multiple outlets (Figure 18.33). Again, a permanent pool is maintained by a first (small) overflow outlet. During high flow events, that outlet is not capable of passing the full flow, and the water level rises until a second (larger)

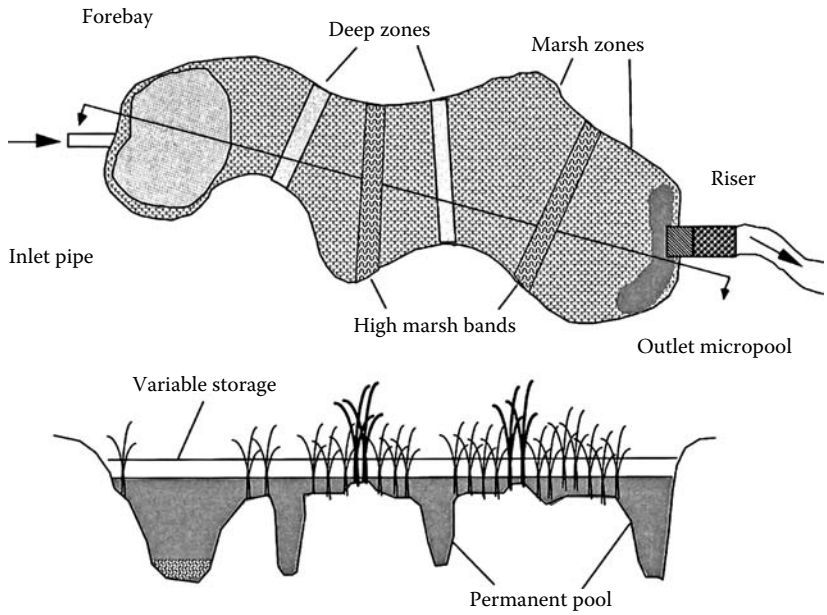

**FIGURE 18.31** Conceptual configuration of an urban stormwater treatment wetland.

outlet begins to function. During extreme flow events, both outlets may be overwhelmed and levels would rise to the emergency overflow spillway. A drain may also be provided so that all water can be removed from the wetland.

### Supplemental Water Source

Because interevent durations can be large, with dryout conditions, provision is needed for a water supply to maintain the permanent pool. There are two ways that this can be accomplished: by positioning the wetland bottom properly with respect to the regional water table or by providing a source of irrigation water. Clearly the least bothersome is to rely upon the regional groundwater table to maintain the permanent pool but that is not always possible.

Some stormwater wetlands are allowed to dry out. For instance, STA6 in South Florida drys for several months of the year. Many varieties of wetland vegetation can withstand, or even prefer, that hydropattern, and so the existence of that wetland is not threatened. However, there are small penalties for water quality improvement, as discussed in Chapter 14 (see Figure 14.9).

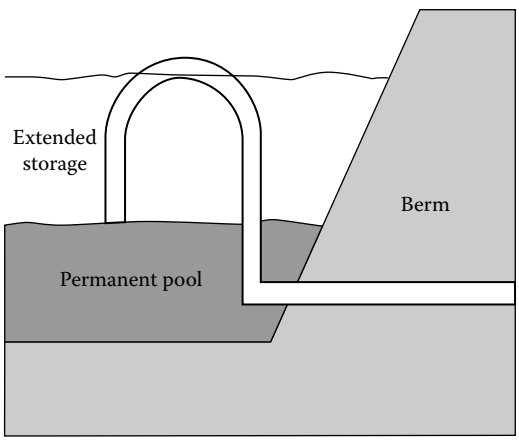

**FIGURE 18.32** Cross section of a siphon outflow structure.

## 18.6 WETLAND CONSTRUCTION

At one extreme, wetland construction can be an enjoyable experience of creation, and at the other extreme it can be a living hell of frustration and financial ruin. Almost any consultant or contractor who has built a wetland will tell you that there is no substitute for actual experience. The purpose of this section is to provide information that will increase chances for successful wetland construction the first time around, and to help with understanding and overcoming difficulties that may arise during construction of wetland treatment systems.

Wetland treatment system construction can be broken into two topics: site civil construction and vegetation establishment. Site civil construction is a broad discipline of engineering and has been refined through centuries of experience. This chapter does not attempt to discuss all aspects of this engineering practice but rather describes the highlights of site civil construction that are most relevant to wetland treatment system construction. A general discussion of wetland site civil construction is provided by Tomljanovich and Perez (1989).

### Site Preparation

Wetland treatment systems are usually constructed in nonwetland sites. The greatest amount of site preparation is typically required when an upland site has existing vegetation or structures. In some cases, these vegetation and/or structures must be removed to allow construction of wetland cells. Clearly,

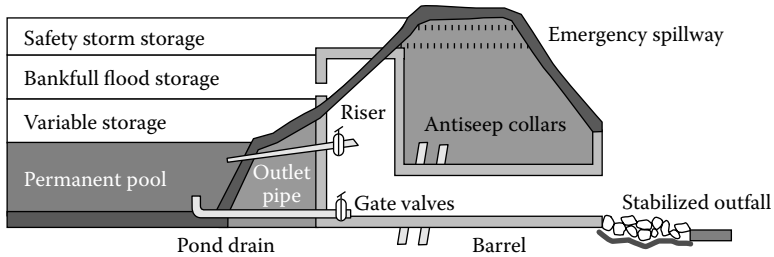

**FIGURE 18.33** Cross section of a typical wetland outflow structure. (Adapted from Schueler (1992) *Design of Stormwater Wetland Systems: Guidelines for Creating Diverse and Effective Stormwater Wetlands in the Mid-Atlantic Region*. Metropolitan Washington Council of Governments: Washington, D.C.)

construction costs can be reduced if existing vegetation and structures are avoided during project design. Assuming that design cannot avoid these features, the first step in construction is typically site clearing. Site clearing might include demolition and removal of rubble from existing structures or alternatively involve clearing of trees, rocks, or other obstacles present on the site. Tree clearing may involve the recovery of valuable timber followed by the uprooting and toppling remaining trees and stumps with a bulldozer.

As part of site clearing for a constructed wetland project, it is important to remove any belowground obstacles that might interfere with site grading or with the integrity of site soils or with plant growth. Grubbing refers to the removal of stumps and roots following removal of trees and shrubby growth on a site. Grubbing should also remove any unwanted, buried structures such as utilities and foundations on previously developed sites. Cleared vegetation may be chipped and temporarily staged with other debris in an upland area. Chipped material can serve as mulch for terrestrial planting operations. Nonrecyclable material should be disposed at a landfill.

Erosion on-site and off-site should be prevented as much as possible during wetland construction. Before any construction activities that might result in the disturbance of the existing soils at the proposed location of the constructed wetlands, soil erosion and sediment control measures should be constructed in accordance with the appropriate state standards for soil erosion and sediment control. The objective is to prevent sediment from being washed from the excavated areas into undisturbed areas. All soil erosion and sediment control measures should be maintained in good condition and left in place until permanent vegetation cover is established. Silt screens can be used to minimize off-site erosion, which consist of PE fabric or hay bales anchored by use of wooden or metal stakes. Geotextiles and fabric cloth can also be used to protect berms and high-flow areas within the constructed wetlands from erosion.

### Grading and Subgrade Preparation

Following site clearing and grubbing, basic landforming can begin. Using soil grading and hauling equipment, the contractor will generally remove and stockpile topsoils from the footprint of future wetland cells to be reused for final wetland-planting media. Following removal of the topsoil, the general contours of the wetland site are graded and all site features are horizontally located by standard surveying methods. The constructed wetland site is excavated to the contours, according to the detailed specifications prepared during the design process, in the form of cross-sectional and contour drawings showing the current and finished grades. Following removal of the topsoil, the subsoil material should be removed to a rough grade, approximately 15–30 cm below the final grade consistent with the planned elevations. This allows room in the excavation for placement of the liner (if required).

Preparation of the subgrade is an important part of the construction process. It is important that the subgrade be properly compacted to a design density because this will reduce settling under the liner and avoid the associated stress. Grading tolerance specifications, before placement of liner materials, should be kept within ±5 cm. Heavy construction equipment should be kept off rough grades if the subgrade is unable to support the vehicle weight without deformation. Final site grading follows construction of berms, deep zones, and islands. Because a small amount of erosion can negate this work, in rainy climates it is advisable to establish ground cover on berms before final grading. Final grading typically consists of leveling the wetland cell bottom to allow for a uniform thickness of rooting soil in the completed wetland. Generally, bottom elevation is constant from side to side within the wetland cell and decreases slightly or is flat from the upstream to the downstream end of the wetland. Finish subgrades of the wetland bottom may have tighter tolerances, ±3 cm, which can be accomplished by use of a laser-leveling system or by hand raking. Hand raking works well in small cells by pulling a level string across the width of the cell and working downgradient. Laser leveling with laser-equipped bulldozers and scrapers works best for larger sites.

Wetland cell berms are typically constructed in lifts or successive steps of placing and compacting soils. Interior berm cores and any wire meshing needed for muskrat burrow prevention should be placed in the berm during this process. Soil moisture is critical during compaction of berms

and internal cell liners, and construction may be delayed by excessively moist weather conditions.

As soon as berms have been shaped and dressed with any topsoils that are specified, they should be protected from erosion by use of straw and/or cover crops of grasses. Typically, a mixture of grass species is specified to allow establishment under variable climatic conditions. Hydroseeding with a mixture of grass seeds, shredded newsprint, and fertilizer has been found to be an effective method for rapid cover establishment on wetland berms. All cover crops should be irrigated as needed to insure good germination and growth of plants.

### Liner Placement

Wetland liners are placed following final cell grading. If large or sharp rocks are present in the subgrade, then liner protection is required. Geotextile mats are recommended if the subgrade cannot be prepared without jeopardizing liner placement. Geotextiles are easier to place than sand and have the advantage of staying on the sloped berms. If a sand layer is used, 15–30 cm is typically used.

The installation and testing of liners is an important element of a successful wetland project (Interstate Technology and Regulatory Council, 2003). This activity requires specialists and would usually be subcontracted. Specifications should include some reference requiring written approval of the subgrade by the liner installer before its installation. Written acceptance of subgrade preparation by experienced liner installers is usually a condition for maintaining manufacturers' warranties. Site preparation is very dependent upon the type of liner but will usually include compaction before to installation. Following installation of liners, wetland cells should be leak-tested before further installation of topsoils, media, or wetlands vegetation.

A protective layer of sand is sometimes placed to protect the liner from sharp objects in the rooting soil or from activities involved in rooting soil placement and planting (Figure 18.34).

### Rooting Soil Placement

Following site preparation and grading, a layer of appropriate soil is placed to serve as a medium for plant establishment and growth. Suitable substrate (at least 20–30 cm deep) is brought into establish the topographic contours of the constructed wetlands to final grade. Topsoil for backfilling should consist of a soil suitable for supporting plants in that region. Rooting soil may vary from topsoil to subsoil, depending on the application and the design requirements. Generally, hydric soils need not be used as fill material, because in wetlands, hydrologic regimes are such that hydric parameters will develop over time. The organic content, typical of wetland soils, will develop as a function of both aboveground and belowground plant production. However, the use of hydric soils as fill can assist in the introduction of wetland vegetative species into the system, depending on the location from where the soils were obtained. Because of the need to protect natural wetlands, it is necessary, in many cases, to obtain regulatory permission for the borrowing of wetland soils from off-site. The original topsoils from the site may be usable and may be transferred from a stockpile to the wetland floor.

Emergent wetland plants require suitable soil conditions for rapid initial growth, and long-term propagation and survival. Loamy soils, containing a mixture of sand, silt, and clays, are optimal for growth of most plants. These soils have adequate texture and organic matter to retain moisture, allow diffusion of oxygen and carbon dioxide, and retain nutrients for absorption through the plant roots. Although sandy soils provide good gas exchange and allow for relatively unencumbered root development, they do not retain nutrients or moisture well. As long as nutrients and moisture are adequate through continual flooding with enriched wastewaters, sandy soils can be used for constructed wetland development. Clays

**FIGURE 18.34** Covering the liner at the Lake Nebagamon, Wisconsin, treatment wetland.

or other fine-textured soils have poor characteristics for gas exchange and root development, and may limit water movement to the wetland plant roots. However, clays typically have high cation exchange capacities and provide excellent binding for important plant growth nutrients. In tight clays, the nutrient advantage is overwhelmed by the poor texture for root development, resulting in very slow plant growth. When mixed with sands and silts, organic soils are frequently the best medium for growth of wetland plants. Good agricultural topsoils frequently provide an excellent medium for wetland plant growth and should be stockpiled for use during wetland construction.

In those applications where the wastewater is nutrient poor (i.e., groundwater remediation or tertiary effluents), this topsoil may be amended with agricultural fertilizer at a rate typically used to cultivate a grass crop, which can be determined by soil analyses and recommendations from the local agricultural extension agent.

If the wetland is constructed on a compacted clay or plastic liner, soil will have to be placed on the liner so that the finished surface is level and free of vehicular tracks. Wetland cell floors may also be seeded with a cover crop of grasses if final construction or wetland planting will be delayed due to the need for a seasonal-planting window.

### Piping and Structures

Wetland water conveyance systems may be fabricated off-site, and then brought to the site and installed, or in some cases may be totally fabricated on-site. Wastewater conveyance systems typically include piping and pump stations, and water control structures such as splitter boxes, weirs, and flumes. Wastewater may be conveyed to a wetland treatment system site by use of a pressurized forcemain, by a gravity pipeline, or by an open channel. Construction of pump stations, pipelines, and open channels are not described in this chapter, and the reader should consult general references on hydraulic design and construction for more information. Once the wastewater is brought to the wetland site, it is typically distributed into the wetland via some distribution system consisting of pipes, channels, or coarse rock beds. Construction related to these wetland distribution systems is briefly discussed.

As described previously, effective flow distribution is critical to optimizing wetland treatment performance. Wetland distribution system construction is important to increase the ability of the system to achieve this potential. Gravity distribution systems rely on firm foundations and level installation across the width of the wetland cells. Ample footings should be provided for pipe-support structures. Frost protection must be considered for cold climate systems. If wetland design allows for outlet height adjustment, then vertical control tolerances are less critical.

Weirs and flumes should be constructed using standard site civil construction techniques. Heavy structures require adequate footings on noncompressible soils and adequate reinforcement. If organic or high-clay soils are present in locations where footings are to be constructed, they should be removed and replaced with better geotechnical materials.

## 18.7 VEGETATION ESTABLISHMENT

Wetland systems owe much of their public acceptance to the vegetative communities they support. Plants play an extremely important role in FWS wetlands. They shade the water column, provide surface area for biofilm growth, and aid in the cycling of nutrients and organic carbon. Thousands of plant species are adapted to grow in wetlands. However, only a few plant species have been widely used in constructed wetlands. Plants in treatment wetlands should be tolerant of the water quality of the project and be able to propagate. They also must be tolerant of continually saturated soil conditions and be able to thrive in the soil environment created by the particular wastewater under consideration. A number of references are available to provide guidance with wetland plant establishment (Gearheart *et al*., 1989; Hammer, 1992; Thurnhorst, 1993; U.S. Army Corps of Engineers, 2000; Allen *et al*., 2002; Wallace and Knight, 2006).

### Selection of Plants

Thousands of plant species are adapted to grow in wetlands. However, only a few plant species have been widely used in constructed wetlands. Ideally, plants in treatment wetlands should be tolerant of high-nutrient levels and be able to propagate through rhizome spread. They also must be tolerant of saturated soil conditions and be able to thrive in an anaerobic environment. In addition, wetland plants must be readily available from local plant nurseries. When selecting plant species for treatment wetlands, designers should consider the following factors:

- *Hydrology.* Natural wetlands develop a plant community that self-designs in response to the frequency and duration of saturation, and/or inundation (U.S. Army Corps of Engineers, 1987). Constructed wetlands usually have a simplified hydrology because they treat a relatively constant flow of wastewater. However, designers should identify areas that will normally be inundated and the depth of water within these areas. It is important to evaluate the water levels at both normal and peak flow rates to ensure plant survival.
- *Climate and latitude.* Selected plants must be able to survive in the local climate. Because some species such as cattails (*Typha spp.*) have very wide geographic distributions, it is important to specify planting stock that is available within a reasonably close proximity to the project site (e.g., 500 km) and/or produced in the same climatic region.
- *Method of introduction.* Vegetation may be planted or natural colonization may be allowed to occur.

Natural regrowth takes longer and is subjected to the availability of regional sources of propagules and their transport. Planting allows initial control of the species mix and usually takes less time to develop a mature wetland ecosystem.

- *Cost and availability of planting stock*. Plant species native to the region are preferred. Introduction of exotic plant species can result in penalties, ranging from significant permitting delays to violation of state/provincial and federal laws. Designers need to understand which plants are native to the region and, among those native plants, which ones are available in reasonable quantities at a reasonable cost.
- *Plant size*. Wetland vegetation should be selected based upon the project budget and the size of plant that is available from local suppliers. Plants with larger root biomass will have a higher survival rate. However, larger plants cost more, so the designer must balance the plant cost (and thus, plant size) against the project budget. If small plant stock is chosen, plant maintenance may need to be increased to prevent weeds and unwanted plant species from dominating the system.
- *Rate of colonization of the selected plant species*. Plant species that spread rapidly require less planting stock, which will reduce the cost and minimize the potential for weed invasion. However, aggressively spreading species will likely crowd out other plants, resulting in a less diverse plant community in the wetland.
- *Water quality (including salinity, pH, ammonia, sulfide, and oxygen demand)*. For successful establishment, the selected plant species must be able to tolerate the water quality characteristics within the wetland.
- *Project goals*. Is the wetland expected to provide high-quality wildlife habitat? If so, a more diverse planting would be appropriate. If treatment is the primary project goal, a simplified planting scheme, resulting in less diversity, may better suit project goals.
- *Maintenance*. Vegetation management is crucial during the first year of plant establishment, primarily via water depth control.

## Treatment Potential

As discussed in Chapter 3, the structure of the plant community is a more important determinant of pollutant removal performance than the species. There are numerous studies that look at the initial uptake of various nutrients and contaminants; for instance, see Tanner (1996) or Iamchaturapatr *et al*. (2007). But, to the extent that vegetation is directly involved in removals, it is the entire biogeochemical cycle that matters, not initial uptake. Further, it is the presence of physical structures below water that determines the site densities for microorganisms and algae, which in many wetlands are a major contributing factor to removals. Emergent wetland plants provide a wide range of treatment mechanisms in FWS wetlands, (Sinclair Knight Merz, 2000) including:

- Increased sedimentation by reducing wind-induced mixing and resuspension
- Additional surface area for increased biofilm growth and uptake of soluble pollutants
- Increased surface area for particle interception
- Shade from the plant canopy over the water column to reduce algae growth
- Induced flocculation of smaller colloidal particles into larger, settleable particles

Most of these mechanisms are structural in nature. Consequently, selecting the "perfect" plant species is not nearly as important as establishing a functional plant canopy. Thus, performance results often show little difference among species mixes of the same general structure (see Table 18.3, for example).

The designer has wide latitude in the selection of plant species and mixtures thereof. Greenway (2003) studied seven wetlands in Queensland, Australia, and concluded that a large variety of aquatic plants were suitable for surface flow constructed wetlands to polish wastewater effluent. However, species such as *Typha, Phragmites, Paspalum*, and *Ipomoea* were capable of displacing other species and forming dense monotypic stands. Floating and submerged species have higher nutrient content than emergent species; they also remove nutrients directly from the water column. Greenway (2003) recommended a mixture of species to maximize nutrient removal and enhance the ecological value of treatment wetlands.

Genetically engineered plants are on the horizon for consideration for future applications. Nandakumar *et al*. (2005) have demonstrated that it is possible to genetically engineer *Typha latifolia* to achieve the long-term objective of introducing candidate genes for phytoremediation.

## Diversity

Establishing diverse wetland vegetation is a stated goal in most wetland mitigations and, to the extent practicable, should also be a goal for treatment wetlands. This is desirable for a variety of reasons. A relatively large number of species means an array of environmental tolerances is represented. As the new wetland experiences fluctuations—such as water level, temperature, and herbivory—in various environmental conditions over time, some plants or species will not survive, but others may thrive. If the project is dominated by a few species, there is a possibility that the project will fail with the death of only one species. Planting a variety of species increases the chances for success of at least a few species. A more diverse mix of plant species will be better able to accommodate changes in water quality and flow.

**TABLE 18.3**
**Percent Removals for the Oregon State Side-by-Side Animal Waste Treatment Cells with Different Vegetation Types**

| Vegetation Type | | BOD | COD | TSS | TKN | $NH_4$-N | TP |

*Source:* Data from Moore and Niswander (1997) *Constructed Wetlands for Animal Waste Treatment*. Payne Engineering, CH2M Hill (Eds.), Gainesville, Florida, pp. II-31–II-33; NADB database (1998) *North American Treatment Wetland Database (NADB), Version 2.0*. Compiled by CH2M Hill. Gainesville, Florida.

Monocultures, or communities with a single dominant species, are often considered to have a limited ecological value. The ecological benefits of diverse communities are numerous, given that the number of plant species and structural complexity of natural ecosystems generally correlate with wildlife species richness, particularly for birds. Consequently, a diversity of wetland plants within a system increases wildlife value. Various plant species association and hydrological conditions provide required habitats for different life history phases of animals such as feeding, winter cover, and breeding.

Table 3.1 summarizes the number of plant species reported for the treatment wetlands in the North American Treatment Wetland Database (NADB database, 1998; U.S. EPA, 2000a; Knight *et al*., 2001). More than 800 species of macrophytic plants have been reported in natural and constructed treatment wetlands. Of these observed plant species, 693 are emergent herbaceous macrophytes, 36 are floating aquatic species, 12 are submerged aquatics, 57 are shrubs, 55 are trees, and 18 are vines. The NADB v.2 lists 593 macrophytic plant species reported from constructed treatment wetlands and 427 species from natural treatment wetlands. Emergent herbaceous macrophytes account for 501 species in constructed treatment wetlands and 290 species in natural treatment wetlands. A significant variety of tree and shrub species occur in a few constructed wetlands (primarily in the constructed cells of the Orange County, Florida, system). Tree and shrub species are well represented in natural treatment wetlands with 88 different species recorded. Although the NABD v.2.0 data collection effort provided some insight into the plant diversity at constructed and natural treatment wetland sites in North America, the level of investigation varied widely between sites. These numbers should be considered as the minimum number of plant species that actually occur in treatment wetlands.

## Natural Selection and Convergence

It may be argued that the vegetative community of a treatment wetland is not, in the long term, a choice of the designer. The plants that are best adapted to the hydrologic regime and water quality of the wetland will prevail eventually if not controlled by weeding or herbiciding. Studies by Mitsch and Zhang (2004) showed that the plant communities and performance of two wetlands converged after about three years of development. One wetland was planted with 13 species; the other was unplanted.

Most FWS treatment wetlands undergo a process of alteration and self-design after the initial planting. The plant community that develops over time is a function of organic and nutrient loadings, hydrology, and climate. FWS wetlands that are heavily loaded with organic matter and nutrients will typically develop a less-diverse plant community because fewer plant species are able to tolerate the reducing conditions that develop under these circumstances. In polishing wetlands with very high water quality, a diverse species composition may develop.

## Natural Recruitment

One option is to allow for natural colonization of the wetland basins. Natural colonization of wetland restoration and establishment projects can be a highly successful method of establishing vegetation if sources of seeds and plant propagules are nearby. Reinartz and Warne (1993) reported finding 142 species of vascular plants in naturally colonized created marshes of southeastern Wisconsin. They found that the diversity and richness of native wetland plants and the proportion of total plant cover that was comprised of native marsh plant species increased from one- to three-year-old wetlands. The diversity and richness of native wetland species increased with proximity to the nearest native marsh with a marked decrease in

species richness beyond 700 m to the nearest marsh. These results indicate that sources of seeds of wetland species must be relatively close to the project site for dispersal of a diversity of species in adequate quantities to vegetate a site. The decision of whether adequate natural sources of seeds or vegetative propagules are available depends on the type of desired plants. For example, marshes containing desirable species that occur within 500–700 m of the project site are likely to be good seed sources of herbaceous plants, assuming the presence of dispersal vectors for the various seed types. Seed densities of windblown or animal-dispersed species decline rapidly with distance from the source. Water-dispersed seeds can be carried great distances, presumably for many kilometers, but the sources must be upstream of the project site.

It is possible to supplement the natural importation mechanisms by use of rooting soils that contain wetland plant seeds. This approach to establishing a wetland plant community is to harvest the seed bank from a neighboring wetland (natural or constructed) that has a plant community similar to the one desired for the new constructed wetland. This seed bank is harvested by scraping the top 10–20 cm of topsoil or muck from the donor wetland, and then redistributing this muck in strips or over the entire surface of the new wetland. An adequate moisture regime, resulting in saturated but not flooded soil conditions, is absolutely essential for the success of this approach. It is difficult to predict the development of vegetative cover from a transferred seed bank. Sometimes seed bank studies in greenhouses provide reasonable forecasts, but this is not always the case. The postrecruitment vegetative composition and structure from a seed bank cannot be predicted. Although many site factors, such as erosion, inundation, and drying, will affect emergence, results of a seed bank study can be used with caution to estimate the types of vegetation that will emerge on the project site.

Natural recruitment begins with the sprouting in the spring season, provided that moist soil conditions prevail (see Figure 18.35). The key to encouraging development of the existing seed bank is to maintain moist soil conditions, not deep-water conditions.

**FIGURE 18.35** This stand of cattails developed without assistance in a wet, fallow corn field near extensive *Typha* marshes associated with Wind Lake, Wisconsin. The row of dead corn stubble is seen in the foreground, proceeding from left to right.

In tropical climates, this process can be complete within one growing season but may require two or more seasons in colder temperate climates. In the event that the project schedule does not permit the time needed for natural recruitment, wetland vegetation can be established using any one of several types of propagules. A one-year delay in the imposition of permit requirements allows for natural regrowth and can save a considerable amount of money.

### Plant Propagules and Sources

When considering planted wetlands as a treatment option, designers must take steps to ensure that planting stock will be available in the quantity and quality needed for the project at a cost-effective price. Options for plant materials include:

- *Commercially available planting stock*. This is the most common method of obtaining planting stock for small to mid-size FWS projects; large projects may require contract growing with a commercial nursery.
- *Donor plants from another treatment wetland*. This option is often chosen for small projects when the plant species involved are very easy to propagate, e.g., common reed (*Phragmites australis*) or reed canary grass (*Phalaris arundinacea*).
- *Onsite plant nursery.* For large projects, a plant nursery can be created at the project site to provide the required planting materials.
- *Natural wetlands.* Field-harvesting materials from roadside ditches and native wetlands are labor intensive if done manually; often, plant collection permits are required.

Propagation and sale of wetland plant species has become a big business in several areas of the United States, and in Great Britain and Europe. Wetland plant nurseries supply thousands of plants that are used to renovate altered landscapes, such as phosphate and coal mining areas, and to create landscaped wetlands and ponds (aquascaping) for wildlife habitat. Although most of these plants are currently being propagated for use in habitat creation projects, this market has attracted suppliers who can propagate the types and quantities of plants required for constructing large wetland treatment systems. Plant propagules that are frequently used to establish constructed wetlands for wastewater treatment include seeds, bare-root seedlings, rhizomes, greenhouse-grown potted seedlings, and field-harvested plants.

If the wetland is to be planted, the cost and availability of plant materials must be addressed early in the design process. If suitable planting stocks cannot be obtained from local nurseries, the option of establishing an on-site wetland plant nursery must be decided very early because mature plants (one to two years old) are preferred. Mature plants have the energy reserves necessary to survive transplanting

and extend leaf tissues above the surface of the water, whereas very young plants may not.

### Seeds

Wetland plants can be established directly from seeds, given suitable seed stock, soil moisture, light, and temperature conditions. Seed germination is highly dependent on the soil/seed contact and the moisture regime of the soil. It is preferable to establish wetland plants using a native soil-rooting substrate. Some species have seeds that can be field harvested in very large numbers, whereas others produce few seeds. For example, a typical cattail seed head contains thousands of individual seeds, whereas mature bulrush culms may contain only 20–30 seeds each. Also, seed viability varies widely among plant species. If sufficient quantities can be obtained, most wetland seeds can be applied by using rotary seeders (or applied by hand) and then lightly raked into the surface soil layer. Broadcast methods have a disadvantage due to the development of areas that have poor cover, which may subsequently be dominated by undesirable species. Establishing new wetlands from seed has the advantage of lower initial cost. Seeds can generally be harvested and planted for a considerably lower cost than bare-root seedlings. However, it takes considerable time to establish a viable plant community that will provide adequate cover to allow system start-up and initiation of water quality treatment. Because bare-root seedlings pass their first several months of growth in greenhouse conditions, they have a comparable time advantage over seed germination in the constructed wetland.

### Bare-Root Plants

Both herbaceous and woody wetland plants may be provided as bare-root plants. Bare-root seedlings are typically planted in shallow, hand-dug holes. Their survival rate is significantly higher than for field germination of seeds and can generally be maintained at 80% or better with healthy plant stock and an adequate moisture regime. Initial success is largely dependent on the size of the bare-root plants; plants with small rootstock typically lack the energy reserve necessary to survive the transplanting process. To produce bare-root seedlings, nurseries plant germinated seeds in flats containing potting soil. The flats may hold dozens of individual plants that are later thinned. Bare-root seedlings are harvested from these flats after a few months when they have reached a height of 20–50 cm. Their roots are cleaned of potting soil, and the plants are wrapped together with moistened paper towels for temporary storage and eventual transportation to the planting site.

Bare-root seedlings are easily planted in the field in shallow individual holes prepared with a shovel, trowel, spike, or dibble. The survival rate of bare-root seedlings is significantly higher than for field germination of seeds, and can generally be maintained at 80% or higher with healthy plant stock and an adequate moisture regime. Use of bare-root seedlings at sufficiently close spacing can insure rapid establishment of a dense, monospecific plant cover in a short time. This success is critical for projects where minimal start-up time is of the essence.

### Rhizomes

Herbaceous wetland plants may be obtained as rhizomes or tubers. Rhizomes may be shipped to the project site while still dormant; plants that have broken dormancy often have the stems clipped back to facilitate shipment and planting. Larger rhizomes have more stored energy available to support plant establishment. Sprouting is typically from nodes along the rhizome, and cuttings should have at least two undamaged nodes. They are planted in moist soil.

The energy stored in the rhizome provides the energy to get the plant started; larger tubers or rhizomes offer a much better chance of success than small stock. Rootstock in the form of tubers should be at least 1.5 cm in diameter. Rootstock in the form of rhizomes should be at least 5 cm long. Plant count should be based on the number of roots or tubers, not the number of buds or shoots, because each tuber may have multiple buds or shoots.

### Potted Plants

To establish planting materials with a developed root structure, seedlings can be planted and grown in containers filled with potting soil. Potted plants have a greater advantage for initial growth over seeds and bare-root seedlings, primarily because they have larger stored energy reserves (if properly sized), and damage to the root structure during planting is minimal. However, the disadvantage of potted plants is the high initial cost. They are not only more expensive to grow but also expensive to transport to the newly constructed wetland.

Potted plants should be in at least 10-cm pots. The bound soil/root mass should be the same size as the container (otherwise, the product could be a 5-cm plant in a 10-cm pot). Plants in peat pots should be well rooted through the sides and bottom of the pot, and firmly anchored. If plants are growing at the time of installation, they should appear healthy with no leaf spots, insect damage, or wilting.

### Field-Harvested Plants

In some cases, herbaceous wetland plant stock can be field harvested and used to plant a newly constructed wetland. This planting technique is used in areas with abundant natural wetlands and high regional water tables, where wetland plants such as cattails and bulrush are common in roadside ditches, man-made ponds, and along canals. A plant collection permit may be required, depending on local regulations. Existing treatment wetlands are another potential source for planting stock. Field harvesting can occur by hand harvesting or by using a backhoe to scoop wetland plants from the ground and spread them on an open, upland area where they are separated by hand into manageable units. This method tends to be the most labor-intensive of any of the plant stock sources.

Field-harvested plants have several advantages over nursery grown stock. Because herbaceous wetland plants store most of their growth reserves in their roots, rhizomes, corms, and tubers, these plant parts can produce shoots and mature

plants faster than newly developing seedlings. In fact, a carefully tended rhizome generally produces numerous daughter plants in a few weeks, each of which in turn produces new rhizomes and a second generation of daughter plants. This growth results in faster development of adequate plant cover so that water quality treatment can begin earlier than otherwise possible. A second advantage of using plants that have been locally harvested is that these plants are more likely to be adapted to local climatic conditions, including their phenology and genetic tolerance to temperature and moisture regimes.

Invariably, other wetland plant species are introduced into a newly constructed wetland in the rootstock and attached soil of field-harvested plants. These additional plant species come in as small seedlings or as seeds in the existing seed bank from the donor wetland. For example, at the West Jackson County, Mississippi, constructed wetland near Ocean Springs, use of field-harvested cattails and the existing seed bank in the site soils resulted in the presence of 48 different plant species growing in the constructed wetlands one year after construction. This introduction of volunteer plant species is generally an advantage because it provides diversity in a constructed wetland that might otherwise be nearly monotypic.

### Planting Density

Only a small fraction of the ultimate plant density is planted in a new wetland. Planting densities range from 1,000–40,000 plants per hectare, depending on the rate of spread of the selected plant species in the climatic region, and the acceptable time frame and economics of plant establishment. As a reference, one plant per square meter, (a one-by-one meter spacing), corresponds to 10,000 plants per hectare. Through vegetative reproduction, these plants will eventually spread to much greater densities. The counting process after vegetative development usually involves stem counts rather than plant counts with densities of 100–800 stems per square meter being common. As the first round of plants mature and die, rhizomes send up new shoots. Consequently, the rate of rhizome spread is a factor that should be considered in design because rapidly-spreading species will eventually occupy much larger areas within the wetland than slow-spreading species, even if the initial planting quantities were the same. For instance, *Phragmites* and *Typha* are capable of spreading 10–20 m/yr (see, for example, Figure 3.12). Some species, such as *Schoenoplectus*, spread concentrically with ever-increasing clump diameters.

The potential for plants and seeds to grow and increase their coverage on the project site depends on several factors. If hydrology, nutrients, competition, and herbivory are not limiting to plant growth, it is not uncommon in wetland projects for rhizomatous grasses, other herbs, and some shrubs planted to less than 5% coverage to reach 100% coverage in less than three years by spreading vegetatively.

### Planting

After delivery to the job site, plant material should be stored in the shade and kept cool and moist. Plant stock left out in the sun can dry out and be useless within a few hours. Most wetland plant species have extremely poor drought tolerance. Field-harvested plants must be protected from excessive heat or cold, kept moist but not wet, and must be used within a few days to minimize mortality.

Planting is usually done by hand on small to moderate projects. Attempts to plant field-harvested rhizomes by mechanical planting have had varied success. Holes may be prepared with a shovel, a posthole digger, or a hand or tractor-mounted auger. In all cases, the hole must be deep enough to allow the rhizome or root material to be completely buried without excessive folding, and with the node between rhizome and shoot at the ground surface. Planting field-harvested plants is more difficult than planting nursery-grown seedlings because of the size of the propagules. Rhizomes and attached shoots and leaves are usually larger than bare-root seedlings and require a larger hole for planting.

Plants have a growing season and are dormant for the rest of the year in temperate and subtropical climates. Annual plants die in each fall or winter and must be reestablished from the seed in the following spring or summer. Fortunately, most plants used in treatment wetlands are perennials that lose their aboveground tissues and become dormant during the cold season, and regrow from storage reserves in belowground tissues during the next growing season. In some cases, new growth is timed to take advantage of predictable rainfall and moisture conditions rather than specific day length or temperatures. Knowledge of these climatic influences is important in planting specifications and during wetland planting.

The best time to establish new plants in a constructed wetland is in the beginning or height of the growing season, which usually coincides with spring or early summer. During this period, available light is increasing daily, and competition from previously established weeds or damage from pests and pathogens is minimal. Most plants are genetically adapted to grow during this period. Also, planting at the beginning of the growing season provides ample time for full plant development and attainment of suitable plant cover before the onset of cold temperatures and declining plant growth rate. A wetland treatment system can typically begin operation when the plant cover is at least 60–80%. If this percent cover can be obtained during the first growing season after planting, the wetland system can begin operating during the ensuing fall.

### Plant Establishment

The best technique for establishing rapid plant cover is to maintain saturated soil conditions without surface flooding. The higher soil oxygen conditions resulting from the absence of flood waters allow maximum root metabolism, effective nutrient use, and rapid development of the original plant propagules and their daughter plants within the wetland. This soil condition should optimally be maintained until the plants achieve complete cover (100%) or at least the minimum cover required for system start-up (about 60–80%).

**FIGURE 18.36** After planting, the Columbia, Missouri, wetland was allowed to dry because of disagreements about responsibility for watering. The initial planting was lost.

Once the soil is in place and the plants have been planted, water may be increased gradually to match plant growth. The best method to maintain soil saturation without excessive flooding is to start planting at the downgradient end of the wetland and continue planting upgradient while gradually raising water levels using the wetland outlet water level control weirs. When planting is complete, water levels can be dropped or raised as needed to maintain saturated soil conditions.

Incorrect control of soil moisture is the most frequent cause of failure to establish wetland plants (Figure 18.36). Inadequate soil moisture results in desiccation of roots and shoots, and causes wetland species to be replaced by weedy upland plant species that may be in the seed bank of the constructed wetland soils. Too much water results in oxygen depletion in the root zone and slow growth or plant death because of insufficient oxygen for root metabolism—otherwise known as drowning. The correct amount of moisture can be maintained through adequate planning and attention during the construction period.

To maintain suitable soil moisture during plant establishment, there must be a reliable and adequate supply of water for site irrigation. This requirement can be quite large when constructing wetland systems more than a few hectares in size. When practical, the best water source for site establishment is usually the wastewater that will be treated in the wetland. This water can generally be used if an existing treatment system is being retrofitted or expanded by the addition of a constructed wetland. If the wetland influent water is not available, then another irrigation supply must be provided. This irrigation source might be a potable water supply, an existing or temporary well, a pond or lake, or a nearby stream or river. Adequate pumps, piping, and sprinklers or hoses must be provided to allow even-flow distribution.

Design specifications for vegetation establishment in constructed wetlands should clearly delegate responsibility for plant maintenance from the time of initial planting through plant establishment. Successful establishment requires periodic inspections to document soil moisture conditions, plant survival, and plant growth. The frequency of these inspections is project-specific but must be often enough to deal proactively with potential problems.

Initial plant inspection should examine the viability of the planted propagules, whether seeds, seedlings, or field-harvested mature plants. Subsequent plant growth is monitored by estimating percent cover and average plant height. These nondestructive techniques are used to ascertain the status of plant development before and during wetland treatment system operation. Plant cover is an estimate of the percentage of the total ground area covered by stems and leaves. This parameter can be estimated by walking through or next to a plant stand and visually determining a cover category for the plants.

A controversial aspect of plant establishment is dealing with wildlife grazing. FWS wetlands can attract flocks of waterfowl, such as Canadian geese (*Branta canadensis*), which can obliterate planting stocks if host populations are high enough (Figure 18.37). Successful plant establishment

**FIGURE 18.37** The Hayward, California, wetland experienced great problems with waterfowl grazing. The only plantings that remain in this photo were in exclosures built to prevent such eat-out.

requires dealing with these issues in a proactive manner, via acceptable methods of animal control (screening, deterrents, etc.).

## SUMMARY

The physical design of a FWS wetland requires numerous decisions concerning siting and layout. The compartmentalization and number of flowpaths are specified, as well as the aspect ratios of the cells. The internal design of a cell involves possible use of deep zones as well as patterns of vegetation that enhance treatment. All such decisions are subject to the constraint that the wetland must pass the design flows without excessive head loss and inlet flooding. The height of the berms and depth of excavation are balanced so that material is neither exported nor imported to the site. The type and thickness of a liner are chosen, if one is necessary. Structures are selected to control the depth of water in the wetland, and to spread and collect the water efficiently.

As long as a few simple guidelines are followed and common sense is employed by contractors and field engineers, wetland project construction can help insure the success of a good design. Site civil construction activities, pump stations, forcemains, and open-channel conveyance systems are standard experience for most wetland contractors. For wetland systems, it is important to not create conditions that will ultimately limit the wetland treatment system from accomplishing its water quality treatment or habitat creation goals.

The presence of a healthy, dense population of emergent plants is an important requirement for pollutant assimilation in wetland treatment systems. Plants provide the structural surface area occupied by the microbial flora that attack dissolved pollutants; they provide the physical filtration that reduces particulate pollutants; and they shade the water surface, preventing algal regrowth, and dampening temperature fluctuations. In addition, the wetland plants provide a vast amount of fixed organic carbon important for microbial growth and denitrification and are the basis for a complex food web of wetland biota.

Wetland plants can be established successfully by a number of different methods that have varying benefits and limitations. Designer preference and planting cost will guide selection of the appropriate plant propagation technique. Care must be taken with the health of the plant propagules, soil and site preparation, planting, and soil moisture maintenance. The time required for vegetation establishment is often critical to meet scheduled system start-up.

# 19 Ancillary Benefits

When wetlands are used to reduce pollutant concentrations and peak stormwater flows, ancillary benefits can be achieved through thoughtful site selection and design. This chapter summarizes the ancillary benefits of wetlands used for pollution control and recommends design features to optimize these benefits. The primary objective of most wetland pollution control projects is water quality enhancement through assimilation and transformation of sediments, nutrients, and toxic chemicals. Secondary benefits that can be incorporated in wetland treatment designs include (1) vegetative biodiversity; (2) protection and production of fauna; and (3) aesthetic, recreational, commercial, and educational human uses. Realization of these benefits usually requires extra land and extra expenditures. Some of the features that are added are illustrated in Figure 19.1. The potentials for including each of these benefits in treatment wetlands are described in the following text. Research and manuals on wetland evaluation techniques (Golet, 1978; Greeson *et al*., 1978; Richardson, 1981; Kusler and Riexinger, 1986) may be used to compare the additional benefits of treatment wetlands with natural wetland functions.

## 19.1 VEGETATIVE BIODIVERSITY

Because of the presence of ample water, the wetland environment is generally characterized by a high diversity and abundance of plants. In many cases, wetland plant communities include multiple vertical strata, ranging from groundcover species to shrubs, and subcanopy trees to canopy tree species. Wetland plant diversity is important in determining wildlife diversity because of the creation of niches associated with differing vegetative structure, reproduction strategies, flowering and seeding phenologies, gross productivity, and rates of decomposition (Mitsch and Gosselink, 2000b).

The wetland treatment system designer should not expect to create or maintain a system with just a few known species. Such attempts frequently fail owing to the natural diversity of competitive species and the resulting high management cost associated with eliminating competition, or because of imprecise knowledge of all the physical and chemical requirements of even a few species. Rather, the successful wetland designer creates the gross environmental conditions suitable for groups or guilds of species; seeds the wetland with diversity by planting multiple species, using soil seed banks, and inoculating from other similar wetlands; and then uses a minimum of external control to guide wetland development. This form of ecological engineering results in lower initial cost, lower operation and maintenance costs, and a most consistent system performance.

This section presents an overview of the floristic diversity that naturally develops in treatment wetlands as well as some details of the growth requirements of commonly occurring plant species in wetland treatment systems. These microbial and plant species are typically the dominant structural and visual components in treatment wetlands. An understanding of their basic ecology will provide the wetland designer or operator with insight into the mechanics of their "green" wastewater treatment unit.

### Wetland Plants

#### Algae

There are multiple designations of the algal component of wetland vegetation. The term *periphyton* describes the community of organisms that grows attached to emergent and submerged plants. Although periphytons usually begin colonization of new plant surfaces by attaching algal growth of filamentous and unicellular species, this functional component also includes mat-forming assemblages of algae, fungi, bacteria, and protozoans. Benthic algae are attached to the sediment–water interface. Planktonic or free-floating algae are generally not a large component of wetland ecosystems unless open or deep water areas are present. Plankton spend most of their life cycle suspended in the water column and are of potential concern as a source of total suspended solids (TSS).

Algae are often the first colonizers in sparsely vegetated, newly constructed wetland basins. They are capable of rapid colonization, and for some months may outcompete the macrophytes. Eventually, emergent plants will fill in, block the light, and reduce the algal populations.

Algae are only rarely selected as the dominant plants in treatment wetlands. Exceptions include the technology known as *algal turf scrubbing* (Adey *et al*., 1993; Craggs *et al*., 1996; Craggs, 2000) and the use of periphyton, known in Florida as *periphyton stormwater treatment* (Vymazal, 1989; Kadlec and Walker, 2004). Algae are not the target of attempts at planting or management and would not be considered a major factor in system diversity.

#### Macrophytes

The term *macrophyte* includes vascular plants that have easily visible tissues. A wide variety of macrophytic plants occur naturally in wetland environments. The U.S Fish and Wildlife Service has more than 6,700 plant species on its list of obligate and facultative wetland plant species in the United States. Godfrey and Wooten (1979; 1981) list more

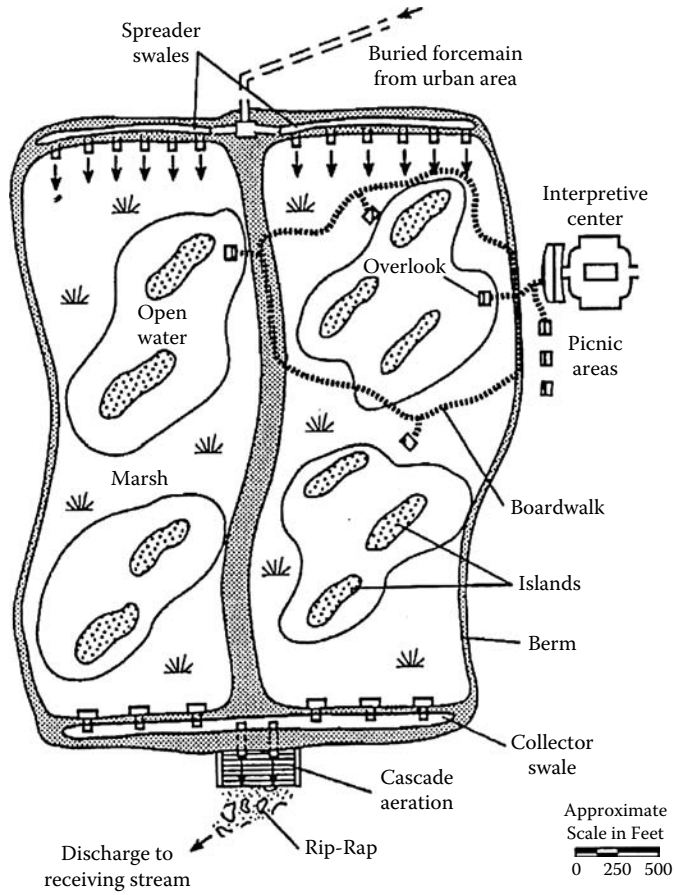

**FIGURE 19.1** Conceptual plan for treatment wetlands with ancillary benefits. (From Kadlec and Knight (1996) *Treatment Wetlands*. First Edition, CRC Press, Boca Raton, Florida.)

than 1,900 species (739 monocots and 1,162 dicots) of wetland macrophytes in their taxonomy of the southeastern United States. Obligate wetland plant species are defined as those that are found exclusively in wetland habitats, whereas facultative species are those that may be found in upland or in wetland areas. There are many guidebooks that illustrate wetland plants, for example, Hotchkiss (1972) and Niering (1985). Lists of plant species that occur in wetlands are available, for example, RMG (1992).

Wetland macrophytes are the dominant structural component of most wetland treatment systems. The terms *emergent*, *floating*, and *submerged* refer to the predominant growth form of a plant species. In the emergent plant species, most of the aboveground part of the plant emerges above the waterline and into the air. These emergent structures are generally self-supporting. Emergent wetland plant species are the primary concern in this section because they provide the dominant visual impression in wetland treatment systems. Floating and submerged vascular plant species may also occur in wetland treatment systems. Floating species have leaves and stems buoyant enough to float on the water surface. Submerged species have buoyant stems and leaves that fill the niche between the sediment surface and the top of the water column. Floating and submerged species are more typical of deeper, aquatic habitats within the wetlands, and they may dominate in wetlands when water depth exceeds the tolerance range for rooted, emergent species.

## Water Regime

The hydropattern, or water regime, of the water is the most important contributor to the wetland type or class (Gosselink and Turner, 1978; Gunderson, 1989). The concept of water regime includes two interdependent components: (1) the duration of flooded or saturated soil conditions (the hydroperiod as a percentage of time with flooding), and (2) the depth of flooding (Gunderson, 1989). Whereas *hydroperiod* refers to the duration of flooding, the term *water regime* refers to hydroperiod as well as to the combination of water depth and flooding duration (depth–duration curve). The importance of this factor as a determinant of wetland ecology cannot be overstated, because an incorrect understanding of the hydroperiod and water regime limitations of wetland plant species is the most frequent cause of vegetation problems and shifts in constructed wetlands.

Plant survival in flooded environments is a balance between the severity of oxygen limitation and the adaptations available to overcome this oxygen shortage. Thus, hydrophytic plants may be adapted to survive and flourish

in specific flooded conditions, for example, for three months each year, or in "clean" or flowing water, which might have higher *in situ* dissolved oxygen concentrations (Gosselink and Turner, 1978). However, these same plants may not be able to grow or survive during five months of flooding or in stagnant or "dirty" water conditions. Likewise, plants may have adaptations that allow prolonged survival in 0.3 m of water, but not in 0.6 m. It may be hypothesized that this balance is tilted unfavorably at higher water levels because of reduced aerial plant stem surface area to provide oxygen to the roots through the lenticels and aerenchymous tissues. This proposed explanation is supported by the finding that hydrophytes generally respond to flooding by growing taller—a growth response that allows a more favorable balance between emergent and submerged plant organs (Grace, 1989).

## Propagation

Wetland plants increase their numbers and density through asexual and sexual reproduction. Asexual reproduction refers to an increase in the number of individuals of a plant species through vegetative growth and typically occurs through the growth of roots or rhizomes, with subsequent emergence of new aboveground stems and leaves. Technically, a cattail bed that developed vegetatively from a single parent plant is a single plant. However, when these rhizomes are cut or decay, the individual daughter plants may remain viable and continue to spread vegetatively. A number of woody wetland plant species can spread vegetatively through coppice growth from viable root systems.

Most wetland plant species also may increase their numbers through sexual reproduction. In sexual reproduction, two individual plants, or the male and female flowers from a single plant, contribute gametes to form seeds with new combinations of genetic material. Sexual reproduction is important in providing alternative strategies for plants to survive from year to year through seasonal extremes, to propagate the species over large distances, to rapidly colonize new habitats, and to provide genetic variants that can adapt to changing environmental and competitive conditions.

Because of the potential for year-to-year hydrological variations in natural herbaceous wetlands with large numbers of annual plant species, many species produce seeds that remain viable for years. These seeds accumulate during productive years and remain dormant until conditions are favorable for germination, frequently after a period of desiccation and rewetting. This storage of viable seeds is known as a seed bank and has been studied in a number of marsh ecosystems (Pederson, 1981; Leck *et al*., 1989). In some cases, soil from a natural wetland with a seed bank can be used to establish a new constructed wetland. Most seeds in seed banks are annuals, but in some marshes, up to 50% may be perennials. Numbers of seeds range from <100/m$^2$ to >375,000/m$^2$ (Leck *et al*., 1989). A typical freshwater marsh in Manitoba had 4,582 seeds/m$^2$ and 34 species in emergent areas and only 93 seeds/m$^2$ in open water areas (Pederson, 1981).

## Biodiversity

Constructed treatment wetlands are typically dominated by emergent marsh, floating aquatic plant, or submerged aquatic plant communities. Emergent marsh species are frequently intermingled and codominant with populations of small floating aquatic plants such as duckweed (*Lemna* spp.). Most constructed treatment marshes in the United States are dominated by cattails (*Typha* spp.) or bulrush (*Scirpus* spp.) and, in Europe, by common reed (*Phragmites australis*) or grasses *(Phalaris arundinacea* or *Glyceria maxima*); however, many treatment marshes are dominated by other species or by a complex admixture of plant species, which include cattails, bulrush, grasses and/or reed as the dominant species. These plants are selected because they are robust and can survive in a wide variety of environmental conditions—in other words, they are survivors. They are inexpensive, plentiful in supply, and easy to propagate. However, they may also be viewed as a nuisance species owing to their ability to crowd out other species and assume visual dominance.

In the United States, species such as *Phalaris arundinacea, Lythrum salicaria, Typha* spp., and *Phragmites australis* are considered by many to be undesirable and aggressive invaders. These may take over natural wetlands and also be a component of treatment wetlands. Pollutant removal processes do not require these species. They are often selected on the basis of cost and survivability. Unfortunately, many people now erroneously equate free water surface (FWS) treatment wetlands with the low biodiversity and nuisance species.

Many constructed treatment wetlands undergo plant succession during their operational life. Constructed marshes tend to remain as marshes as long as flooding is nearly continuous and water depths exceed about 5 cm. However, if the water is too deep, then some emergent species will give way to submerged and floating plants. In any case, new plants find their way into the system. For instance, Schwartz *et al*. (1994) found numerous volunteer species in a Florida constructed wetland. The system was established by planting a diverse set of 21 species. After one year, 185 species were found in the system. A side-by-side study of wetland vegetation changes was conducted at the Olentangy River wetlands site in Ohio (Mitsch *et al*., 2004). As seen in Table 19.1, the effect of the initial planting strategy (planted or unplanted) was gone in three years. The volunteer cattails were then eaten out by muskrats and replaced by volunteer bulrushes in both wetlands. The Tres Rios, Arizona, wetlands were planted in an elegant mosaic with *Scirpus validus* (soft-stem bulrush) and *Scirpus olneyi* (three-square bulrush), having varying numbers of deep zones and islands (CH2M Hill, 1995). During the spring and summer of the third year after startup, almost all the vegetation died in all four wetlands for reasons that have not been fully resolved. The three possible causes were drowning, starvation, and sulfide toxicity (Kadlec, 2006b).

Thus, it is probable that the species patterns and types set by ecological or botanical designers will not survive in many circumstances. Such "designer" wetlands are likely to evolve

**TABLE 19.1**
**Progression of Two Side-by-Side Wetlands at the Olentangy River Wetlands Park over a Start-Up Period of Nine Years**

| | Wetland 1 (Planted) | Wetland 2 (Unplanted) |
|---|---|---|
| Year 1 (1994) | Algal pond with few macrophytes | Algal pond with few macrophytes |
| Year 2 (1995) | Plants developed, particularly around the perimeter, to about 13% macrophyte cover | Essentially no macrophyte cover |
| Year 3 (1996) | Continued to develop in vegetation cover, with about 39% cover | Developed to about 35% macrophyte cover by August, essentially catching up with the planted wetland within 3 growing seasons |
| Year 4 (1997) | About 54% cover | About 58% cover |
| Year 5 (1998) | Wider diversity of cover; not dominated by *Typha* | Began to be dominated by *Typha* |
| Year 6 (1999) | Dominated by *Typha* | Dominated by 3–4 of the planted species |
| Year 7 (2000) | Similar to 1999, except muskrats began to have a dramatic effect | Similar to 1999, except muskrats began to have a dramatic effect |
| Year 8 (2001) | Maximum muskrat impact, vegetation cover was lower than 1995 | Maximum muskrat impact, vegetation cover was lower than 1995 |
| Year 9 (2002) | Drawdown from April through June; developed cover of *Schoenoplectus tabernaemontani* | Drawdown from April through June; developed cover of *Schoenoplectus tabernaemontani* |

into other species mixtures and patterns. Wetlands that rely on antecedent seed banks and natural importation will develop more slowly, but are more likely to be regionally adapted. "Self-designed" wetlands may not be avoidable. It seems reasonable that new wetlands should be established with a species mix that provides a headstart for a number of regional species that can tolerate the water quality and hydropatterns deemed proper for water quality improvement.

Table 3.1 summarizes the number of plant species reported for the treatment wetlands in the North American Treatment Wetland Database, v.2 (NADB database, 1998). Almost 600 species of macrophytic plants have been reported in constructed treatment wetlands. Of these observed plant species, 501 are emergent herbaceous macrophytes, 31 are floating aquatic species, 12 are submerged aquatics, 17 are shrubs, 25 are trees, and 5 are vines. While the NADB v.2 data collection effort provides some insight into the plant diversity at constructed treatment wetland sites in North America, the level of investigation varied widely between sites, and these numbers should be considered as the minimum number of plant species that actually occur in treatment wetlands.

Wetland plant diversity is a poorly understood subject both in unaffected natural wetlands and in treatment wetlands. Wetlands are frequently dominated by a few plant species (for example, cattail, sedge, or sawgrass marshes) that are best adapted to stressful environmental conditions, such as low nutrient or soil oxygen levels and fluctuating water levels. Other unaffected natural wetlands have higher plant diversity and greater evenness between multiple dominant plant species. Constructed treatment wetlands cover the same range of plant dominance and diversity as unaffected natural wetlands. Information collected for NADB v.2 indicates that hundreds of plant species occur in a variety of treatment wetlands. Even when treatment wetlands are dominated by cattails or bulrush, dozens of other herbaceous and woody plant species are typically present. Thus, the issue is not so much of diversity as it is of dominance.

It is possible to start the treatment wetland with a variety of regionally prevalent plants so that these have an opportunity to compete during the successional development of the system. This philosophy has been implemented at a number of treatment wetlands, including 21 species planted at the Orange County Eastern Service Area in Florida (Schwartz *et al*., 1994), 20 species at Victoria, Texas (Reitberger *et al*., 2000), and 14 species at Wakodahatchee, Florida (Bays *et al*., 2000). The Oregon Gardens treatment wetland used dozens of native wetland plants (Figure 19.2), and the Lapeer, Michigan, wetland used four species that did not include treatment wetland species, although bulrushes were used on the fringes (Figure 19.3).

## 19.2 WILDLIFE

Numerous wildlife species of all taxonomic orders depend on wetlands as habitat. Plant structures that are lost into the aquatic portion of the food chain are typically degraded by a complex assemblage of small aquatic organisms that include invertebrates (protozoans, worms, molluscs, arthropods, and others). These organisms, in turn, serve as the basis of the food chain for other invertebrates, and for diverse vertebrate groups such as fish, amphibians, reptiles, birds, and mammals. Above-water plant materials may also be processed as food by nonaquatic fauna that have no direct contact with the water in the wetland.

We know from qualitative observation that a diversity of microscopic invertebrates such as protozoans and

**FIGURE 19.2** The Oregon Gardens treatment wetland, near Silverton, Oregon. A tremendous diversity of vegetation was introduced. The wastewater is better than secondary at the wetland inflow.

microarthropods is present, but there are no comprehensive lists of even the most common species in these groups. The macroinvertebrate groups most commonly studied are annelids (worms), arachnids (spiders and mites), crustaceans (amphipods, isopods, copepods, water fleas, and crayfish), insects, and molluscs. Fish are an obvious component of most aquatic ecosystems, but knowledge of their role in wetlands is limited. Amphibian and reptile (herptile) populations in wetlands tend to be variable and secretive and, therefore, difficult to quantify. Birds are extremely mobile, and many species include wetlands in some part of their life history. Because birds are one of the fauna groups that people appreciate the most, study of this wildlife group in treatment wetlands has been more extensive than for any other. Many mammal species use wetlands as an important component of their total habitat. Some depend greatly on wetlands, whereas others use wetlands for specific and narrow life history requirements.

### Macroinvertebrates

Information concerning wetland macroinvertebrate populations is infrequent in the published literature. A number of specific findings from wetland treatment systems are described in the following text to provide an indication of typical macroinvertebrate population densities and diversities in these systems.

A total of 518 species of aquatic invertebrates have been recorded from treatment wetlands in NADB v.2 (Table 19.2). These include 14 species of aschelminthes (cavity worms), 55 species of crustaceans, 10 species of arachnids, 23 species of molluscs, and 343 species of insects. Thirty-two treatment wetland systems listed in NADB v.2 have invertebrate data, although, in most cases, only species lists are available. The average Shannon-Weiner diversity (H') of benthic macroinvertebrate collections was 1.36 units (with a total of 342

**FIGURE 19.3** The Durakon treatment wetland, near Lapeer, Michigan. Most of the plants selected for the wetland are not in common use in treatment wetlands (*Carex lacustris, Sagittaria latifolia, Alisma plantago-aquatica, Pontederia cordata,* and *Sparganium eurycarpum*). Only narrow fringe zones were planted with species with established treatment performance (*Scirpus* spp.) The wastewater inflow is lagoon effluent.

species reported) for constructed treatment wetlands. Benthic macroinvertebrate evenness averaged 0.56 for constructed wetlands. Average benthic populations in the NADB v.2 are 6,083 individuals per square meter for constructed treatment wetlands. Total populations of mosquito larvae and pupae in treatment wetlands from a few projects had an average of 1,144 individuals per cubic meter for constructed treatment wetlands (Hemet and Sacramento, California).

## Fish

The number of fish families that typically occur in wetland environments in North America is small compared to pond, lake, and stream environments. The fish species typical of wetlands are either adapted to obtaining oxygen in low-oxygen waters or only visit wetlands on a seasonal or shorter basis. The most widely distributed fish species in warmer temperate, subtropical, and tropical wetland treatment systems is the mosquitofish (*Gambusia affinis*) in the topminnow family. This species has been widely disseminated in North America and abroad in shallow wetlands and ponds because of its noted ability to consume the larvae and pupae of mosquitoes. In more northern climates, the black-striped topminnow (*Notrophus fundulus*) is a mosquito predator, and the central mudminnow (*Umbra limi*) is an important wetland fish species.

Seventy-seven fish species are reported from 13 treatment wetland sites in NADB v.2 (70 species from constructed treatment wetlands and 15 species from natural treatment wetlands). Table 19.3 summarizes fish data by site and system in NADB v.2.

Fish enter treatment wetlands from inlet and outlet streams as well as from other sources, such as raptor drops. For example, smallmouth bass (*Micropterus dolomieui*) and sunfish (*Lepomis macrochirus*) swam up the outlet structures at the Hillsdale, Michigan, treatment wetland, and took up residence in all deep zones. Drawdown of the wetlands, for purposes of maintenance and retrofitting, killed the fish. They were effectively precluded after the deep zones were filled for muskrat control. Bass and sunfish also are found in the Incline Village, Nevada, constructed wetlands, which are abutted by natural wetlands with deep water habitats. Tilapia (*Oreochromis* spp.) found their way into the Tres Rios, Arizona, wetlands, although there appeared to be no route open to them from either downstream with entering water (WWTP) or upsteam from receiving water (drop boxes and cascades). Drawdown of the wetlands, for research purposes, killed the fish. Tilapia also are prolific in the Lakeland, Florida, constructed wetlands—again with no obvious route for them to have emigrated.

Fish may be problematic in treatment wetlands, particularly those that feed or nest on the bottom. For instance, at the Des Plaines constructed wetlands in Illinois, carp (*Cyprinus carpio*) were unintentionally introduced into the wetland from the pumped source water (Des Plaines River), presumably as very small individuals. Over the course of two years, the fish grew in size to about 15 cm. These larger fish were observed to stir bottom sediments and impair suspended solids removal. The carp were removed from the wetland through a winter drawdown and freeze. A similar phenomenon occurred at the Tarrant County constructed wetlands in Texas, where floodwaters from the source river brought carp (*Cyprinus carpio*), shad (*Dorosoma cepedianum*), and bullheads (*Ictalurus* spp.) into the system. The activity of the fish caused severe bioturbation of the sediments during feeding and spawning activities (APAI, 1994). The cells were dewatered, and egrets and herons effectively removed the stranded fish.

A 21-ha constructed wetland has been used for final polishing of an industrial effluent since 1999 in Victoria, Texas. Fish populations in the eight wetland cells have been used as an indicator of environmental condition at or near the top of the wetland aquatic food chain (Reitberger *et al*., 2000). This constructed treatment wetland includes three different types of cells arranged in parallel and in series. Treated effluent from a conventional activated sludge treatment facility is distributed into the stage 1 wetland cells, which are colonized primarily by cattails (*Typha* spp.) and contain transverse deep water zones colonized by submerged and floating aquatic plants. Water from these cells flows into the stage 2 cells containing a diverse marsh plant community and transverse deep water zones. Water flows finally into a habitat cell with diverse water depths (up to 3 m). Six fish species have been collected; mosquitofish (*Gambusia affinis*) have the highest density, and populations of other species are variable from year to year, presumably in response to climatic conditions and water quality conditions. Sunfish (*Lepomis macrochirus* and *Lepomis gulosus*), bluefin killifish (*Lucania goodie*), silversides (*Menidia beryllina*), and gizzard shad (*Dorosoma cepedianum*) populations are sporadic in the habitat cell.

### Amphibians and Reptiles

Amphibians and reptiles (known jointly as herptiles) are part of the top consumer structure of wetlands, including treatment wetlands. The four most important groups are frogs (anurans), turtles, snakes, and alligators. Twenty-one anuran species are reported from six constructed and three natural treatment wetlands in NADB v.2 (ten from the constructed treatment wetlands). Turtles are found primarily in wetland treatment systems that have areas of deeper, open water, and especially in pretreatment lagoons. Species of turtles frequently found in these habitats include snapping turtles (*Chelydra serpentina*), mud turtles (*Kinosternon subrubrum*), and painted turtles (*Chrysemys picta*). A wide variety of snakes are associated with wetlands and wetland treatment systems and play an important ecological role by feeding on fish, invertebrates, birds, and small mammals. In North American treatment wetlands, the snakes that receive the most interest are the venomous species, including the cottonmouth or water moccasin (*Agkistrodon piscivorus*), the copperhead (*Agkistrodon contortrix*), and timber rattlesnakes (*Crotalus horridus*), which occasionally inhabit wetlands. In fact, most snakes in wetlands are nonpoisonous species of water snakes (Genus *Natrix*), swamp snakes (*Liodytes* and *Seminatrix*), rat snakes (*Elaphe*), and king snakes (*Lampropeltis*). Alligators (*Alligator mississippiensis*) have been observed at relatively high densities in wetland treatment systems having open water areas and high fish populations (Figure 19.4). Densities in the Florida stormwater treatment constructed wetlands have reached proportions sufficient to allow hunting.

### Birds

About 600 different bird species (one third of the total resident bird species) are either partially or wholly dependent on wetlands for some part of their life history in North America (Kroodsma, 1978). The diversity and abundance of birds in and around wetlands attract many bird watchers, who repeatedly have observed that their species lists are longer and their counts higher when they include wetlands in their counting areas. Where these water bodies are enriched by nutrients and

**FIGURE 19.4** Alligators are at the top of the food chain in wetland systems across the American south. (Photo courtesy J. Bays.)

| Orlando Easterly, Florida | 494 | 141 | 0.29 (0.11–0.54) |
| Lakeland, Florida | 498 | 63 | 0.38 (7.7–13.5) |

organic matter from wastewater and stormwater discharges, bird watchers usually find even better success in their sport.

A number of wetland bird species are game species and are hunted. Treatment wetlands frequently provide good waterfowl habitat. In a few cases, these treatment wetlands have been used for duck hunting as a recognized secondary benefit. The stormwater treatment constructed wetlands in Florida are open to duck hunting and are deemed the best hunting spots in the entire state. In other cases, wastewater has been found to improve the waterfowl breeding and feeding habitat as a secondary or nonessential side effect (Wilhelm *et al*., 1989).

A few quantitative studies of bird populations in wetlands treating wastewaters are available. If the wetland is constructed on previous upland, increases in bird species and abundance have been observed, compared to the previous upland habitat (Hickman, 1994). During the summer of 1991, the U.S. EPA conducted a study of the environmental condition of six constructed wetland treatment systems in the United States (McAllister, 1992; 1993a; 1993b). This inventory included two systems in the arid west (Incline Village, Nevada, and Show Low, Arizona), two systems along the coastal plain of Mississippi (Ocean Springs and Collins), and two systems in peninsular Florida (Orlando Easterly and Lakeland). Bird surveys were conducted by local ornithologists using slightly different methods. Table 19.4 summarizes the major findings of this research.

The EPA bird surveys at constructed wetland treatment systems confirmed that these systems have high species richness and population densities compared to control wetlands. The total number of bird species observed at each site during the 1991 study ranged from 33 to 63, with average daily population densities of all wetland-dependent species ranging from about 7 to 19 birds/ha. Densities of wading birds at the two central Florida constructed wetland treatment systems averaged 0.29 birds/ha at Orlando and 0.38 birds/ha at Lakeland. These densities were as high as, or higher than, comparison data from marshes along the St. Johns River, the central Everglades, and Central America. Highest total bird densities were noted at the arid region sites where there are few natural wetlands available to compete as alternative habitats. The EPA studies also concluded that the constructed treatment wetlands are important habitats for a number of endangered or threatened wetland-dependent bird species.

Bird usage of the 16-ha DUST (Demonstration Urban Stormwater Treatment) marsh in Coyote Hills Regional Park near Fremont, California, was studied by Duffield (1986). Weekly or biweekly bird censuses were conducted in the DUST marsh and a nearby 18.3-ha control from mid-January 1984 through mid-June 1985. The mean abundance of wetland birds in the marsh areas ranged from 100 to 300 (6.25 to 18.75 birds/ha) in the DUST marsh and 90 to 420 (4.91 to 23.0 birds/ha) in the control marsh. The mean number of species per census ranged from 14 to 23 in the DUST marsh and 10 to 18 in the control area. Highest mean species counts were observed in both marshes during the winter and spring seasons. During all seasons, the dabbling and diving ducks preferred the control marsh, and shorebirds, gulls, and terns preferred the DUST marsh. Individual fish-eating wading birds were generally present in greater numbers in the DUST marsh than in the control area. These populations were enhanced by the presence of roosting black-crowned night herons (*Nycticorax nycticorax*). Shorebirds preferred the mudflat areas of the overland flow cell in the DUST marsh. The most common shorebirds were American avocets (*Recurvirostra americana*), black-necked stilts (*Himantopus mexicanus*), and marbled godwits (*Limosa fedoa*).

Bird populations at the Victoria, Texas, constructed treatment wetland have been quantified by designed studies and by birdwatcher counts (Reitberger *et al*., 2000). A total of 188 bird species had been observed using the wetland as of June 2000. Annual species numbers ranged from 106 to 144, with average numbers of species per count from 34 to 53; average annual bird densities ranged from 19 to 26 birds per hectare. Bird population numbers were dominated by grebes, cormorants, ibis, waterfowl, vultures, coots, rails, stilts, sandpipers, gulls, doves, swallows, wrens, warblers, and blackbirds. This site is open to school groups and the public, and bird watching continues to be one of the most important ancillary benefits of the wetland.

The Wakodahatchee, Florida, wetlands are attractive to wildlife (Bays *et al*., 2000). The numbers of bird species observed within the wetlands totaled 119 and 142 in 1997 and 1998, respectively. Thirteen of these species are considered commercially exploited, threatened, or endangered by state and federal agencies. Bird densities estimated for 1997 averaged 53 per hectare. At least 13 species of birds were observed to have nested on the site, indicating that the

**FIGURE 19.5** Thousands of blackbirds move in and out of the Sweetwater constructed wetlands in Tucson, Arizona.

system is providing suitable avian nesting habitat for certain species.

Bird use and water quality treatment are not always totally compatible uses of constructed wetlands. There may be conflicts between maintenance activities and the lifestyles of threatened or endangered species. For example, the nesting habits of stilts and burrowing owls lead them to prefer the levee areas of drained or dewatered wetland cells. This has interfered with system restarts in the stormwater treatment constructed wetlands in Florida. Huge flocks (thousands) of yellow-headed blackbirds (*Xanthocephalus xanthocephalus*) have been implicated in recontamination of water by pathogens in Arizona (Orosz-Coghlan *et al*., 2006) (Figure 19.5). Waterfowl have been implicated in turbidity increases at the Columbia, Missouri, constructed wetlands (Knowlton *et al*., 2002). Waterfowl, particularly geese, can also be devastating on new transplants and can effectively wipe out an entire planting.

## Mammals

A wide variety of mammals reside in or visit treatment wetlands. Some of the more common for North America are listed in Table 19.5. Shrews (Family Soricidae) are found along the edges of wetlands and moist fields and feed on insects. But by far the largest and most important group of mammals associated with wetlands are rodents. Small rodents are also found in FWS systems, such as mice and voles, most of which are herbivorous species that graze on plants and seeds and are prey to fish, wading birds, and raptors. However, it is the larger rodents that have proven problematic in many treatment wetlands. These rodents are briefly discussed herein.

### Muskrats

Muskrats (*Ondatra zibethica*) cut large numbers of emergent herbaceous plants, primarily cattails (Latchum, 1996), and build feeding platforms and nests (mounds). This grazing can change treatment wetland areas from densely vegetated to a patchwork of open and emergent areas (Kadlec *et al*., 2007). Muskrats consume a portion of the annual net primary productivity, principally rhizomes, but their mounds represent a greater share of this production. Densities of 20 or more animals per hectare have been found, which can destroy the majority of the macrophyte standing crop in a given year. At such an exacerbated scale, muskrat herbivory may be termed as an "eatout," and it is evidenced by the removal of essentially all emergent plant parts (Figure 19.6). Destruction of the wetland vegetative infrastructure may create an attendant loss of some water quality functions, but may not harm others. No designed research studies have been conducted to quantify the effects of muskrat eatout on wetland water quality performance, but potential impacts may

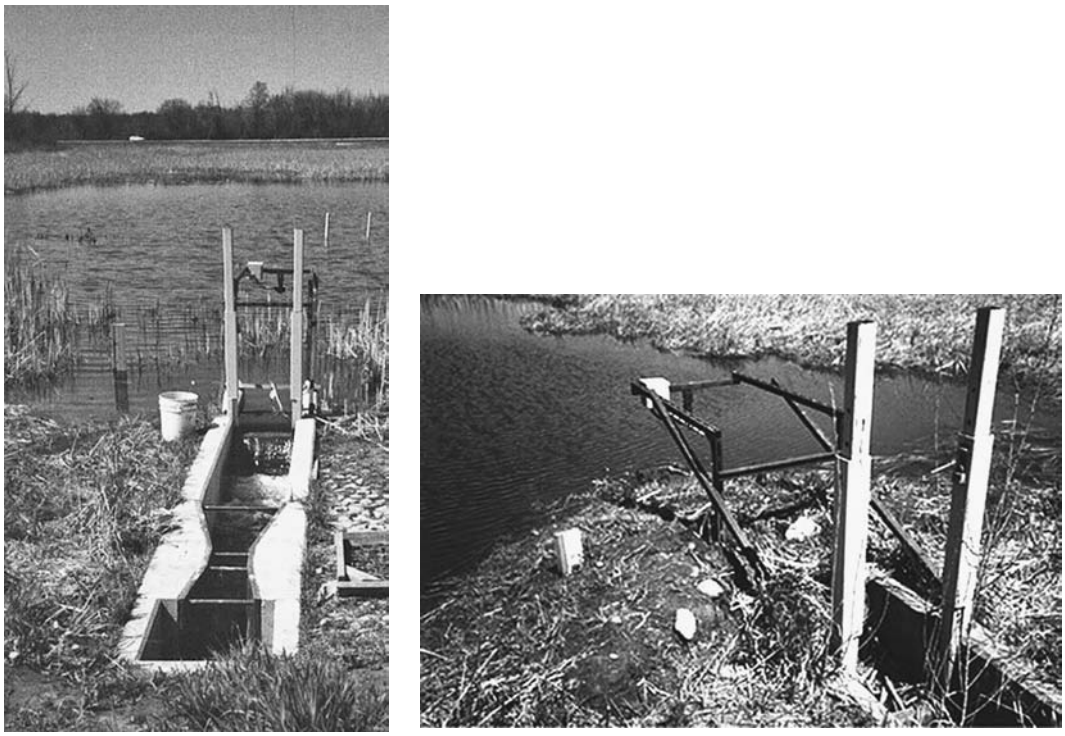
be speculatively identified. Two water quality measures are very liable to change because of denudation: dissolved oxygen (DO) and total suspended solids (TSS). Increased potential for atmospheric reaeration is present in the plant-free wetland, and plankton can generate oxygen within the water column because there is sufficient light. A 2-ha wetland in Commerce Township, Michigan, provided data to support these intuitive concepts. In an early, fully vegetated phase, this wetland had an annual average outflow of 6 mg/L TSS and 9.8 mg/L DO. After a 100% muskrat eatout, TSS rose to 12 mg/L and DO rose to 10.4 mg/L. There were also possible muskrat impacts at the Olentangy, Ohio, wetlands. An eatout occurred in the year 2000, five years after system start-up (Mitsch *et al*., 2004). Thereafter, turbidity increased upon passage, in contrast to decreases that occurred prior to the eatout. A similar response for total phosphorus was observed. However, such results are not conclusive because of other factors in system operation.

The integrity of berms may be threatened by burrowing. Impacts on wetland hydraulics are also possible. In all cases, loss of emergent vegetation has been viewed with dismay by owners, regulators, and the general public. The damage caused by muskrats, primarily by burrowing in containment and separation berms, is not a matter of conjecture. There are several examples of compromised parallel cells in which divider berms have been breached by burrows: Estevan, Saskatchewan (Duncan *et al*., 1999); Corcoran, California (Gao *et al*., 2003); and Sacramento, California (Nolte and Associates, 1998b). At the Manitoba Interlake site 1, it was found that muskrat burrows were extensive and were threatening to breach the dikes at several locations. Roads have been damaged by burrow collapse at Saginaw, Michigan (unpublished), and at Sacramento.



When muskrats eat all the emergent plant parts, there is a large visual impact, regardless of physical or water quality damage. A common perception is that wetlands should be lush and green to be effective in treatment. This is an intuitive carryover from agriculture, where lush green fields are a strong indicator of a good crop. Consequently, owners, regulators, and the general public equate good emergent stands of plants with the highest treatment capability. This may or may not be the case, but the urge to "fix it" is irrepressible in many cases. From the point of view of treatment efficiency, an eatout calls for careful scrutiny of performance to ascertain if the damage has, in fact, impaired pollutant removal. If not, then muskrat control becomes an expense associated with the ancillary benefit of a green emergent appearance. At Brighton, Ontario, where water quality was relatively unaffected by extensive muskrat herbivory, the aesthetic aspect became a concern. Residents of the community viewed the partially vegetated wetland as ineffective and expressed concern that there might be environmental consequences.

### Nutria

Nutria (*Myocastor coypus*) are an introduced species from South America, but they now range across the southern and northwestern United States. Nutria cause all the same problems as do muskrats, except that the animals are larger, and each individual is capable of more damage to vegetation. Mature nutria are large and have fewer natural predators. Nutria are strictly herbivorous and feed on a broad range of plants in treatment wetlands, including cattails, grasses, water hyacinth, duckweed, and young tree seedlings. Nutria cut vegetation in a manner similar to muskrats and build feeding platforms and nest mounds. They are prolific and commonly reach damaging population densities unless they are controlled by trapping or shooting. Nutria have occurred in problematic numbers in many treatment wetlands, including Halsey, Oregon; Victoria, Texas; and West Jackson County, Mississippi.

### Beavers

Beavers (*Castor canadensis*) are found in wetland treatment systems from Texas to the Canadian provinces. Beavers feed

(a) (b)

**FIGURE 19.7** Beaver activity caused complete closure of this outlet Parshall flume structure at Des Plaines River, Illinois, wetland EW3. A dam of soil, rocks, and sticks was constructed. Note the staff gage in the left panel is incorporated into the dam in the right panel.

on bark, twigs, and leaves from a variety of trees and, consequently, may cause undesirable herbivory damage in and around wetland treatment systems. For instance, the Roblin, Manitoba, constructed wetland was integrated into the adjoining terrestrial landscape with poplar tree (*Populus* spp.) plantings (PFRA, 2002). With an abundance of their favored aquatic habitat and favorite food (poplar), the beavers built lodges and decimated the tree plantings.

However, beaver damage to constructed wetlands does not stop with herbivory. When beavers find flowing water, such as in a treatment wetland structure, they construct a dam to contain that water, and create a deep-water habitat that will protect their nesting lodge from predators. The animals are large, up to 40 kg body weight, and can move stones of several kilograms, small logs, sticks, and mud to create stoppages in flows (Figure 19.7). Plugging of structures is clearly inimical to the proper performance of the wetland. Problems with beavers plugging structures have been experienced at many locations, including Fort Worth, Texas; Tres Rios, Arizona; and Des Plaines River, Illinois. Removal of the obstructions is not effective, because the animals can rebuild a dam literally overnight. Removal of the animals is the only recourse.

Beavers construct travel trails to facilitate movement with minimum risk from predators. These may be water-filled ditches leading to and from deeper water areas in upland margins or deepened areas in marginal shallows. In treatment wetlands, these travel trails may connect deep zones, thus providing increased opportunity for hydraulic short-circuiting.

Beavers burrow into banks as an alternative to lodges made of branches and small logs, or as an adjunct to such lodges. These burrows may create significant leakage from the wetland or compromise the integrity of containment berms. For instance, beaver burrows caused failure of the containment berm of a constructed infiltration bed/wetland at Houghton Lake, Michigan, causing over 1,000 $m^3$ of soil to wash out in one event.

These several effects of the presence of beavers are of considerable concern and often warrant removal of the animals.

## Predators

The richness of the invertebrate, avian, and small mammal populations in treatment wetlands provides good hunting for a number of predators. Mink (*Mustela vison*) prefer muskrats as food and will harvest a sizeable fraction of the resident population in the constructed wetland. Coyotes (*Canis latrans*) will prey upon waterfowl nestlings, provided the water is not too deep. As a consequence, wetlands that are subject to seasonal drawdown and dryout during the nesting season are vulnerable to coyote predation. This situation exists for the Incline Village, Nevada, wetlands, because water is diverted to crop irrigation starting in the nesting season.

Raccoons (*Procyon lotor*) and bobcats (*Lynx rufus*) are frequent visitors to wetland systems, from Arizona to Michigan in the United States. Alligators (Figure 19.4) are extremely numerous in the South Florida stormwater treatment areas.

### Incidental Visitors

There are numerous animals that may, from time to time, visit treatment wetlands and, in many instances, create problems. The Florida stormwater wetlands are very large and have very large inlet structures through which an occasional manatee (*Trichechus manatus*) may pass into the system. These large, gentle aquatic mammals are not a threat to the treatment system, but the habitat is wrong, and efforts are made to move them back to their natural habitat. The Tarrant County wetlands in central Texas were periodically visited by wild pigs (*Sus scrofa*), an abundant introduced species (more than one million animals estimated for Texas), with pernicious effects on the native ecosystems (Pimentel *et al*., 1999). The tubers of wetland plants were rooted up and eaten in the pilot wetland cells. SSF wetlands are also susceptible to these grazing problems; damage to plantings due to whitetail deer (*Odocoileus virginianus*) have occurred near Lutsen, Minnesota, and by wild pigs (*Sus scrofa*) near Nassogne, Belgium. On a worldwide basis, the list of potential troublemakers grows to include animals such as monkeys, which ruined a pilot treatment wetland vegetated with *Cyperus immensus* in Kenya (Abira *et al*., 2005).

## 19.3 DESIGN AND WILDLIFE USE

Each new treatment wetland situation brings a need to balance the wildlife value added and the potential impairment of the structure and function of the system for water quality improvement. To some extent, wetland design can influence this balance, but management can still be an important feature of wildlife control and enhancement. Management strategies are discussed under operations and maintenance in Chapter 22.

### Design to Encourage Wildlife

The general concept of maximizing wildlife values in treatment wetlands was elucidated by Sather (1989):

> In as much as plant community diversity is the key to faunal diversity, primary attention should be devoted to basic factors responsible for plant community diversity. The magnitude of ancillary benefits realized from wetlands constructed for wastewater treatment will be primarily dependent upon the degree of complexity and the amount of interspersion of the hydrophytic plant communities. Engineering design, therefore, should be sensitive to the hydrologic regimes and soil characteristics required to produce these types of plant communities.

Worrall *et al*. (1997) concluded that if constructed wetlands were to support wildlife as an integral function, they should be structurally diverse, with variations in plant types and cover, water depth, and substrate. Further, the wetland should be of sufficient scale and extent to support target species and populations: bigger is better.

The U.S. Environmental Protection Agency (U.S. EPA, 2000c) recognized that multiple values could be obtained from treatment wetlands. The degree of wildlife habitat provided by constructed treatment wetlands varies broadly across a spectrum. At one end of the spectrum are those systems that are intended only to provide treatment for an effluent or other water source and little to no wildlife habitat. At the other end are those systems that are intended to provide water reuse, wildlife habitat, and public use, besides providing a final polishing function for a pretreated effluent or other water source. The guidance provided by the U.S. EPA (2000c) primarily addresses the latter end of this spectrum. To promote wildlife values, constructed treatment wetland designs should avoid rectangular basins and straight channels and rather use diverse and sinuous edges and native vegetation whenever possible. It is desirable to incorporate the constructed wetland into the existing natural landscape with the natural transition zones as margins, perhaps including woody vegetated buffer areas around the site. Where appropriate, the constructed treatment wetland should provide habitat with a diversity of native species comparable to similar wetlands in the region. To the extent practicable, vegetative species diversity should be maximized without increasing the proportion of weedy, nonindigenous, or invasive species at the expense of native species. The biological diversity of the project is likely linked to, or dependent on, physical heterogeneity. This could include providing some areas of open water, creating nesting islands for waterfowl, and leaving some upland and buffer areas for other nesting species.

Waterfowl populations are enhanced if open water areas are interspersed with deep emergent marsh and upland islands. An approximate 1:1 ratio of wetland area devoted to marsh and to open water will provide maximum habitat for a variety of waterfowl species (Weller, 1978). Generally, wetlands adjacent to upland habitats will have greater floral and faunal diversity in proportion to the amount of the edge between adjacent ecosystems. Extending the perimeter does, however, carry added cost. Wading birds prefer a different habitat mix. These species require shallow, sparsely vegetated, littoral areas or perching substrates adjacent to open water areas. To benefit wading bird populations, constructed wetland treatment systems can be designed to provide a broad shelf of emergent marsh with water depth <20–30 cm. Deep, open water areas next to a shallow marsh provide additional foraging habitat. Open water areas and the transitional ecotones among marsh, open water, and adjacent uplands also help promote growth of herptile and fish populations which, in turn, provide food for wading and diving birds.

Depending on regional occurrence and available habitats, other bird varieties will colonize constructed wetlands, too. For example, if living or dead trees are included in the wetland, they will serve as perching and possible nesting sites (Hair *et al*., 1978). Nesting boxes might attract wood ducks and owls. Upland islands surrounded by open water

**FIGURE 19.8** Human and animal exclusion may necessitate fencing. At this Hillsdale, Michigan, remediation wetland site, there is a tall fence to exclude humans and a short fence to exclude muskrats. Whitetail deer (*Odocoileus virginianus*) have been observed jumping over the two-meter chain-link and barbed wire.

provide protection for ground-nesting bird species such as waterfowl.

### Design to Discourage Incompatible Wildlife

Project plans may include mechanisms to control or eliminate undesirable species. Design techniques vary, depending on the species of animal perceived as a possible threat. For instance, beavers may be prevented from plugging structures if the intakes and discharges are diffuse and noiseless and under more than a meter of water. Inlets and outlets may be screened to block entry by larger animals, such as turtles. Chain-link or coarse mesh fencing can block some intruders, such as domestic livestock.

A lack of predator habitat protects muskrats from predators such as hawks and owls. Erecting dead tree stubs or utility poles in an upright position that are of sufficient height to attract raptors can serve as a perch for these aerial predators. Such structures have been very effective in the Show Low, Arizona, wetland environments. Mink, the primary muskrat predator, is ubiquitous across the range of muskrats. These small animals can and will enter treatment wetlands in search of prey and are not deterred by chain-link fencing. Attempts to allow access to larger predators, such as foxes and coyotes, proved ineffective at a remediation wetland in Hillsdale, Michigan.

Exclusion fencing is an effective, but often expensive, option for controlling access by some animals. For example, muskrats have been effectively excluded from the Ducks Unlimited treatment wetlands at Oak Hammock, Manitoba. The exclusion fencing was erected prior to vegetating the site. Ducks Unlimited, Canada, uses 5 cm × 5 cm galvanized stucco wire mesh (hardware cloth), with about 0.30 m of the mesh vertically buried, about 0.5 m upright, and another 0.3 m set to a 45° angle sloped away from the wetland. It is important to ensure that the fencing is placed such that the muskrats cannot burrow underneath or between connected sections. Based on reports from the Ducks Unlimited domestic wastewater treatment wetland at Oak Hammock, Manitoba, similar fencing was installed at the Hillsdale, Michigan, treatment wetland, where it was also successful (Figure 19.8) (Kadlec *et al*., 2007).

Riprap placement along berms and bank slopes can be very effective at preventing burrowing. This involves the placement of up to 50–150 mm riprap in a 200–300 cm layer that extends from the wetland bottom to the top of the berm. Note that although this approach reduces the potential for burrowing into the berm directly at water level, experience at Nanticoke, Ontario, showed that the muskrats burrowed down into the roadway at the topmost edge of the riprap, which was 3 m from the water edge along the three to one side slope. An alternative is chain-link fencing laid into the final deep zone of the wetland and extended to the top of the berm, a technique that has been used successfully at the Lambton, Ontario, wetlands. There is probably a trade-off between mound building and bank burrowing, because both mounds and burrows are acceptable refugia. Thus, by denying bank access, mound building will be encouraged, and vice versa.

### Ecological Risk Analysis

The expanding use of treatment wetlands for remediation of contaminated groundwaters and for various industrial effluents poses a potential threat to resident or migratory animals. Bluntly put, the treatment wetland should not be a health threat to wetland creatures. For many specific chemicals there are water quality standards set to protect the aquatic environment, and these may serve as guidelines for FWS treatment wetlands. There are also standards for sediments in freshwater systems in some cases. In the event that it is determined that a threat may exist, other treatment alternatives such as SSF wetlands should be considered.

The tools for evaluating potential hazards are collectively known as *ecological risk assessment*. Ecological risk assessment is a process that evaluates the likelihood that adverse ecological effects may occur or are occurring as a result of exposure to one or more stressors. The process is used to systematically evaluate and organize data, information, assumptions, and uncertainties to help understand and predict the relationships between stressors and ecological effects in a way that is useful for decision making. This process consists of three elements, as indicated in U.S. EPA (1998):

1. Problem formulation, the first phase, has the purpose of articulating the assessment. The problem is defined, and a plan for analyzing and characterizing risk is determined. Initial work in problem formulation includes the integration of available information on sources, stressors, effects, and the ecosystem and receptor characteristics. From this information, two products are generated: assessment endpoints and conceptual models.
2. Analysis, the second phase, is directed by the products of problem formulation. During the analysis phase, data are evaluated to determine how exposure to stressors is likely to occur (characterization of exposure) and, given this exposure, the potential and type of ecological effects that can be expected (characterization of ecological effects). The first step in analysis is to determine the strengths and limitations of data on exposure, effects, and the ecosystem and receptor characteristics. Data are then analyzed to characterize the nature of potential or actual exposure and the ecological responses under the circumstances defined in the conceptual model(s). The products from these analyses are two profiles, one for exposure, and one for stressor response.
3. During risk characterization, the third phase, the exposure and stressor-response profiles are integrated through a risk estimation process. Risk characterization includes a summary of assumptions, scientific uncertainties, and the strengths and limitations of the analyses. The final product is a risk description in which the results of the integration are presented, including an interpretation of potential ecological adversity, descriptions of uncertainty, and lines of evidence.

As an example, suppose that a treatment wetland is proposed for removal of trichloroethylene (TCE) from the water. One of the endpoints of ecological risk assessment would be the effects on muskrats that inhabit the system. The model could be the transfer of TCE from water to soils, from soils to cattails, and from cattails to muskrats that eat them. Characterization of the exposure would be the computation of how much TCE might be ingested. Characterization of the effect would be a determination of the acute and chronic doses that the muskrat could stand. If the estimated ingestion was well below the harmful dose levels, say, by several orders of magnitude, then the risk would be deemed low and ranked accordingly. This brief example was, in fact, part of the ecological risk assessment for the Hillsdale, Michigan, project (Ecology and Environment, 1996).

Obviously, the use of partially treated water engenders some degree of risk for humans and wildlife within the wetland. The most conservative course of action might be to monitor all potential indicators of contamination that might contribute to a problem of the health of some sector of the ecology—invertebrates up to the carnivores. Wren *et al.* (1997) outline an example of a three-tier, ultraconservative monitoring program. Unfortunately, the cost of such a program would usually be the fatal flaw for the entire project.

## 19.4 HUMAN USE

Humans appreciate wetlands for their commercial values (plant harvesting, livestock grazing, hunting, and aquaculture) and nonconsumptive values (aesthetics, recreation, and research) (Nash, 1978; Reimold and Hardisky, 1978; Sather and Smith, 1984; Smardon, 1988).

### Consumptive Activities

Wetland plants have been used historically for a number of purposes. Various sedges are used for fodder (marsh hay), and cedar (*Thuja* spp.) timber is highly valued. Cranberries (*Vaccinium macrocarpon*) are a high-profit cash crop grown in bogs, and blueberries (*Vaccinium* spp.) are grown commercially in peatland soils.

In North America, at least 46 native tribes were reported to use *Phragmites* historically (Kiviat and Hamilton, 2001). There were approximately 75 different uses of *Phragmites,* of which the most frequent were arrowshaft (17 tribes), cigarette (13), flute (12), whistle (7), pipestem (7), and matting (6). The number of uses per tribe was highest in the southwestern quadrant of North America. In modern times, in Europe, *Phragmites* is used for roof thatching, and it provides a very high-quality structure.

Plant harvest can possibly provide an economic profit from constructed wetlands. Solano *et al.* (2004) assayed two macrophytes, cattail (*Typha*) and reed (*Phragmites*). High levels of biochemical oxygen demand (BOD), chemical oxygen demand (COD), and TSS removal for all treatments were obtained, but cattails showed the greatest production of biomass (22 tons of dry matter per hectare). Both cattails and reeds presented high heating values (17–20 MJ/kg). Ciri *et al.* (2005) speculated that *Typha*, harvested from treatment wetlands, could be an economic fuel. A new rice variety (*Oryza sativa* "Kusahonami") developed for livestock feed was utilized for treating nutrient-polluted river water (Zhou and Hosomi, 2007).

Consumptive uses of wetland animals via hunting and trapping are more easily quantified than nonconsumptive functions. For example, over 10 million ducks and $35 million worth of furs are harvested from wetlands annually (Chabreck, 1978). Constructed treatment wetlands at Orlando (Florida), the stormwater treatment wetlands of Florida, and the Incline Village (Nevada)

**FIGURE 19.9** The Tollgate urban stormwater wetland in Lansing, Michigan.

system are used for waterfowl hunting. An ancillary benefit of the stormwater treatment areas (STAs) is that vegetation and shallow waters have attracted many ducks, such as teal (*Anas discors*), pintails (*Anas acuta*), widgeon (*Anas Americana*), ringnecks (*Aythya collaris*), and canvasbacks (*Aythya valsineria*). The South Florida Water Management District (SFWMD) and the Florida Fish and Wildlife Conservation Commission have opened some of the STAs to limited duck hunting by permit, starting in 2001. The hunting has generally been excellent, with the STAs producing an average of four to five ducks per hunter, which is unheard of for a public waterfowl area. As a result, hunters have come from all over Florida, as well as other states, to enjoy the STAs. United Waterfowlers Florida President Newton Cook stated that "STA 5 is the #1 public waterfowling marsh in the United States and is nationally known."

STA-5 was opened for the first year for alligator hunting in 2006 (SFWMD, 2006).

### Passive Activities

Nonconsumptive uses of wetlands constructed primarily for water quality treatment include recreation, nature study, aesthetics, and education. Increasingly, designs of treatment wetlands have incorporated attractive and informative parklike areas. For instance, stormwater treatment wetlands in urban settings such as Greenwood Park in Orlando (Florida), the Tollgate Wetlands in Lansing (Michigan), and Coyote Hills east of San Francisco Bay are used frequently for field trips and other educational purposes (Figure 19.9; Table 19.6). Wetlands constructed for wastewater treatment in Arcata, California; Hillsboro, Oregon; and Orlando and Palm Beach counties in Florida, are vital recreational areas, which offer jogging and bird watching. In South Florida, STA 5 and STA1W are open for guided bird-watching tours. The visitor will typically not be disappointed because these treatment wetlands are frequented by very large numbers of subtropical birds, including roseate spoonbills (*Ajaia ajaja*).

These human uses of wetlands, including the satisfaction of having a wetland and wildlife at the edge of town, are perhaps the most important factors behind public support of protection and enhancement of existing wetlands.

### Conflicts

Although most reasonable human use is acceptable in treatment wetlands, there are some potential conflicts. These are generally in two categories: destructive human activities and liabilities of the project owner—both real and perceived.

Humans can be destructive, either maliciously or unintentionally. An illustration of the unintended damage issue

**TABLE 19.6**
**Use Estimates for the Arcata, California, Treatment Wetlands**

| Use | Density (persons/day) | Duration (hours) | Management |
|---|---|---|---|
| Picnicking, relaxing | 57–175 | 0.3–0.8 | Traffic control, parking, garbage cans, and cleanup |
| Birdwatching, nature study | 5–50 | 2–4 | Traffic control, parking, viewing blinds, and docent program |
| Walking, jogging | 20–80 | 2–4 | Designated trails, maintenance, mosquito control program |
| Education | 2–6 | 2–4 | Designated trails, maintenance, signage |
| Photography | 1–2 | 2–4 | None |

is the case of a small treatment wetland in Dixboro, Michigan, which treats runoff from a botanical garden. Elementary school children visit the facility frequently, and one of their activities was catching frogs and dragonflies in the wetland. But about 30 children running around in the 850-$m^2$ wetland caused severe damage to sediments and vegetation, and the activity had to be cancelled.

More problematic is malicious damage. Signage has been defaced with spray paint (Show Low, Arizona), distribution pipes cut with an axe (Houghton Lake, Michigan), and stolen autos driven into the wetland (Howell, Michigan).

Issues of public safety combine with issues of facility protection to lead to limitation of access to treatment wetlands. Insurance against public injury has led to exclusion fencing at many treatment wetlands. This is more important for wetlands treating waters that may be hazardous to human health, which include some remediation sites as well as wetlands treating primary effluents. Nevertheless, there are no known instances of human injury in a treatment wetland.

## 19.5 DESIGN FOR ANCILLARY BENEFITS

The previous sections described the secondary features of wetland treatment systems, which are useful for encouraging wildlife. This section focuses on design considerations to enhance ancillary benefits in general, while optimizing the primary functions of pollutant removal and flood attenuation. Only a scattering of papers on wetland design for ancillary benefits have appeared through the past 15 years—for instance, Knight (1992; 1997); Worrall *et al*. (1997); and Conner and Luczak, (2002). As noted in an ancillary benefit design review by Conner and Luczak (2002), the U.S. EPA Design Manual (U.S. EPA, 2000a) "pays little attention to the conservation aspects of these treatment systems." The same may be said for Crites and Tchobanoglous (1998), Water Environment Foundation (2001), and Crites *et al*. (2006). The book by Campbell and Ogden (1999) considers sustainable development and how wildlife considerations may be woven into design; however, Conner and Luczak (2002) note that "the lack of detail limits its usefulness for design purposes." Outside of North America, there is scant attention paid as well, with the exception of the book by Merritt (Ed.) (1994), which provides useful information on the conservation aspects of systems in the United Kingdom. However, virtually all treatment wetlands in the United Kingdom are subsurface flow with *Phragmites*, and contain no concessions to wildlife or humans. In summary, there is no comprehensive manual on how to blend treatment and ancillary benefit designs. Ony a few manuals attempt to blend the concepts of mitigation wetlands and treatment wetlands, such as Sutula and Stein (2003).

Wetland design considerations include siting, cell size and configuration, water flow and depth control, planting, and species stocking. Because this book assumes that the treatment wetland's primary function is pollution control for wastewater, the water source itself is not an ancillary design decision. However, the level of pretreatment is important to determine the potential for secondary benefits. Developing a wide variety of habitat type within a treatment wetland will enhance higher wildlife diversity. Controls in the design of the treatment wetland, which affect habitat and plant diversity, include seasonal hydroperiods, depth and flow changes, vegetative succession, and accumulation of sediments (U.S. EPA, 2000c). Habitat quality can be enhanced by providing for areas of open water, creating nesting islands for waterfowl, and leaving some upland and buffer areas for other nesting species. Because the selection of plant palette is one of the major controls on habitat quality in a treatment wetland, it is important that the following recommendations be considered in the design:

- Provide habitat with native species mixtures comparable to similar wetlands in the region (U.S. EPA, 2000c).
- Create gentle slopes to allow for plant establishment and diversity. Incorporate water level fluctuations in the operation plan.
- Maximize vegetative species diversity without increasing use of weedy, invasive species at the expense of native species. Project plans may include the means to control or eliminate undesirable species.

Figure 19.1 shows some of the features that might be incorporated in a constructed wetland to control water pollution and to provide secondary wildlife and recreation benefits. In this conceptual plan, the wetlands are sized and configured to meet specific water quality treatment goals, and operation is based on meeting effluent criteria. However, the wetland also may be designed to take advantage of the potential for wildlife habitat creation by incorporating deeper, open water areas in the marsh and providing habitat islands as a refuge from human access and predators. Constructed wetland treatment systems providing a multitude of ancillary benefits now exist at a number of project sites.

### Siting

Siting wetlands to treat municipal and industrial wastewater is relatively flexible because the effluents are often pumped to the wetland. However, wetlands to control stormwater must be sited close to stormwater sources or further downstream in a watershed, intercepting a tributary. The location of a stormwater treatment wetland will determine the quantity and timing of the influent, which will affect the ancillary functions of the wetland. Generally, wetlands located in headwater areas will receive more irregular and less dependable inflows, resulting in prolonged dry conditions unless soils are impermeable or groundwater is normally high. This relative lack of flooding will limit ancillary benefits, such as primary and secondary production. In these cases, maintaining a healthy stand of wetland-dependent vegetation may be difficult, and upland or transitional species may eventually predominate. This type of system certainly will have some upland values

and may support faunal assemblages seasonally. However, overall production of wetland-dependent species likely will be lower than in a perennially flooded wetland.

Siting the constructed stormwater treatment wetland further downstream in the watershed may yield a different constraint: too much water during stormwater runoff periods. To control high stormwater volume, the downstream wetland can be designed to be off-line (out of the main flow path) so that it captures only some flood flow, preventing the washout of vegetation and berms. A series of off-line constructed wetlands, each capturing a portion of the storm flows, can be used to deal with high volumes. Wetlands located downstream in a watershed are more likely than wetlands at headwaters to have perennial water because of more constant base flows and higher groundwater levels. In turn, downstream stormwater treatment wetlands generally will have more wildlife and more food-chain support.

The siting of wetland treatment systems to optimize ancillary benefits may also consider the advantages of locations with adjacent donor wetlands (sources of plants and wildlife to colonize the area), adjacent undeveloped uplands (habitat diversity), or proximity to humans (aesthetics).

### Cell Size and Configuration

The wetland cell size depends primarily on water quality treatment needs and cost considerations. Because large cells require less berm construction per unit area and fewer inlet and outlet structures, per-area project costs are lower. For example, a 100-ha constructed wetland may cost about $10,000/ha to construct, whereas a smaller constructed wetland may cost about $50,000/ha. Although cell size may influence the use of wetlands by larger wildlife, it has minimal affect on plant productivity or secondary production of most wetland animals (Sather and Smith, 1984). A higher berm-to-cell area ratio, typical of smaller wetland cells, may result in increased beneficial edge effects. As long as berms are infrequently mowed or visited, the larger edge area provides nesting and feeding habitat for more mammal and bird species.

Islands surrounded by marsh or open water provide excellent habitat for nesting waterfowl. In many wetlands, islands with trees are preferred nesting habitat for wading bird rookeries (see Figure 19.1). Nesting islands for waterfowl should be about 0.6 m above the normal high water, whereas higher and lower islands may also be valuable for other species for feeding, resting, or nesting.

Open water areas may improve the water quality treatment potential of constructed wetlands, but they definitely enhance their ancillary benefits for wildlife. Mallard duck production is maximum in wetlands with almost even areas of marsh and open water (Ball and Nudds, 1989). Open water areas can be created by excavating at least 1.5 m below the normal water level. Deeper excavations can also provide fisheries habitat. To prevent hydraulic short-circuiting, open water areas should not be connected along the flow path but rather interspersed with densely vegetated shallow marsh habitat (average water depth of about 0.3 m or less). In general terms, areas will be larger when ancillary benefits are desired. Ponds, islands, and edge amenities are not required for treatment.

Cell number and configuration in series or in parallel are major considerations when determining treatment capability and operational flexibility. These design considerations primarily affect ancillary wetland benefits because of their importance in depth control.

### Water Depth and Flow

Water depth and the flow rate are important factors affecting dissolved oxygen in wetlands. Higher flow rates resulting from shallow water tend to provide higher dissolved oxygen concentrations in marshes because of atmospheric reaeration. These higher dissolved oxygen levels generally result in higher secondary production of aquatic invertebrates and vertebrates, thereby increasing ancillary wetland benefits. Although deeper water in a marsh may increase hydraulic residence time, this longer reaction time does not always result in enhanced water quality treatment (oxidation of organic matter and ammonia) because of the resulting reduction of dissolved oxygen concentrations.

Water depth is one of the main factors that affect wetland plant growth. High water levels will stress the growth of emergent macrophytes and encourage the dominance by floating or submerged plants or algae. The hydrological tolerance range and optimum hydroperiod of any desired vegetation type should be known and closely adhered to when water level control structures are designed. Ideal design allows water levels to be varied from zero (drained) to the maximum depth tolerance of desired wetland plant communities. Stop logs or weir plates should seal the leaks to help maintain water levels during periods of limited inflows. Multiple inlet and outlet weirs between adjacent cells allow greatest hydroperiod control flexibility.

### Vegetation

The plant species selected for a constructed wetland will greatly influence ancillary benefits such as primary and secondary productivity. The selection of improper plant species will result in low productivity, and a lengthy adaptive period may be necessary until available plant species, either planted or natural volunteers, rearrange themselves according to hydrologic and water quality factors. High plant diversity can be initially achieved by assisting existing soil seed banks to colonize areas that are graded and shallowly flooded or by spreading muck and propagules from a donor wetland area (Gilbert *et al.*, 1981). Wetland vegetation establishment is most rapid when plants are closely spaced, less than 1 m on centers, and planted during the growing season (Lewis and Bunce, 1980; Broome, 1990). Wildlife use all marsh plant species directly for food or shelter or, indirectly, through the detritus food chain, so expensive management to exclude "noxious species" or to select favored species may lower

overall wildlife use in favor of optimizing specific wildlife species. Burning marshes may be good management for waterfowl species but poor management for fish, small mammals, or other bird species.

### Pretreatment

In addition to wetland hydroperiod, water quality is a key determinant of a wetland's form and function. Primary water quality characteristics, which affect wetland plant communities, include nutrients (especially nitrogen and phosphorus), suspended solids, salts, pH, and temperature. Except for nutrient concentrations, these same water quality characteristics also influence faunal populations. Inflows of biodegradable solids and the ammonia form of nitrogen can affect wetland flora and fauna indirectly by their impact on dissolved oxygen concentrations.

If high loads of suspended solids are released in the constructed wetland, the solids can smother plant growth in inflow areas (Kuenzler, 1990). Generally, solid loads can be controlled by conventional pretreatment. In stormwater systems, the problem can be minimized with a forebay or pond prior to the wetland (Livingston, 1989). If the pretreatment area traps the mineral-suspended solids (clays, silt, and sand), the wetland treatment system will need to be maintained less frequently.

Inlet ponds also can reduce nutrient levels, although nutrient reduction may not be the primary goal in constructed wetlands designed to enhance wildlife. As noted earlier, higher nutrient levels generally result in higher primary production of wetland plants which, then, support increased wildlife populations.

As a consequence, the wetland should not be used as the first interceptor of urban runoff, particularly in industrial or highly urbanized sites (Schueler, 2000). Specific recommendations include the following (Sutula and Stein, 2003):

- Control source of pollutants where possible (e.g., street sweeping, removal of sediment and debris from storm drain inlets, improving infiltration, and other land-based best management practices (BMPs).
- Use oil and grit interceptors in industrial sites or highways.
- Install floating berms to trap trash and large debris.
- Utilize sediment collection/settling forebays. Design and locate the forebays for ease of maintenance and removal of sediment.
- Segment the wetland such that the primary treatment is provided in the forebay or initial pond and the remainder of the wetland is used for polishing and/or wildlife enhancement.

### Human Access

Recreational facilities that provide public access to the STAs of South Florida include asphalt parking areas, composting toilets, landscaping, and information kiosks. Pedestrian gates, signage, and fencing are included as needed to define public access areas. Associated road improvements are sometimes needed, such as an acceleration and deceleration lane in the vicinity of the entrance to the parking lot. Some facilities include a canoe launching site, access footbridges, and boardwalks.

Although public access to a created wetland might disturb wildlife populations, disturbances can be minimized with controlled access to certain areas and design features such as islands for roosting and nesting. Visitors typically appreciate guidance, and signage is therefore an important aspect of design for human use (Figures 19.10 and 19.11). Although clearly marked walking trails suffice for wetlands of limited size (Figure 19.10), boardwalks are the preferred means of protecting both the visitors and the wetlands in large systems (Figure 19.11). These are not restricted, however, to large systems (Figure 19.12). Boardwalks facilitate nature study and outdoor recreation, and enhance the scientific research benefits of a constructed wetland. Observation towers are valuable because they provide an opportunity for visitors to get an overview of what is generally a flat landscape (Figure 19.13). Wildlife viewing blinds can greatly enhance the ability to observe wildlife with minimal disturbance to the animals. An interpretive center allows small groups to assemble with shelter from sun and rain (Figure 19.14). In some very large treatment wetlands, boat launching facilities are provided (Figure 19.15).

It is not uncommon for scientists to visit treatment wetlands. This human use is typically not accompanied by any special facilities; such visitors are deemed knowledgeable enough to fend for themselves (Figure 19.16).

It is noteworthy that there are no reports of accidents involving humans and treatment wetlands.

### Examples

The popularity of treatment wetlands for public use is very high. Perhaps the best way to illustrate the design features that contribute to public use is to describe examples.

#### Palm Beach County, Florida

Originally conceived in 1992 as part of a cooperative effluent reuse study between the Palm Beach County Water Utilities Department, the City of West Palm Beach, and other municipalities, the Wakodahatchee Wetlands have been designed to demonstrate the following ancillary benefits of reclaimed water reuse (see Figure 19.11):

- Creation of significant wildlife habitat accessible to the public in a parklike setting
- Maintenance of biological diversity and open space in a highly developed landscape
- Recharge of local water supplies through infiltration to the surficial aquifer
- Provide limited public use for passive recreational activities

(b)

**FIGURE 19.11** The Wakodahatchee Wetlands in Palm Beach County, Florida, has a very user-friendly boardwalk.

**FIGURE 19.12** Even this short boardwalk at the University of Michigan Matthaei Botanical Gardens treatment wetland is a popular place to stop and look.

**FIGURE 19.13** Wetland observation tower at the Hennepin–Hopper (Illinois) site.

**FIGURE 19.14** Public viewing shelter at the Tucson, Arizona, Sweetwater wetlands.

**FIGURE 19.15** Boardwalks and boat launching sites are features of the South Florida Stormwater Treatment Areas.

**FIGURE 19.16** Scientific visits are an important human use of treatment wetlands, such as this at the leachate treatment wetlands at Reguengo, Portugal.

The Wakodahatchee Wetlands are part of the Southern Region Water Reclamation Facility, completed in 1997. The wetland area totals 16 ha on the 23-ha site, with individual wetland cells ranging from 0.9 ha to 4.4 ha. The marsh area is designed to operate at an average depth of 15 cm but may be operated normally at depths to 45 cm. High rainfall can elevate wetland water levels to even greater depths of 60 cm or more for short periods. Deep zones, consisting of ponds 1.5 m or more in depth, variable in width, and oriented transverse to the direction of flow, are interspersed throughout each wetland. A total of 28 deep zones and 8 habitat islands are included. Nominal detention time varies from a maximum of 40 days at 2,000 $m^3$/d of flow to ten days at 8,000 $m^3$/d.

Marshes comprise about 70% of the wetland area, vegetated by native emergent, forested, and transitional wetland species and designed to emulate native South Florida wetland plant communities. Emergent marsh zones are composed of bulrush (*Scirpus validus, S. californicus*), duck-potato (*Sagittaria lancifolia*), arrowhead (*Sagittaria latifolia*), spikerush (*Eleocharis cellulosa*), fireflag (*Thalia geniculata*), and pickerelweed (*Pontederia cordata*). The wetlands are maintained to be free of nonnative and nuisance plant species, and the surrounding berms and entry areas are landscaped to maintain an aesthetic and comfortable experience for wetland visitors. The combined efforts to manage the vegetation, maintain the boardwalk facility, monitor water quality, and maintain the grounds cost on the order of $150,000/yr.

Snags and perching posts were added for wildlife use. The numbers of bird species observed within the wetlands totaled 119 and 142 in 1997 and 1998, respectively. Thirteen of these species were considered by state and federal agencies to be commercially exploited, threatened, or endangered. Reptile diversities were high and increased over the first two years. Mosquitofish densities were high and consistent between the two years. Mammal and amphibian diversities were low.

The public makes extensive use of the Wakodahatchee Wetlands. Parking facilities are available, and there is a boardwalk through the wetlands, with associated gazebos, which provide an attractive and comfortable setting for walking, bird-watching, nature photography, environmental education, and related passive activities (Figure 19.11). The Audubon Society of the Everglades has identified the Wakodahatchee as one of the birding hot spots within Palm Beach County. Available data on site use indicate that the numbers of daily visitors to the wetlands have increased from 165 people in 1997 to over 1,500 through the first half of 2000. This high level of interest has led the Water Utilities Department to construct another wetland facility with an interpretive center on 70 ha of farmland adjacent to the Wakodahatchee Wetlands for treatment and disposal of up to 38,000 $m^3$/d of treated effluent.

### Victoria, Texas

The DuPont Victoria constructed wetland was built to treat wastewaters from a petrochemical plant that manufactures precursors for nylon and polyethylene. The 21.5-ha wetland receives about 12,000 $m^3$/d of water that has been pretreated in a biological plant. The wetland is configured in three stages (Figure 19.17). Stage 1 consists of five cells in parallel, which discharge into two parallel Stage 2 cells, both stages containing deep zones. Water then passes to Stage 3 wetlands, which are primarily intended for wildlife habitat. There are deep open-water zones for waterfowl, and islands add protected upland features to the habitat. Twenty species of native plants were used. Public access features include a parking area, an outdoor education center suitable for classroom groups, an observation platform, information kiosk, bird watching blind, walking trails, a boardwalk across the wetland, and a water sampling pier.

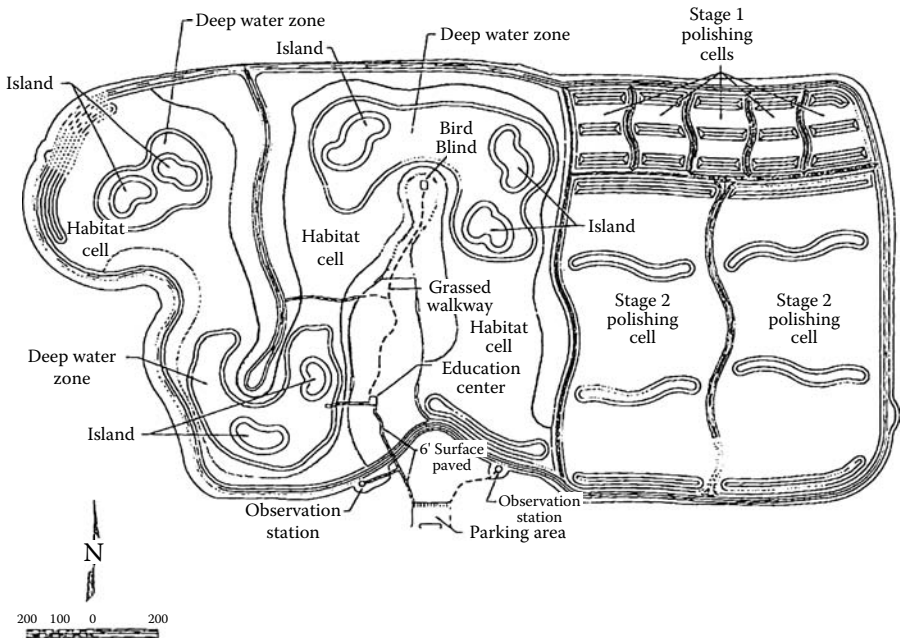

**FIGURE 19.17** Layout of the DuPont Victoria, Texas, treatment wetland. (From Reitberger *et al*. (2000) *Achieving Multiple Benefits from a Constructed Wetland*. Reddy and Kadlec (Eds.), Proceedings of the 7th International Conference on Wetland Systems for Water Pollution Control, 11–16 November 2000; University of Florida and IWA: Lake Buena Vista, Florida, pp. 749–758. Reprinted with permission.)

The wetland provides valuable habitat for migratory and resident birds. In excess of 180 species were identified in a 1999 survey, which increased to over 195 by 2002. An additional 28 species of plants had volunteered by 1998, and by 2002 there were 85 species of plants. Five species of fish live in the wetland and are just as healthy as their counterparts in the reference pond. Many larger animals have been attracted by the abundance of the wetland, but a problem was the invasion by nutria (*Myocastor coypus*), a nonnative aquatic rodent. The wetlands suffered significant loss of vegetation because of herbivory by the nutria. Population control methods are being employed, including attracting alligators to the site. Hunting and trapping methods were developed that provided effective population control without using firearms. Revegetation efforts have taken place despite continued nutria activity. Measures include replanting, nutria exclosures, and water level adjustment, which have successfully reestablished vegetation in most impacted areas.

Education programs are provided to students from Grade 4 through college via the Wetland Environmental Science Education Encounter (WE SEE). The program encompasses treatment benefits along with the inherent natural benefits of a wetland. A full-time on-site educator is the first such person located at an industrial wetland. The program is housed at a state-of-the-art education center and offers a wide variety of science education learning opportunities to area schools. Given that many young persons will be in a natural environment, there have to be rules. There is an inherent danger in any "natural" setting. To minimize the chance of injury, the students are cautioned to do the following:

- Do not leave trails or enter any area of high grass or brush.
- Do not attempt to capture any animal known to sting or bite. This includes such insects and arachnids as spiders, scorpions, bees, wasps, hornets, ants, and caterpillars.
- Do not attempt to capture or harass any mammal, bird, amphibian, or reptile in the wetland. Be on the lookout and avoid snakes.
- Watch for and do not attempt to touch plants with stems bearing leaves clustered in threes (poison ivy or poison oak). This plant has not been found in the wetland yet. If not sure, ask. Some plants in the wetland have thorns, so be careful of the brush.
- Walk, and do not run anywhere in the wetland, including on the trails, pier, boardwalk, and inside the education center.
- Follow proper field and laboratory safety procedures.

As of August 2006, over 27,000 students had participated.

### Renton, Washington

The Waterworks Garden is a stormwater treatment system with emphasis on not only the usual natural features of wetlands but also on elements conceived for their artistic value. An environmental artist (Lorna Jordan) worked with landscape architects and engineers to develop the combination of wetland treatment and art. Visitors pass through "rooms" that

**FIGURE 19.18** The water enters the Waterworks Gardens urban stormwater wetlands in Renton, Washington, under a paved colonnade.

symbolize a journey from the civilized to the wild (Campbell and Ogden, 1999). The walking path parallels the course of the water, moving from the "Knoll" inlet structure through more natural water forms ("Funnel," "Grotto," "Passage," and "Release") before discharge to the river (Figure 19.18). The planting scheme is symbolic; plants at the top of the garden where the runoff is still contaminated are species Native Americans consider bad omens (France, 2003). The entire system is just a few hectares, but the cost of the art was $1.3 million in 1995, the year of completion.

## SUMMARY

Wetlands for water quality improvement are being constructed throughout North America at an accelerating rate. However, many wetland designs do not incorporate ancillary benefits to the extent possible. With thoughtful design, constructed wetlands can provide benefits beyond effective water treatment, such as wildlife enhancement and recreational opportunities. In fact, with the decline of the total area of natural wetlands, constructed treatment wetlands are a viable and cost-efficient way to compensate for the loss of productive wetland habitat.

Pretreated wastewater and stormwater can nourish hydrologically altered natural wetlands or create natural wetland functions in constructed marshes. Wastewater constituents can be controlled to enhance a wetland's ancillary benefits. For example, nutrients promote plant growth at the bottom of the food chain, which then supports other wildlife species. By considering certain design features such as cell configuration, hydroperiod control, vegetation and wildlife stocking, and human access, wetlands can be designed to meet water treatment goals as well as provide additional benefits.

# 20 Sizing of SSF Wetlands

The design of subsurface flow (SSF) wetlands may be roughly divided into two categories: sizing calculations and physical specifications. Sizing requires characterization of the incoming water and regional climate as well as the goals of wetland treatment, as discussed in Chapter 16. This chapter discusses different sizing methodologies for SSF wetlands. Chapter 21 deals with the physical considerations, including the number of cells, layout, liners, bed depth, media size, plants, and water level control. It is recognized that SSF wetlands are not stand-alone treatment devices but rather form part of an overall treatment process.

For HSSF wetlands, primary treatment, at a minimum, is required to remove settleable and floating solids prior to the wetland bed. This is typically provided through the use of settling tanks. Some projects may employ a higher level of pretreatment through the use of activated sludge systems, lagoons, or other treatment processes. Vertical flow (VF) wetlands may or may not have such preliminary treatment stages, and biosolids systems will receive material of different quality depending on the nature of the overall treatment process. This chapter focuses on the sizing of SSF wetland components, recognizing that this will be only one part of the overall treatment process.

To date, most SSF wetlands have been sized using prescriptive criteria. The most common approach has been to tie the required wetland size to a parameter that presumably defines the influent conditions. Influent loadings, population equivalents, detention time, and number of bedrooms have all been used to create these scaling factors. Prescriptive criteria represent a reasonable approach to wetland sizing when there is a large body of preexisting performance data for well-defined pollutants (loading charts), and a more detailed understanding of the internal dynamics of the wetland is not necessary. As a result, prescriptive criteria are used mainly for the design of SSF wetlands that treat domestic wastewater.

However, for other projects, there is limited information, and prescriptive criteria cannot be developed. Pilot-scale treatability studies may have to be conducted to measure rate constants and temperature effects. First-order modeling is often employed to interpret these results and make predictions on the anticipated performance of a full-scale wetland. Also, first-order modeling can be used to represent internal profiles of pollutant reduction within the wetland. This book employs the *P-k-C** model for performance-based wetland design.

## 20.1 PRESCRIPTIVE SIZING CRITERIA

Prescriptive criteria have been the most popular method for sizing SSF wetlands because these methods are quick and mathematically simple. This has led to the widespread use (and sometimes misuse) of prescriptive methods.

Prescriptive criteria are only reasonable when they are based on the observed performance of large numbers of wetlands built to the same physical specifications treating the same type of wastewater under the same climatic conditions. If treatment is acceptable under a specified condition, and the data set is large enough to capture inter- and intra-system variability, it may reasonably be expected that future wetlands operated under the same conditions will also provide acceptable treatment (and that deviations from the mean are acceptably small or infrequent). Unfortunately, prescriptive criteria have been adopted in many situations where there is insufficient data to support their use.

### Loading Charts

Loading charts are design tools, which can be used to size wetland systems. An influent loading rate is selected to produce a targeted effluent concentration. The wetland area is calculated from the influent mass load. Recent examples include U.S. EPA (2000a) and Wallace and Knight (2006).

Loading charts that can be used in this manner are also included in this book. They are composed, mainly, of wetland data from Europe, North America, the United Kingdom, and New Zealand; so the vast majority of the systems represented in these charts is from cool temperate climates. For HSSF wetlands, these charts include

| | |
|---|---|
| TSS: | Figure 7.30 ($C_{out}$ versus $Load_{in}$) |
| BOD: | Figure 8.26 ($C_{out}$ versus $Load_{in}$) |
| Organic N: | Figure 9.18 ($C_{out}$ versus $Load_{in}$) |
| Ammonia N: | Figure 9.38 ($C_{out}$ versus $Load_{in}$) |
| TKN: | Figure 9.24 ($C_{out}$ versus $Load_{in}$) |
| Total N: | Figure 9.30 ($C_{out}$ versus $Load_{in}$) |
| Total P: | Figure 10.36 ($C_{out}$ versus $Load_{in}$) |
| Fecal coliforms: | Figure 12.12 ($C_{out}$ versus $C_{in}$) |

For VF wetlands, these charts include

| | |
|---|---|
| TSS: | Figure 7.32 ($C_{out}$ versus $Load_{in}$) |
| BOD: | Figure 8.31 ($C_{out}$ versus $Load_{in}$) |
| TKN: | Figure 9.25 ($C_{out}$ versus $Load_{in}$) |

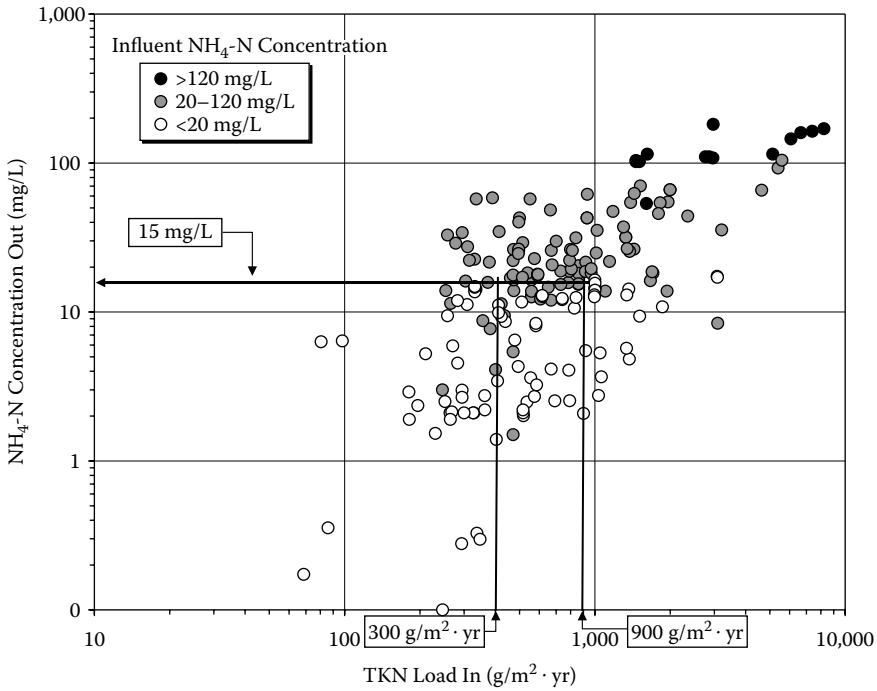

**FIGURE 20.1** TKN–Ammonia loading chart, with forecasted treatment performance.

Because there is considerable scatter in the loading of chart data, selection of the wetland area will likely be an iterative process; selection of a lower influent loading (larger wetland area) will result in lower estimated effluent concentrations. For instance, consider the case of ammonia in Figure 20.1 (replotted from Figure 9.39).

A TKN loading rate of 900 g/m$^2$·yr (approximately 5 m$^2$/PE; $C_i$ approximately 120 mg/L) results in a predicted effluent ammonia concentration of approximately 15 mg/L. Because of scatter in the data, this estimate of effluent concentration can only be considered a central tendency. In other words, approximately half of the wetlands loaded at this rate will return ammonia concentrations greater than 15 mg/L.

If the loading rate is decreased to 300 g/m$^2$·yr (approximately 15 m$^2$/PE) for the same influent concentration, the probability that the wetland will produce an effluent ammonia concentration equal to or less than 15 mg/L is increased considerably. This is consistent with the operational experiences with HSSF wetlands, where loadings less than 600 g/m$^2$·yr (10 m$^2$/PE) are necessary to return low-ammonia effluents (Geller, 1996).

It is tempting to estimate the probability that the wetland will not perform to this standard by counting the number of data points above the targeted performance goal. For instance, there are seven system·years above the targeted performance level (15 mg/L at 300 g/m$^2$·yr) out of 47 system years at or below this loading rate, so the probability that the wetland will meet the median effluent performance goal is roughly 85%. This predictor only describes median performance over the data averaging period used to construct the loading chart. Because these data averaging periods are often long (annual or period of record), important aspects of system performance, such as seasonal or stochastic variations in effluent concentrations, are lost. More importantly, this "point counting" approach does not take into account the effect of the influent concentration ranges. For instance, many data points in Figure 20.1 are for $C_i$ less than 20 mg/L, which is considerably lower than the 120 mg/L influent concentration used in this example.

Because the data averaging period for Figure 20.1 is annual (198 system·years of data are represented), no information on seasonal or monthly variation is contained in the chart. This is a problem when the regulatory compliance interval is short (weeks or months). Some design references have attempted to address this by using shorter data-averaging periods, such as system·months (Wallace and Knight, 2006).

However, tools such as those shown in Table 9.35, Chapter 9, can be used to assist the designer in this regard. As indicated in the table, the 90th percentile trend multiplier on the effluent concentrations ($1 + \Psi$) is 1.76. Figure 20.1 indicates that at an influent loading of 300 g/m$^2$·yr, the central tendency in the effluent ammonia concentrations is approximately 5 mg/L. If the wetland performs at or near this central tendency, 90% of the effluent results should be less than 8.8 mg/L ($1.76 \times 5$ mg/L). The probability that the wetland will have poor annual and stochastic results can be crudely estimated by multiplying the probability factors.

It should be noted that the amount of data available on the performance of treatment wetlands is much less than statisticians are used to working with; thus the application of statistical tools to wetland performance is inherently limited by the lack of current performance data.

Tools such as those shown in Figure 9.50, Chapter 9, indicate that some of this variation is likely to be seasonal.

There are obvious limitations to the loading chart method. First of all, there must be a functional relationship between the inlet loading and effluent concentration. Figure 7.29 in Chapter 7 is an example where the effluent TSS concentration is essentially independent of the influent loading. This is because removal of the influent TSS occurs in only a small region at the inlet of the HSSF wetland bed, and the overall wetland size (and hence, loading) does not play a significant role in determining effluent TSS concentrations. Secondly, there is considerable scatter in loading chart data, because wetland design, climatic, and loading parameters are not implemented in the same, exact fashion for all systems comprising the data set. The resulting data scatter means that a large component of the wetland design must necessarily rely on the best professional judgment of the designer. Some performance features, such as the role of influent concentration (independent of influent load), are also lost.

Because loading charts require few mathematical calculations, they are an attractive design tool. They have also been misused by designers who do not understand the inherent limitations of the loading chart method. It is important to remember that loading charts will not predict system performance if the physical configuration of the wetland is changed from the parent data set, the pollutant type or concentration changes, or the wetland is in a different climatic region. For instance, loading charts based on the BOD in domestic wastewater will not necessarily apply to industrial effluents where the organic compounds making up the BOD are not the same, and they will likely have different degradation rates (*k*-rates). Also, a loading chart based on a parameter such as BOD will not predict effluent performance for another pollutant, such as ammonia. Also, as loading charts are based on inlet–outlet data, predictions about pollutant reductions within the wetland (internal profiles) cannot be made.

## Scaling Factors

Many efforts have been made to reduce the information contained in a loading chart down to a single parameter—a prescriptive scaling factor. This is done to further simplify the design process. In general, these scaling factors attempt to describe two aspects of system performance:

1. Median system performance at a specified inlet condition.
2. A "margin of excursion containment" that is intended to allow for intersystem (seasonal and stochastic) as well as intrasystem (differences in the performance response of different wetland systems) variabilities.

This margin of excursion containment is rarely defined in the treatment wetland field; the only exception to date is Wallace and Knight (2006).

There is often an underlying assumption that *bigger is better* (larger wetland area for a given influent condition), and this has often been used as an excuse to not rigorously collect or analyze performance data. As a result, many prescriptive criteria are overly conservative and hinder, rather than help, the reliability of the wetland. There are numerous examples of "bad" or outmoded concepts that are imbedded in various "prescriptive rules." Examples include making the wetland excessively large (exacerbating freezing problems in cold environments and water loss to *ET* in arid climates), specifying long length:width ratios (maximizing the cross-sectional loading and associated clogging problems) for HSSF wetlands, and specifying deep beds to increase the hydraulic retention time (exacerbating vertical stratification of the flow).

### Scaling Factors for HSSF Wetlands

Scaling factors provide the simplest approach to wetland design; thus it is not surprising that this is the most commonly used design method for HSSF wetlands. Examples of some existing criteria include

- 5 $m^2$/PE (BOD loading equivalent to 8 $g/m^2 \cdot d$) to produce an effluent BOD of less than 30 mg/L for primary-treated domestic wastewater
  *Source:* (EC/EWPCA Emergent Hydrophyte Treatment Systems Expert Contact Group and Water Research Centre, 1990)
- 3.1 cm/d
  *Source:* (TVA, 1993)
- Bed sizing ≥ 5 $m^2$/PE (BOD loading equivalent to 8 $g/m^2 \cdot d$)
  *Source:* (ATV, 1998; ÖNORM B 2505, 2005)
- 6 $g/m^2 \cdot d$ of inlet BOD loading to produce an effluent with less than 30 mg/L BOD
  *Source:* (U.S. EPA, 2000a)
- 8 $g/m^2 \cdot d$ of inlet BOD loading to produce a median effluent concentration of 30 mg/L; 5 $g/m^2 \cdot d$ to produce a median effluent concentration less than 25 mg/L BOD
  *Source:* (Wallace and Knight, 2006)
- 10 to 13 days' nominal hydraulic retention time
  *Source:* (Gustafson *et al.*, 2001)
- 41 $L/m^2 \cdot d$; two to three days' nominal hydraulic retention time
  *Source:* (Lesikar, 1999)
- 28 $m^2$ per bedroom per day; trenches 30 cm wide and 92 m long per bedroom
  *Source:* (Iowa Department of Natural Resources, 2001)

### Scaling Factors for VF Wetlands

Scaling factors have also been widely employed to size intermittently loaded VF wetland systems, especially in Europe. Scaling factors that are currently in use are summarized in Table 15.1, in Chapter 15.

### Cautions Regarding the Use of Scaling Factors

These summaries are by no means a complete list of all the scaling factors existing in the treatment wetland field. Obviously, these examples bear little functional relationship to each other; all are clearly artifacts of the available data, regulatory situation, and climatic conditions where they were developed. The designer is thus cautioned that extrapolating these types of prescriptive rules beyond their local regulatory jurisdiction will likely result in inappropriate wetland sizing; also, many of the physical specifications contained in these prescriptive rules are obsolete and have not withstood the test of modern data analysis in the treatment wetland field.

### Empirical Equations

Empirical equations are another means of predicting system performance. These equations are developed based on a preexisting data set (similar to those summarized in the loading charts presented in this book). This data set is then analyzed to determine a mathematical relationship that has the highest level of statistical correlation. It is important to note that this method makes no attempt to describe the internal dynamics of the wetland system and is utterly dependent on the input–output data set being analyzed. Recent examples of this method are included in Crites *et al.* (2006) and Figure 8.27, Chapter 8, of this book.

Empirical equations can best be thought of as a sliding-scale "rule of thumb." All the limitations inherent in the loading chart method and scaling factors also apply to empirical equations. As a result, designers are cautioned that applying empirical equations to situations not representative of the parent data set will often result in inappropriate designs.

## 20.2 PERFORMANCE-BASED WETLAND SIZING

In performance-based design, the effects of degradation rate coefficients (*k*-rates), temperature (θ-factors), and the combined effects of internal hydraulics and pollutant weathering (*P*TIS) are considered discretely. The great advantage of this method is that it allows prediction of treatment wetland performance across different hydraulic and temperature regimes.

Historically, early HSSF designs were based on first-order modeling with the assumption of plug flow (EC/EWPCA Emergent Hydrophyte Treatment Systems Expert Contact Group and Water Research Centre, 1990). In the realm of proprietary wetland designs, this method was extended to waste-specific *k*-rates and pollutant weathering for soil-media HSSF wetlands (Kickuth, 2002), although these results were not reported to the international scientific community.

The first-order approach was largely abandoned in Europe in favor of simple scaling factors because the majority of HSSF wetlands were implemented for small flows of domestic wastewater under similar climatic conditions.

In North America, implementation of HSSF wetlands was less rapid than in Europe. However, there has been an expanding interest in using HSSF wetlands for applications other than domestic wastewater treatment, resulting in the continued development of sizing models using first-order kinetics (Kadlec and Knight, 1996).

This book includes a performance-based approach to HSSF wetland sizing using the first-order *P-k-C** model. Conceptually, this is a tank-in-series (TIS) model using a relaxed parameter, *P*, to account for both hydraulic and weathering effects. The *P-k-C** model is discussed in detail in Chapter 6.

This performance-based approach is in contrast to most of the currently existing wetland manuals, which advocate a prescriptive loading approach for HSSF wetland design. In this book, loading charts are proposed as a means to check the relative conservativeness of a proposed wetland sizing.

The *P-k-C** model has a number of advantages for HSSF wetland sizing, which include

- Loading charts cannot predict internal profiles of pollutant reduction, but this is easily done through first-order modeling.
- Differences in hydraulic efficiency or pollutant weathering can be explicitly addressed. This is especially important when designing full-scale wetlands based on pilot system data, which may have different hydraulic properties.
- The first-order approach allows the modeling of sequential removals, such as for nitrogen.
- Effects of a nonzero background concentration, *C**, may be explicitly addressed.

The procedure outlined here is for a constant influent flow situation. Different influent flow rates may need to be considered to deal with daily or seasonal peaking factors. Different seasons may need to be considered so that the design-limiting ("bottleneck") period of the year is identified and analyzed. The design-limiting period depends on the goals of the project and the climate of the project location. For instance, for projects in very cold climates, operation of the wetland without freezing during the winter months may be a design priority. In hot, arid climates, water loss due to evapotranspiration (*ET*) may be a major concern.

### Basic Application of the *P-k-C** Model to HSSF Wetlands

The simplest situation is where there are no gains of water from precipitation or losses of water due to *ET* or infiltration. This can be easily described using the *P-k-C** model (Figure 17.1, Chapter 17) and Equation 6.57 in Chapter 6, restated here as Equation 20.1:

$$\left(\frac{C - C^*}{C_i - C^*}\right) = \frac{1}{(1 + k/Pq)^P} = \frac{1}{(1 + k_V \tau/P)^P} \qquad (20.1)$$

**TABLE 20.1**
**Estimated Pollutant Reduction Using a First-Order (*P-k-C**) Model for Constant Flows (*P* = *ET*)**

| Input Parameters | | Calculated Values | |
|---|---|---|---|
| Flow rate, $Q$ | 20 $m^3$/d | Volume per tank | 14.3 $m^3$ |
| *P*TIS (system) | 4 | Area per tank | 125 $m^3$ |
| Area, $A$ | 500 $m^2$ | Influent flow, $Q_i$ | 20.0 $m^3$/d |
| Porosity, ε | 0.38 | Effluent flow, $Q_o$ | 20.0 $m^3$/d |
| Bed depth | 0.30 m | Average flow, $Q_{avg}$ | 20.0 $m^3$/d |
| $C_i$ | 200 mg/L | Effluent mass load | 551 g/d |
| $C^*$ | 8 mg/L | Nominal HRT | 2.85 d |
| $k$ | 45 m/yr | HRT based on $Q_{avg}$ | 2.85 d |
| $k$ | 0.123 m/d | HRT based on *P*TIS | 2.85 d |

| Calculated Values | | System In | Exit Tank 1 | Exit Tank 2 | Exit Tank 3 | Exit Tank 4 | System Out |
|---|---|---|---|---|---|---|---|
| Net flow | $m^3$/d | 20.0 | 20.0 | 20.0 | 20.0 | 20.0 | 20.0 |
| HLR, $q$ | m/d | 0.040 | 0.16 | 0.16 | 0.16 | 0.16 | 0.04 |
| Concentration, $C$ | mg/L | 200.0 | 116.4 | 69.2 | 42.6 | 27.5 | 27.5 |
| Nominal HRT | days | 2.85 | 0.71 | 0.71 | 0.71 | 0.71 | 2.85 |

where

$k$ = modified first-order areal rate constant, m/d
$k_V$ = modified first-order volumetric rate constant, $d^{-1}$
$P$ = apparent number of TIS

An example is detailed in Table 20.1. This hypothetical example is configured for a small HSSF wetland (100 PE) with a BOD loading of 40 g/PE and a flow rate of 200, L/PE ($C_i$ = 200 mg/L). A $k$-rate of 45 m/yr is selected based on the distribution shown in Table 8.7 Chapter 8. The wetland is assumed to hydraulically function as eight tanks in series (see Table 6.2, Chapter 6); a reduced value of $P$ = 4 has been selected here to account for weathering of the BOD mixture as it passes through the wetland. The background concentration, $C^*$, has been estimated at 8 mg/L based on Figure 8.27, Chapter 8.

Equation 20.1 can be solved directly, or the calculation can be completed one tank at a time using a computer spreadsheet, as shown in Table 20.1.

## Water Budget Effects

If there is a net gain or loss of water from the wetland, effluent concentrations will be different from those predicted by Equation 20.1. For HSSF wetlands operating under hot, arid conditions, water loss from *ET* may be a significant design concern, and the effects of the water budget should be considered.

The annual water budget forms the basis for a first approach to understanding pollutant reductions and the area required. Under the assumption of a constant water level, the flows from the wetland may be computed from the influent flow rate and meteorological data from the vicinity of the project site. Calculation procedures have been established in Chapter 2.

The inlet hydraulic loading will be increased by rainfall (≈0.5–1.5 m/yr) and decreased by *ET* (≈0.5–1.5 m/yr). However, there may be seasonal imbalances. These amounts are important if the wetland is to have a very low hydraulic loading, or correspondingly, a long detention time. Net evapotranspiration (*ET* > *P*) has two effects: lengthening of detention time and concentration of dissolved constituents. The inverse is true in net precipitation environments (*P* > *ET*). The use of an average flow rate compensates for altered detention time but not for dilution or concentration. Therefore, it may be prudent to consider worst-case seasonal conditions when calculating water-budget effects on the wetland treatment performance.

Pollutant mass balances are conducted on a cells-in-series basis (see Figure 20.2). Results of the overall water mass balance are apportioned to the cells according the chosen number of TIS. For the first unit in the series (Equation 6.66 in Chapter 6, restated here as Equation 20.2),

$$Q_1 = Q_i + A_1(P - ET - I) \tag{20.2}$$

where

$A_1$ = area of the first segment (tank), $m^2$
$ET$ = evapotranspiration, m/d
$I$ = infiltration, m/d
$P$ = precipitation, m/d
$Q_i$ = inlet flow rate, $m^3$/d
$Q_1$ = outlet flow rate from segment #1, $m^3$/d

The additional data input requirements for the water mass balances are

1. Inflow ($Q_i$)
2. Precipitation (P)
3. Evapotranspiration (*ET*)
4. Infiltration (*I*)
5. Area (*A*)

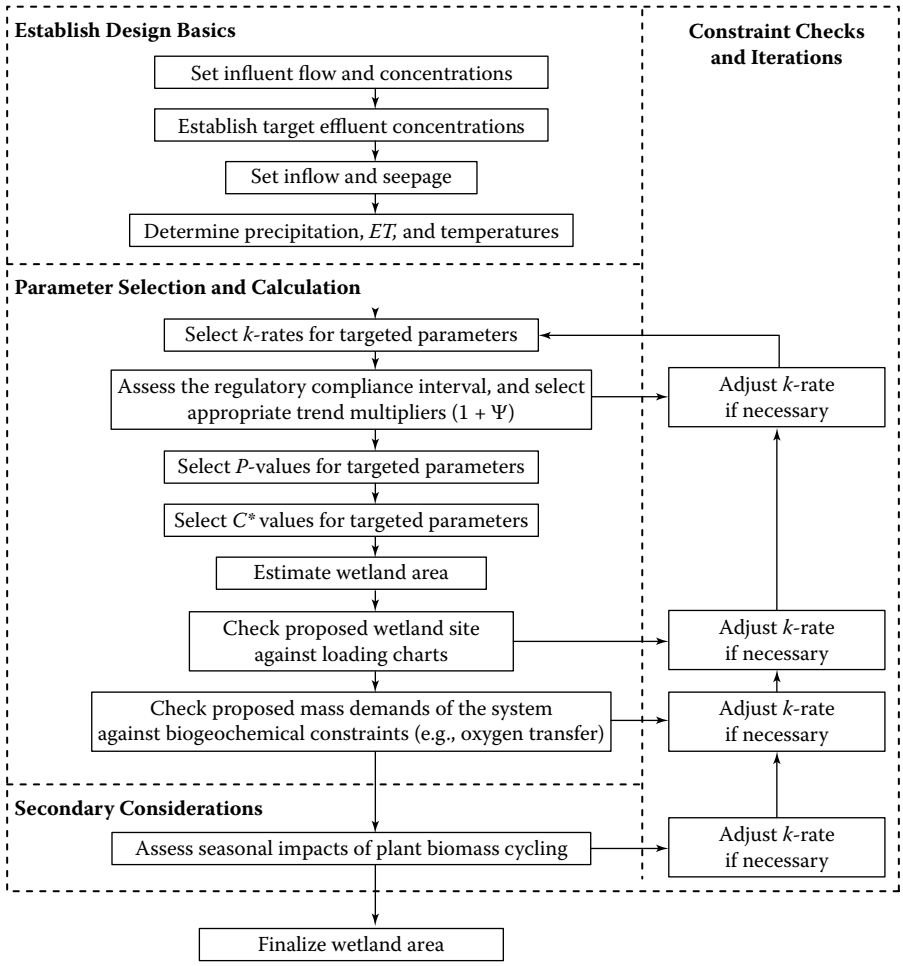

**FIGURE 20.2** Design process flow-chart for HSSF wetlands.

The example of Table 20.1 is continued forward to examine a situation where there is a net loss of water because of *ET*. Results of the hydraulic changes are summarized in Table 20.2. For ease of comparison, the parameter $P$ has been kept at $P = 4$ (even though a higher value could be justified in the absence of pollutant weathering).

As seen in Table 20.2, there is a net change in the flow rate, hydraulic loading, and detention time as water flows through the wetland reaction segments, because in this particular example, approximately 25% of the water flow is lost through the system. Averaging the inlet and outlet flows does not fully account for these effects.

## Pollutant Mass Balances

If there is a net gain or loss of water within the system, the flow in each reaction compartment is different, and it becomes necessary to calculate contaminant removals on a mass basis, as concentration alone no longer adequately describes system performance.

This computation is then repeated for the remaining segments, in each case using the outlet concentrations and flows from the preceding segment. The wetland outlet concentration is that exiting from the final reaction segment. The mass output is calculated from the effluent flow rate and output concentration.

As the flow rate is different for each reaction segment, Equation 20.1 cannot be used to directly calculate the result. Instead, calculations must be carried out sequentially for each reaction segment (tank). This is most easily done using a computer spreadsheet.

Comparison of Table 20.1 with Table 20.2 illustrates that the effluent concentrations predicted by these methods are almost identical. Water is lost to *ET*, which concentrates pollutants within the wetland. However, the volume reduction results in lower hydraulic loading rates (longer detention times), so a greater degree of treatment also occurs within the wetland reactor. Use of average flow accounts for only the longer detention and not the evaporative concentration.

Reviewing the system performance from a mass load basis reveals a very different picture. In the example of Table 20.1, the assumption is of no water loss, so the effluent mass load is 27.5 g/m$^3$ × 20 m$^3$/d, or 551 g/d. In the example of Table 20.2, the effluent flow has been reduced by 24%, so the effluent mass load is 27.6 g/m$^3$ × 15.2 m$^3$/d, or 420 g/d.

**TABLE 20.2**
**Example of BOD Reduction under Variable Flows (*ET* > *P*)**

| Input Parameters | | Calculated Values | |
|---|---|---|---|
| Flow rate, $Q$ | 20 $m^3/d$ | Volume per tank | 14.25 $m^2$ |
| Precipitation, $P$ | 0.5 mm/d | Area per tank | 125 $m^2$ |
| $ET$ | 10 mm/d | Influent flow, $Q_i$ | 20.00 $m^3/d$ |
| Infiltration | 0.02 mm/d | Effluent flow, $Q_o$ | 15.24 $m^3/d$ |
| *P*TIS (system) | 4 | Average flow, $Q_{avg}$ | 17.62 $m^3/d$ |
| Area, $A$ | 500 $m^2$ | Effluent mass load | 420 g/d |
| Porosity, ε | 0.38 | Nominal HLR | 0.0400 m/d |
| Bed depth | 0.30 m | HLR based on $Q_{avg}$ | 0.0352 m/d |
| $C_i$ | 200 mg/L | HLR based on *P*TIS | 0.0341 m/d |
| $C^*$ | 8 mg/L | Nominal HRT | 2.85 d |
| $k$ | 45 m/yr | HRT based on $Q_{avg}$ | 3.23 d |
| $k$ | 0.123 m/d | HRT based on *P*TIS | 3.74 d |

| Calculated Values | | System In | Exit Tank 1 | Exit Tank 2 | Exit Tank 3 | Exit Tank 4 | System Out |
|---|---|---|---|---|---|---|---|
| Net flow | $m^3/d$ | 20.0 | 18.8 | 17.6 | 16.4 | 15.2 | 15.2 |
| Precipitation | $m^3/d$ | 0.063 | 0.063 | 0.063 | 0.063 | 0.063 | — |
| $ET$ | $m^3/d$ | 1.250 | 1.250 | 1.250 | 1.250 | 1.250 | — |
| Infiltration | $m^3/d$ | 0.003 | 0.003 | 0.003 | 0.003 | 0.003 | — |
| HLR, $q$ | m/d | 0.040 | 0.150 | 0.141 | 0.131 | 0.122 | 0.034 |
| Nominal HRT | days | 2.85 | 0.76 | 0.81 | 0.87 | 0.94 | 3.74 |
| Concentration, $C$ | mg/L | 200.0 | 120.5 | 72.3 | 43.9 | 27.6 | 27.6 |

The difference in the predicted effluent mass load can be approximated by the ratio $a = (P–ET)/q_i$, which is the atmospheric augmentation or deficit. The fractional error in a first-order-model prediction of mass load is approximately equal to $a$, for $a > -0.5$. Thus, if 25% of the inflow evaporates, the effluent mass load will be overpredicted by about 25% unless flow corrections are made. If the wetland gains water through precipitation, the inverse is true. It should be noted that averaging the flow will not completely address this problem. Predicted effluent mass loads for the flow assumptions presented in Tables 20.1–20.3 are summarized in Table 20.4.

### Interconnected Pollutants

Some pollutants have sequential degradation processes and thus require a linkage of the mass balances between the parent and daughter processes. A classic example of this is nitrogen: nitrogen species interconvert, thereby linking the mass balances for organic, ammonia, and oxidized nitrogen. It is sometimes possible to disconnect these species, as, for instance, in the case of wetlands that receive nitrate but little or no organic or ammonia nitrogen. However, in many cases it is necessary to account for the (internal) production of ammonia from organic sources—the incoming water or the decomposition of wetland necromass—and the internal production of oxidized nitrogen. The reaction sequence has been presented in Equation 17.8, Chapter 17 (restated here as Equation 20.3). A simple presumed chemistry is

$$\mathrm{ORG-N} \rightarrow \mathrm{NH_4-N} \rightarrow \mathrm{NO_x-N} \rightarrow \mathrm{N_2} \qquad (20.3)$$

In a simplified version of this analysis, uptake and return from biomass is not included. The effects of biogeochemical cycling will be explored in a latter part of the design process. In the case of nitrogen, the three mass balances become

**TABLE 20.3**
**Effluent Pollutant Mass Loads (Based on the *P-k-C** Model) under Different Flow Scenarios**

| Method of Calculation | Predicted Effluent Flow Rate ($m^3/d$) | Predicted Effluent Concentration (mg/L) | Predicted Effluent Mass Load (g/d) |
|---|---|---|---|
| *P-k-C**, based on constant flow | 20 | 27.5 | 551 |
| *P-k-C**, based on average flow | 17.6 | 27.6 | 486 |
| *P-k-C**; *P-ET* corrections based on *P*TIS | 15.2 | 27.6 | 420 |

**TABLE 20.4**
**BOD Removal Based on Performance-Based Criteria; Constant Flow Assumption**

| Input Parameters | | Calculated Values | |
|---|---|---|---|
| Flow rate, $Q$ | 20 m³/d | Volume per tank | 18.5 m³ |
| *P*TIS (system) | 4 | Area per tank | 162.5 m³ |
| Area, $A$ | 650 m² | Influent flow, $Q_i$ | 20.0 m³/d |
| Porosity, ε | 0.38 | Effluent flow, $Q_o$ | 20.0 m³/d |
| Bed depth | 0.30 m | Average flow, $Q_{avg}$ | 20.0 m³/d |
| $C_i$ | 200 mg/L | Effluent mass load | 399 g/d |
| $C^*$ | 8 mg/L | Nominal HRT | 3.71 d |
| $k$ | 45 m/yr | HRT based on $Q_{avg}$ | 3.71 d |
| $k$ | 0.123 m/d | HRT based on *P*TIS | 3.71 d |

| Calculated Values | | System In | Exit Tank 1 | Exit Tank 2 | Exit Tank 3 | Exit Tank 4 | System Out |
|---|---|---|---|---|---|---|---|
| Net flow | m³/d | 20.0 | 20.0 | 20.0 | 20.0 | 20.0 | 20.0 |
| HLR, $q$ | m/d | 0.031 | 0.12 | 0.12 | 0.12 | 0.12 | 0.031 |
| Concentration, $C$ | mg/L | 200.0 | 103.9 | 55.9 | 31.9 | 20.0 | 20.0 |
| Nominal HRT | days | 3.71 | 0.93 | 0.93 | 0.93 | 0.93 | 3.71 |

linked, and the tank equations are

$$Q_1 C_{O1} = (Q_{in} C_{O,in}) - (I\ A_1 C_{O1}) - k_O A_1 (C_{O1} - C_O^*) \quad (20.4)$$

$$Q_1 C_{A1} = (Q_{in} C_{A,in}) - (I \cdot A_1 C_{A1}) - k_A A_1 (C_{A1} - C_A^*) + k_O A_1 (C_{O1} - C_O^*) \quad (20.5)$$

$$Q_1 C_{N1} = (Q_{in} C_{N,in}) - (I \cdot A_1 C_{N1}) - k_N A_1 (C_{N1} - C_N^*) + k_A A_1 (C_{A1} - C_A^*) \quad (20.6)$$

where

$C_O$ = organic N concentration, mg/L
$C_A$ = ammonia N concentration, mg/L
$C_N$ = oxidized N concentration, mg/L
$k_O$ = organic N rate coefficient, m/d
$k_A$ = ammonia N rate coefficient, m/d
$k_N$ = oxidized N rate coefficient, m/d

and the subscript "in" denotes parameters associated with the influent flow for each nitrogen form.

These may be rearranged to solve the outlet concentrations for each tank:

$$C_{O1} = \left( \frac{Q_{in} C_{O,in} + k A_1 C_O^*}{Q_1 + I A_1 + k_O A_1} \right) \quad (20.7)$$

$$C_{A1} = \left( \frac{Q_{in} C_{A,in} + k_A A_1 C_A^* + k_O (C_{O1} - C_O^*)}{Q_1 + I A_1 + k_A A_1} \right) \quad (20.8)$$

$$C_{N1} = \left( \frac{Q_{in} C_{N,in} + k_N A_1 C_N^* + k_A (C_{A1} - C_A^*)}{Q_1 + I A_1 + k_N A_1} \right) \quad (20.9)$$

Equation 20.7 represents the degradation of organic nitrogen. Equations 20.8 and 20.9 contain extra production terms from ammonification in the ammonia balance and from nitrification in the oxidized nitrogen balance. The three must be solved sequentially—20.7, followed by 20.8, followed by 20.9. This can be done through an expanded process of the computer spreadsheet illustrated in Table 20.3, with one sequence of calculations for organic nitrogen, another sequence of calculations for ammonia, and a final sequence of calculations for oxidized nitrogen.

### More than One Parameter

Multi-parameter wetland sizing has been previously summarized in Tables 17.4 and 17.5, Chapter 17, for FWS systems; the same mathematical process can be applied to SSF wetlands.

## 20.3 ACCOMPLISHING PERFORMANCE-BASED SIZING FOR HSSF WETLANDS

The procedure explored here analyzes the effect of changing the wetland area (or equivalently, detention time) on the forecasted effluent concentrations of contaminants. It is presumed that the designer will conduct the design calculations via a computer spreadsheet so that design changes may be easily explored as an iterative process.

The general performance-based sizing algorithm has been previously discussed in Chapter 15 for FWS wetlands. A modified version, more specific to the typical needs and priorities for SSF wetlands, is presented here:

### Establish the design basis

1. Set inlet concentrations.
2. Set target effluent concentrations (regulatory limits and exceedance factors).

3. Set inflow and seepage (typically zero if synthetic liners are used).
4. Determine precipitation, *ET*, and temperature for critical seasons and targeted outflow rates.

**Parameter selection and primary sizing calculations**

5. Select *k*-rates for the targeted parameters.
6. Assess the regulatory compliance interval, and select appropriate trend multipliers ($1 + \Psi$).
7. Select the *P*TIS value. Since *P* incorporates both the hydraulic efficiency (number of TIS) and pollutant weathering effects, the selected *P*-value may not be the same for all targeted parameters.
8. Select *C** parameters for the targeted parameters.
9. Adjust the wetland area until design goals are met.
10. Check the proposed wetland size against loading charts (if available) to assess the relative conservativeness of the design for the targeted parameters.
11. Check the proposed mass demands of the system against biogeochemical constraints (e.g., oxygen transfer).
12. Adjust the wetland area until design goals are met.

**Secondary design considerations**

13. Assess the seasonal impact of plant biomass cycling (potentially important if nitrogen is a targeted parameter).
14. Modify the wetland area, if necessary, to meet secondary considerations.

This is necessarily an iterative process, and the designer may have to iterate at several stages in the overall design process, as illustrated in Figure 20.2.

Of necessity, performance-based wetlands require more mathematical effort than scaling rules, which is easily accomplished using spreadsheets and judicious selection of design parameters. This book provides a variety of resources to assist the designer in using performance-based design tools. These include:

***k*-rate, *C**, *P*TIS**

## Conservatism in Design

Part of the inherent challenge of using a general design model (such as the *P-k-C** model) is that there are so many variables that can be adjusted by the designer. For instance, the designer can introduce conservatism into the design model at many stages, including:

- Choosing a *k*-rate at the lower range of the frequency distribution
- Incorporating effluent multipliers for seasonal variations (see Table 8.13, Chapter 8, for example)
- Choosing a lower value of *P* (lower hydraulic efficiency and/or greater effect of pollutant weathering)
- Selecting a high concentration for *C** (limiting the level of treatment the wetland can achieve)
- Choosing a higher θ-factor (more temperature sensitivity); this is a conservative design assumption in cold climates

A designer who selects the most conservative value for each of these parameters will have an overly conservative design that ignores the many thousands of successful SSF wetland systems operating around the world. The current state-of-the-art design knowledge requires judicious selection of design parameters. The recommended approach in this book is to select median parameters for *P*, *k*, *C**, and θ, predict the system performance, and adjust using variability tables (such as those presented in Tables 8.13, 9.35, and 10.16). Of course, if the physical configuration of the wetland is different than these parent data sets, then designers must use their best professional judgment to select appropriate design parameters, because existing performance data is unlikely to represent the altered wetland configuration.

Fortunately, loading charts (such as those presented in Figures 7.30, 8.26, 9.18, 9.24, 9.30, 9.38, 10.36, and 12.12) provide a simple means to check the relative conservatism of a wetland design against the body of knowledge accumulated from wetland systems already in operation. This iterative check against loading chart data is also described in Figure 20.3.

Let us consider the example wetland previously described in Tables 20.1 and 20.2; the wetland sizing will be determined through system performance rather than a prescriptive scaling factor. In Table 20.1, the HSSF wetland size was set at 5 $m^2$/PE, which is a scaling factor commonly used in Europe (ATV, 1998). In this example, we will assume that the inlet flow of 20 $m^3$/d and inlet BOD concentration of 200 mg/L remain the same and the wetland must achieve a 90% BOD mass load reduction. We will further assume that the *k*-rate

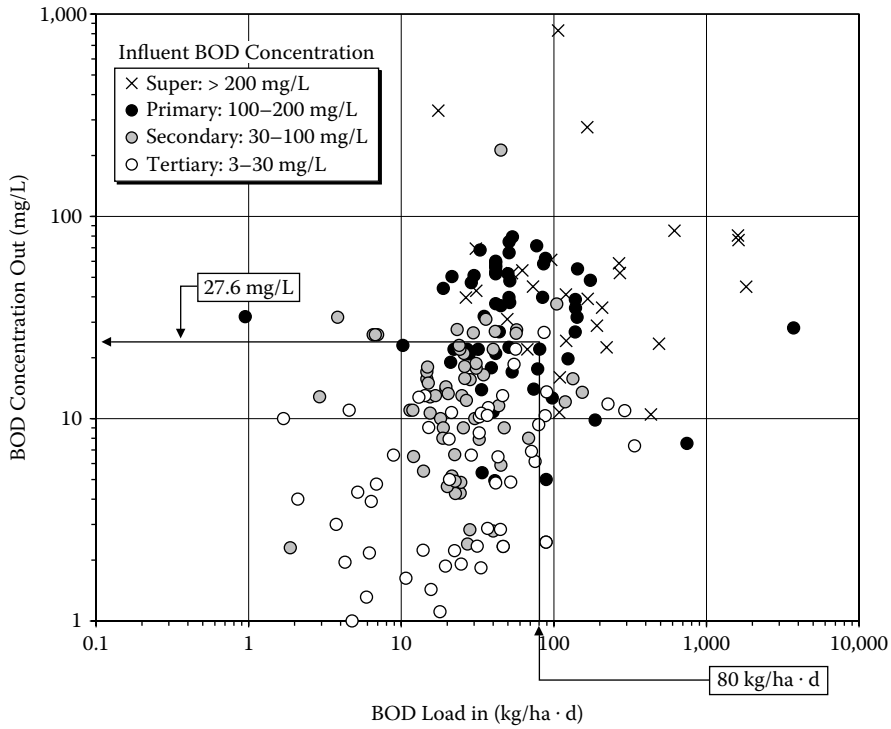

**FIGURE 20.3** Comparison of the *P-k-C** model against existing performance data based on Table 20.2.

(45 m/yr) and *P*TIS (*P* = 4) parameters remain the same as the previous examples for ease of comparison.

### Most Basic Case: Consideration of Concentration Reduction Only, No Change in Flow

If it is assumed that there is no change in flow, then a 90% reduction in mass load corresponds to a 90% reduction in concentration. Equation 20.1 can be used (with some algebraic manipulation) to directly calculate the area required, or a spreadsheet-based approach, such as the one presented in Table 20.1, can be adopted. The spreadsheet can be manually iterated by the designer, or the iteration process can be automated using functions such as the Solver™ routine in Microsoft Excel™. An example of this spreadsheet-based approach (for the assumption of no change in flow) is shown in Table 20.4. The assumption of $C^* = 8$ mg/L has been retained from the previous example.

Table 20.4 summarizes the manual iteration of Table 20.1. In just three manual iterations, a solution of 650 $m^2$ (6.5 $m^2$/PE) is arrived at. This is a prediction of the median annual performance of the wetland under a constant-flow situation ($P = ET$).

### Second Case: Pollutant Reductions under Variable Flow

If precipitation and *ET* are not equal, there will be differences between the calculations for concentration reduction and mass load reduction. The spreadsheet example of Table 20.2 has been utilized here to iterate a solution of 90% mass load reduction for the high *ET* season previously considered. Results are summarized in Table 20.5.

The spreadsheet of Table 20.5 was manually iterated (three times) to converge on a wetland size of 515 $m^2$ (5.15 $m^2$/PE) to achieve the required mass load reduction on median annual basis.

### Role of C* in Pollutant Reduction

The pollutant removal rate, *k*, and the background concentration, *C**, are independent parameters of the wetland under consideration. However, they are mathematically linked in the sizing process. To use the analogy of descending in an elevator through a building, *k* describes how rapidly you drop, and *C** determines what floor you arrive at. A high value of *k* implies a rapid drop from the initial inlet concentration, and a low level of *C** implies that the wetland can remove pollutants to low concentrations (if sized large enough).

Let us consider the case of Table 20.5, with the altered assumption that *C** is now 20 mg/L, not 8 mg/L. This situation could easily occur if there is a significant portion of BOD that is from nondomestic sources. Olive mill processing wastewater and landfill leachates are two examples where a higher level of *C** may be justified. The results are summarized in Table 20.6, which indicates that the wetland must be 700 $m^2$ (7.0 $m^2$/PE) to achieve the design goal of 90% mass load reduction on a median annual basis (even though the effluent concentration leaving the wetland

## TABLE 20.5
## Performance-Based Sizing of HSSF Wetlands under Variable Flows to Achieve Targeted Mass Load Reduction

| Input Parameters | |
|---|---|

| Concentration, $C$ | mg/L | 200.0 | 111.0 | 64.4 | 41.1 | 30.0 | 30.0 |

is 30 mg/L). Thus, the effect of a higher background concentration (in this example) increases the wetland area 36% to meet the same annual performance goal.

### Seasonal and Stochastic Variability

The rate-constant procedure to this point can be considered complete if monitoring the effluent is not required, or the system is only required to meet an annual average limit. However, many systems (especially those discharging to surface waters) will have a more frequent compliance interval (typically monthly or weekly).

In these situations, designing the wetland based on median annual performance is not acceptable because half the effluent values will be above the targeted permit concentration. In these situations, some factors must be introduced into the design to account for seasonal and stochastic changes in effluent quality. There are three basic routes open to the designer to account for these effects:

- Use of temperature correction (θ) factors (e.g. Tables 8.8, 8.9, 9.13, 9.17, 9.32). These factors can be used to adjust removal rates based on temperature dependence; however, many removal processes in HSSF wetlands are not temperature-dependent (with the exception of the nitrogen species); or
- Use of cosine-fitting parameters to account for seasonal changes in effluent concentrations (Table 8.11, Table 10.19); plus
- Use of variability parameters ($1 + \Psi$) to account for short-term fluctuations in effluent quality (Tables 8.12, 9.35, and 10.20).

The example situation considered here is if the specified wetland performance (90% mass load reduction in BOD) must be met on a monthly (as opposed to an annual) basis. Use of variability tools such as those shown in Table 8.12 can assist in this matter; selection of a 90th percentile trend multiplier (1.78) can be used to account for stochastic variations.

The example spreadsheet of Table 20.5 ($C^*$ assumed to be 8 mg/L) is again manually iterated to determine the required wetland size; results are shown in Table 20.7.

Results of Table 20.7 (manually iterated four times) indicate that the required wetland area needed to achieve a 90th percentile of non-compliance (with $C^* = 8$ mg/L) is 719 $m^2$ (7.19 $m^2$/PE) under the variable-flow situation. This is in comparison to Table 20.4, which indicates that the required wetland area is only 5.15 $m^2$/PE to meet the annual load-reduction goals. In other words, as the regulatory compliance interval is shortened, the wetland size must be increased. In this particular example, the size of the wetland must be increased 40% to address seasonal and stochastic

variability in order to meet the targeted load-reduction goal 90% of the time.

An alternate approach would be to construct the wetland as two cells in series. This would conceptually increase the hydraulic efficiency of the wetland, which could be approximated by increasing the *P*-value. If the *P*-value is increased to seven (instead of the original value of four), the required wetland size would be only 662 $m^2$ under the assumption of variable flows, $C^* = 8$ mg/L, instead of 719 $m^2$ (Table 20.7); the results are summarized in Table 20.8.

For this particular example, increasing the hydraulic efficiency of the wetland (by construction as two cells in series) reduces the required area by 8%; however, this increased treatment efficiency comes at a cost; additional berms and water level control structures must be constructed. So, at the end of the design process, the designer must balance the needs for treatment efficiency against the cost of construction. The designer could accept a larger (but less efficient) wetland area or construct a smaller, and more efficient, system, but at the added cost of additional berms and control structures.

## Cross-Checks against Existing Performance Data

As illustrated in Tables 20.4–20.8, application of the *P-k-C** model can yield performance predictions across a wide range of operating and hydraulic regimes. However, the indiscriminate use of this mathematical "tool kit" across all potential operating regimes cannot be recommended, because at present there is insufficient calibration data to address all conceivable operating conditions. Further, it will not be obvious whether the calculations exceed the experience envelope, that is, whether there have been extrapolations. Extrapolations can be extremely dangerous and must be avoided. The following sections of this chapter explore the constraints on the *P-k-C** model that a prudent designer would cross-check before finalizing the design sizing of a treatment wetland system.

Let us consider the example of Table 20.7. In this case, the designer has decided that a wetland of 719 $m^2$ (7.19 $m^2$/PE) should be sufficient to meet the targeted performance goal of a 90% mass load reduction in BOD under a variable-flow situation, and the size of the wetland has been further increased. How do real-world wetland systems perform in this loading range? Loading charts (such as shown in Figure 8.26) can be used to cross-check the forecasted wetland performance against operating data from existing wetland systems.

An example of such a cross-check is illustrated in Figure 20.3. In this example, the predicted wetland performance shown in Table 20.2 has been plotted on Figure 8.26. At a sizing of 5 $m^2$/PE, the equivalent influent BOD loading is 8 g/$m^2$·d (80 kg/ha·d) and the forecasted wetland concentration is 27.6 mg/L. The loading chart cross-check indicates that this performance forecast is close to the center of the data cloud; many existing wetlands operate in this performance

**TABLE 20.8**
**Decrease in Required Area if the Wetland Is Constructed as Two Cells in Series (Compare to Table 20.7)**

| Input Parameters | | Calculated Values | |

range, but the design is not particularly conservative (if the wetland being designed functions similar to the ones described by the performance data).

The design concept has here been illustrated for BOD, but most wetlands will be multifunctional and have multiple regulatory requirements. For instance, nitrogen, phosphorus, TSS, and pathogens may also need to be considered. Therefore, the design procedure is repeated for each design pollutant, and an area required for each determined. The largest area will be selected for the "bottleneck" pollutant. The design calculations for all other constituents must then be repeated for that area, resulting in overtreatment for all other constituents.

## Biogeochemical Cycle Constraints

Tools such as loading charts and *k*-rates can be used to predict system performance; however, it is important that the designer remains aware that the wetland is always an internally cycling biomass and is subject to other constraints, such as oxygen transfer and carbon supply, that can potentially limit system performance. These constraints are not explicitly addressed either in the loading chart or in the *P-k-C** approach; therefore, it is important to cross-check the wetland design against biogeochemical constraints.

### Biomass Cycling

The annual cycle of plant growth, death, and decay imposes a set of cycling processes that exchange carbon, nitrogen, and phosphorus between different compartments within the wetland, as discussed in Chapters 3, 8, 9, and 10. For the HSSF wetlands designed for simple removals, such as BOD, biomass cycling is probably not an important factor (Langergraber, 2005) and can be lumped into the seasonal and stochastic variability tables previously described. However, in other instances, plant biomass cycling may be a significant factor in system performance, and the use of biomass cycling parameters, such as those summarized in Table 17.7, may be used as a cross-check of system performance.

As an illustration, we will here consider the performance of a HSSF wetland cell at New Hanover County, North Carolina (Liehr *et al.*, 2000). This particular cell was supplied with a nitrified landfill leachate that had low BOD levels. Denitrification performance was poor and assumed to be limited by the availability of organic carbon. In 1997, the wetland was loaded at a rate of 628 g/m·yr of nitrogen, 92% of which was nitrate.

Table 17.6 in Chapter 17 suggests that approximately 30 g/m$^2$·yr could have been taken up by the vegetation (moderate second-year growth). The small amount of ammonia (TKN) was about sufficient to meet that need. The amount of organic carbon necessary to fuel conventional denitrification would be 691 g/m·yr of carbon (Table 17.7, Chapter 17). A review of Table 17.6 indicates that if the system was considered to be "nutrient moderate," then there would clearly be insufficient organic carbon from the plant biomass cycle (2,000 g/m$^2$·yr × 10% = 200 gC/m$^2$·yr). At higher plant densities, Table 17.6 indicates there still would not be sufficient organic carbon produced in the biomass cycle. Also, the designer must consider the spatial distribution of the biomass; aboveground plant materials are deposited on the surface of the HSSF bed, and may not readily degrade (within one annual cycle) and return carbon to the water column. (This phenomena is exacerbated under hot, arid conditions when aboveground biomass desiccates). The New Hanover County wetland in 1997 was still a developing system in a phase of plant grow-in during this study; so little biomass degradation products were presumably returned to the water column.

The BOD in the incoming water averaged only 18 mg/L and therefore could not support any high amount of denitrification.

In the case of the New Hanover County system, only 12% of the applied nitrogen was removed during the 1997 season (75 gN/m$^2$·yr), implying a net organic carbon supply of only 83 g/m$^2$·yr. In this particular case, wetland nitrate removal performance was clearly limited by the carbon supply, and neither the incoming BOD nor the biomass production of carbon was adequate to realize the full removal potential.

### Oxygen Transfer

In the normal mode of operation for HSSF wetlands, the water is kept below the surface of the granular media, which is typically covered with accumulated plant detritus (and potentially an insulating mulch layer). Air–water exchanges are discussed in Chapter 5; oxygen transfers can be implied for the removal of nitrogen species; Table 9.26, Chapter 9 is an example for HSSF wetlands.

Whereas the rate of oxygen transfer in HSSF wetlands is debatable (because there is insufficient data to settle the issue), there is clearly an upper limit to the rate of transfer; oxygen transfer is obviously influenced by the temperature and physical barriers between the atmosphere and the water column, thus implying a limitation on treatment reactions that require oxygen.

### Other Biogeochemical Cycles

The designer should keep in mind that the biomass cycle spins nitrogen, phosphorus, and micronutrients in addition to the organic carbon examples described previously. All of the cycle constraints discussed in Chapter 17 also apply to SSF wetlands.

Whereas biomass cycling and oxygen are some of the most common performance limitations encountered in HSSF wetland design, other limitations do exist, and the designer must always check the stoichiometry of the desired treatment reactions. A classic example is the treatment of mine drainage waters. If sulfide precipitation of copper and other heavy metals is a desired treatment outcome, there obviously must be enough sulfate (on a mol-to-mol basis) in the

influent waters and also enough organic carbon (often supplementally added to the system as peat or compost) to drive sulfate reduction within the wetland (Frostman, 1993).

## 20.4 VF WETLANDS (INTERMITTENTLY LOADED BEDS)

Vertical flow (VF) nitrification wetlands are vegetated, intermittent sand filters that are sufficiently wet to support obligate wetland plants. Figure 1.7 shows the section through a typical VF system. The bed consists of layers of graded gravel on top of large stones. Reeds are planted in the layer of coarse sand that provides the top surface. The *Phragmites* or other plants growing on the bed provide an improved microbial environment and help maintain the hydraulic conductivity of the bed. Bacteria that do the BOD removal and nitrification are in the biofilm growing on the sand and gravel particles in the bed. In addition, ammonia adsorption can occur during the downflow, followed by nitrification during the aerobic drainage period. The large stones at the bottom of the bed are placed around a drainage system consisting of drainage tiles or perforated agricultural drainage pipes. The wastewater to be treated is dosed intermittently to the surface of the bed.

A number of dosing systems have been used. In the flooding concept, water is dosed onto the bed in a large batch thus flooding the surface. The water then gradually drains down through the bed and is collected by a drainage network at the base. The bed drains completely, and this allows air to refill the bed. The next dose of liquid traps this air, and this, together with the aeration caused by the rapid dosing onto the bed, leads to good oxygen transfer and hence the ability to nitrify. The frequency of dosing should be timed such that the previous dose of liquid has had time to percolate through the bed so that the void spaces are refilled with air. Other concepts involve spray application and creation of anaerobic pools in the bottom of the bed.

Loading is typically intermittent to the active bed at frequencies that vary from project to project. Typically, loading occurs four to six times a day by means of valves and siphons or pumping devices installed in a feed sump or in a buffer tank. Multiple beds are used sequentially in time to allow a resting period. The number of beds ranges from two to six. Figure 20.4 shows an example of a layout used at Medmenham, United Kingdom, consisting of two units of four beds each in series.

### Development

The earliest VF constructed wetlands in Europe were the so-called infiltration fields in the Netherlands and the Seidel System, also known as the Krefeld System or Max Planck Institute Process (Seidel, 1976; Brix, 1994a). These infiltration fields have been in operation in Europe for approximately 25 years, to treat the wastewater from recreation sites outside the municipal sewer network in the Netherlands (Rijs and Veenstra, 1990). The system is typically comprised of a preliminary settling/distribution ditch, four infiltration compartments with soil/sand media, a discharge via drain, and an effluent ditch. The infiltration fields are planted with *Phragmites australis* and are provided with a drainage system 0.55 m beneath ground level. Raw domestic sewage is discharged into the preliminary settling/distribution ditch. After settling, the sewage is mixed with surface water from the effluent ditch and fed into one of the infiltration compartments every three to four days. The other three compartments are kept dry for a period of 10 to 11 days. The purification results and the composition of the groundwater indicate that extensive removal of pollutants takes place in the soil filter.

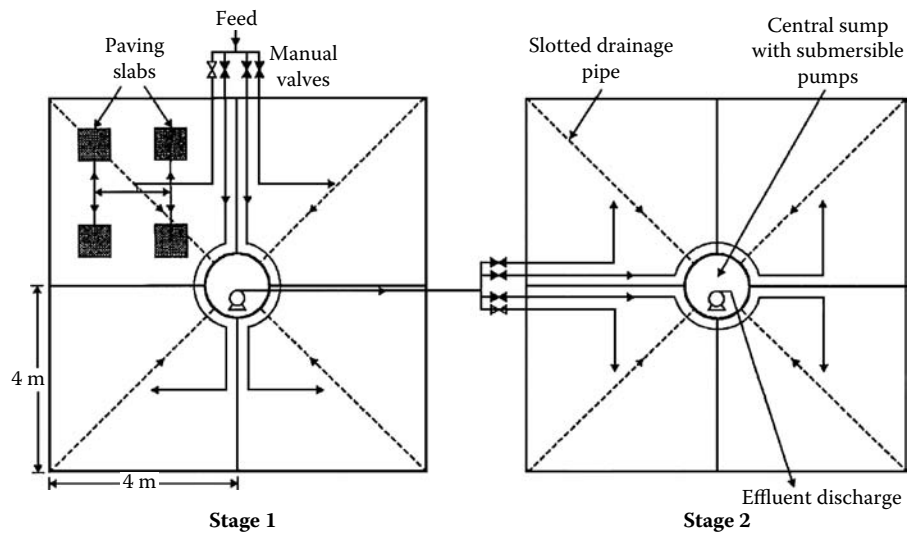

**FIGURE 20.4** Arrangement of the system of VF beds at Medmenham, United Kingdom. This represents a small and intricate set of beds and plumbing. (From Cooper *et al.* (1999) *Water Science and Technology* 40(3): 283–289. Reprinted with permission.)

The Seidel System (Seidel, 1976) consists of several beds laid out in parallel in one or several VF stages in cascades, followed by two or three horizontal flow beds in series. The VF stages are usually planted with *Phragmites australis*, whereas the horizontal flow stages contain a number of other emergent macrophytes, including *Iris, Schoenoplectus, Sparganium, Carex, Typha,* and *Acorus*. The media used in the beds is gravel, topped off with sharp sand in the VF beds to achieve an effective distribution of the wastewater across the bed. The lower, coarser gravel layers are kept aerobic by means of aerated drainage tubes. The VF beds are loaded with pretreated wastewater for one to two days, and are then allowed to dry out for four to eight days. The thin crust of solids that forms on top of the sand layer is mineralized during the rest period and achieves an equilibrium thickness. Variations of these systems have been in operation in different European countries for about 30 years (Burka and Lawrence, 1990; Liénard *et al.*, 1990). Austrian experiences have been very good during the last few years (Schönerklee *et al.*, 1997; Laber *et al.*, 1997).

The development of VF wetlands in the United States has followed more recently than in Europe, in the early 1990s. Watson and Danzig (1993) performed pilot mesocosm experiments that confirmed the European experience and subsequently retrofitted a lagoon-wetland system with a VF bed prior to the wetland. In 1993, the Lamb Weston company began pilot studies of a *Phragmites* VF system at Connell, Washington (Kadlec *et al.*, 1997). This study led to a full-scale facility in which 5,000 $m^3$/d are applied to 4 ha of VF beds, which have operated successfully since 1996 (Burgoon *et al.*, 1999). Other VF facilities have been developed at a variety of scales.

## Sizing

Usually, VF constructed wetlands are applied as biological stages (secondary treatment) for mechanically pretreated domestic wastewater. Experiences have shown that their performance is strongly dependent on pretreatment, i.e., settlement tank, septic tank, package plant, or others. VF constructed wetlands can also be applied as a polishing stage following a conventional biological treatment plant, such as activated sludge. The typical design parameters of VF constructed wetlands are the required area, the depth, the medium, and the application strategy.

### Scaling Factors

To date, scaling factors have been the most widely used sizing method for VF wetland systems. Table 15.1, Chapter 15, summarizes various scaling factors that have been proposed in the literature.

### First-Order Models

The first-order areal model may be used for the calculation of the wetland area as has been detailed for the FWS and HSSF systems. The *k*-values depend on the water-quality parameter and on the different environmental and operational circumstances. The ranges reported in Table 20.9 were deduced from measurements of an unspecified number of practically operated plants (Vymazal, 1998). These rate-coefficient ranges are plug flow values, and therefore are based upon the *P*TIS model with a very large value of *P*. The tracer measurements do not support this presumption, which is surprising, because the vertical unsaturated flows probably do not back-mix and are not subject to effects of wind as are FWS systems. In any case, the wide range of the *k*-values is also a result of the different designs and operations of the systems. It must be further recognized that the internal loading of ammonia, resulting from mineralization of organic nitrogen, has been ignored, and the rate coefficients are, therefore, only apparent values. They do not represent nitrification, which may indeed be much higher. Also, because of the periodic character of the process, the use of such a simple first-order model, as for other types of constructed wetlands, may be inappropriate (Platzer, 1999). It is possible to modify the application of the first-order model to a more complex form involving the dynamics of the filling and draining cycle (Sun *et al.*, 1998). To date, there are no calibrations of such tidal models to domestic sewage treatment systems.

**TABLE 20.9**
**Rate Coefficients for Vertical Flow Pulse-Loaded Wetlands Compared to Those for HSSF Systems; the VF Values Are for Plug Flow**

| Parameter | VF *k*-rate (m/yr) | HSSF Input (mg/L) | HSSF 20th Percentile *k*-rate (m/yr) | HSSF 80th Percentile *k*-rate (m/yr) | HSSF Table Number | HSSF *P*TIS |
|---|---|---|---|---|---|---|
| $BOD_5$ | 20–60 | 30–100 | 20 | 82 | 8.7 | 3 |
| $BOD_5$ | — | 100–200 | 12 | 62 | 8.7 | 3 |
| $NH_4$-N | 10–40 | — | 2.7 | 29.8 | 9.25 | 6 |
| TN | 12–20 | — | 3.3 | 18.1 | 9.19 | 6 |
| FC | 70–95 | — | 43 | 251 | 12.17 | 6 |

### *Biochemical Oxygen Demand*

The BOD rate coefficients for the VF systems in this book are given in Table 8.16, Chapter 8, separated by inlet concentration ranges. These differ widely from those for HSSF, and are considerably higher for VF than for HSSF (Table 8.8, with lower values if plug flow is assumed), by a factor of three to five. The current data set produces about the same *k*-values as those shown in the work of Vymazal *et al.* (1998), under the plug flow assumption (not shown). But Schwager and Boller (1997) conducted tracer tests that indicated *N*TIS = 5 for their VF system (see Chapter 2). When the BOD weathering effect is factored in, it seems probable that a value such as *P*TIS = 2 should apply to VF systems. Under this assumption, the VF BOD *k*-values are much higher.

### *Ammonia*

There seems to be little difference in the ranges of the ammonia reduction rate coefficients for HSSF and the Vymazal et al. (1998) VF wetlands (Table 20.9). Although this seems in conflict with the concept of better nitrification and BOD reduction in VF systems, it is not. Rather, it points to the need to consider hydraulic loadings and the supply constraints that limit the reactions that may occur, as detailed in constraint checks advocated in earlier chapters. The ranges of apparent plug-flow ammonia *k*-values, derived from the database of 72 systems used in this book, are similarly wide (Table 20.10). However, the ammonia rate coefficients are three to five times as high as those for HSSF wetlands (compare Tables 20.10 and 9.25).

## Loading Rates

There are two philosophies of hydraulic loading for pulsed VF wetlands: loadings comparable to HSSF wetlands, and loadings many times higher. Peaks in the reported frequency distribution occur at 4 cm/d and at 40 cm/d. Higher rate constants are associated with higher hydraulic loadings. The Brix *et al.* (2002a) design hydraulic loading is on the order of 20 cm/d. Hydraulic loadings may be fairly high and still yield good BOD/COD and ammonia reduction. Loadings ranging to over 100 cm/d have been employed.

The definition of hydraulic loading rate used here is the long-term average flow rate to the system divided by the total area of beds. Other definitions can be used, and the reader is cautioned to understand the terminology in use for a particular project. For example, beds may be loaded only one third of the time, thus tripling the per-bed loading when in use.

**TABLE 20.10**
**Apparent Rate Coefficients for Ammonia for VF Pulse-Loaded Wetlands**

**Stipulations**

1. Period of record averages are used in calculations.
2. For *k*-value calculations, the following *P*-*k*-*C** parameters are selected:
   a. $C^* = 0$ mg/L.
   b. $P = 8$ TIS.
3. Ranges of variables:

| | HLR (cm/d) | $NH_4$-N In (mg/L) | $NH_4$-N Out (mg/L) |
|---|---|---|---|
| **Mean** | 22.7 | 59 | 21.1 |
| **Median** | 4.3 | 49 | 4.9 |
| **Max** | 222 | 264 | 212 |
| **Min** | 1.00 | 0.20 | 0.03 |

**Results: N·*t* = 120 wetland-years; N = 72 VF wetlands.**

| Percentile | HLR (cm/d) | Apparent Implied Oxygen Utilization ($g/m^2 \cdot d$) | Apparent Rate Constant (m/yr) |
|---|---|---|---|
| 0.05 | 1.9 | 3.1 | 0 |
| 0.10 | 2.2 | 4.2 | 5 |
| 0.20 | 2.4 | 9.4 | 10 |
| 0.30 | 3.1 | 12.8 | 17 |
| 0.40 | 3.5 | 15.1 | 24 |
| 0.50 | 4.3 | 17.7 | 33 |
| 0.60 | 7.6 | 21.0 | 48 |
| 0.70 | 11.5 | 30.6 | 68 |

*Note:* The apparent implied oxygen utilization is calculated as $IOTR = \Delta BOD + 4.6 \cdot \Delta NH_4N$. Both numbers are apparent because they do not include internal ammonia production from organic nitrogen.

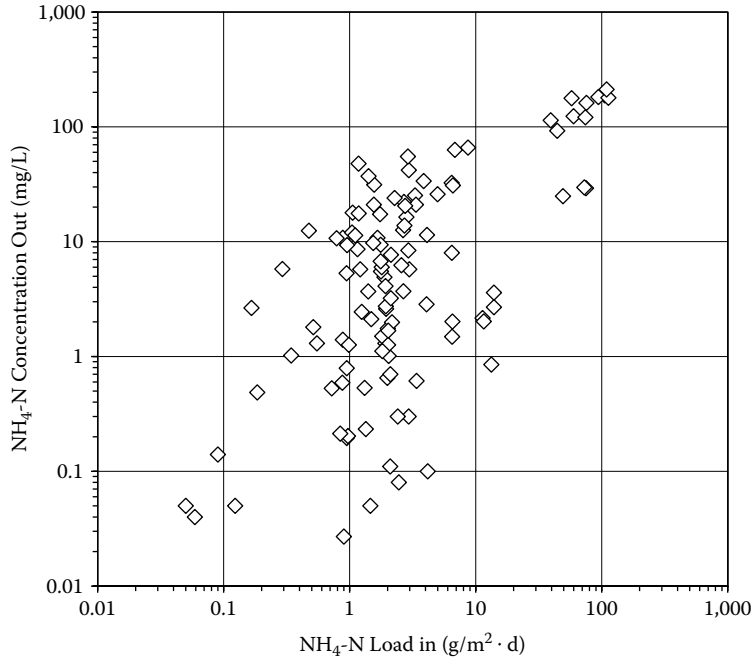

**FIGURE 20.5** Ammonia load response for pulsed VF wetlands. (N = 118 system-years of data.)

Further, pulse loading means that water flows to one of the three beds only a fraction of the time it is in service, meaning that there is an instantaneous, per-bed loading as well.

However, performance (i.e., lower outlet concentrations) increases as loading decreases (Figure 20.5). Thus, increasing bed size, or using the beds in series, is an effective design technique. However, the scatter on the loading chart is too great to be of use in design.

It is likely that the high *k*-values for BOD and ammonia will cause rapid reactions and that this will cause the rate-limiting factor to be the oxygen transfer rate. Therefore, this constraint must be considered in design and can in fact be its basis.

## Oxygen Transfer Rate

A second design approach is to rely on empirical observations of the apparent or implied oxygen transfer rates (IOTR) from operating systems. As discussed in Chapter 9, this procedure rests on some assumptions regarding the stoichiometry of oxygen usage. Here, we shall presume that the maximum IOTR applies to VF wetlands because of the inherently oxic environment that is intentionally created.

Platzer (1999) has measured values of oxygen transfer rate (OTR) in the range 23–64 $gO_2/m^2{\cdot}d$, Green *et al.* (1997a) report 56–60 $gO_2/m^2{\cdot}d$, and Cooper *et al.* (1999) report 50–90 $gO_2/m^2{\cdot}d$. Oxygen consumption is for nitrification and BOD/COD reduction and is estimated as

$$\text{IOTR} = 4.6 \times \Delta(\text{NH}_4\text{–N}) + \Delta(\text{BOD}) \qquad [\text{in gO/m}^2{\cdot}\text{d}] \tag{20.10}$$

This oxygen demand may be lessened by BOD settlement, ammonia volatilization, plant uptake, and denitrification, but increased to support microorganic metabolism. For instance, Cooper (1999) uses a coefficient of 4.3 instead of 4.6. The observed ranges of oxygen supply per unit area may be combined with the estimate of oxygen demand of the entire flow to determine the bed area: area = OD/IOTR = (gO/d)/(gO/m$^2$·d).

The areas so determined are relatively small. For instance, suppose the incoming flow is 1,000 m$^3$/d, $\Delta(NH_4\text{-N})$ = 20 mg/L, and $\Delta$(BOD) = 40 mg/L. Then, the oxygen demand is calculated to be 132 kgO/d. If the IOTR is taken to be 30 gO/m$^2$·d, then 4,400 m$^2$ is required. Brix *et al.* (2002a) calculate VF systems by presuming a surface aeration rate of 30 gO/m$^2$·d, and adding a 25% safety area. If the bed is 1 m deep and intermittently loaded, a nitrification efficiency of 85% is projected.

Table 9.28 in Chapter 9 is preferred for purposes of design over Table 20.10. Although Table 9.28 is based on less data, it has the advantage of including the internal ammonia loading that results from the ammonification of organic nitrogen. As is the case in other sizing calculations, it is left to the designer to select IOTR to be used in a particular design.

## Denitrification

The oxidized nitrogen that is formed by nitrification may be partially denitrified in the bed under some circumstances. There must be an anoxic zone, and there must be a carbon supply. Thus, the systems that remove BOD effectively do not denitrify effectively. Examples are given in Table 20.11.

**TABLE 20.11**
**Examples of Ammonia-N and Nitrate-N Removal/Buildup in VF Constructed Wetlands**

| Location | $NH_4$-N In (mg/L) | $NH_4$-N Out (mg/L) | $NO_3$-N In (mg/L) | $NO_3$-N Out (mg/L) |

### Temperature

Nitrogen removal processes are moderately temperature sensitive. Temperature coefficients from field data in VF wetlands are in general not available and can only be presumed. Nitrification does not entirely shut down at cold temperatures. Further, VF wetlands display the ability to conduct BOD reduction simultaneously with nitrification. It is therefore not necessary to reduce BOD prior to nitrification, but there is probably an advantage in doing so.

### Phosphorus

Phosphorus is not much reduced in VF wetlands, except perhaps for a transitory period of start-up. Sorption sites become loaded, and efficiency declines. Because loadings are sometimes quite high, the removal via the biogeochemical cycle is minimal.

### Variability

Like other types of constructed wetlands, VF systems possess inherent variability in their effluent concentrations. Table 9.36, Chapter 9, provides examples that indicate that the excursion frequencies are not widely different from those for other wetlands. There are annual cosine trends and scatter about them (see Figure 9.50, Chapter 9).

### Number of Beds

The need for bed resting, coupled with the fraction of the long-term period that can be devoted to resting, determines the number of separate VF beds needed. For instance, if it is decided that beds must rest two thirds of the time to avoid clogging layer buildup, then three beds are needed, to be used in rotation one at a time. Note that the Medmenham, United Kingdom, project used four beds (Figure 20.4).

## 20.5 VF WETLAND SIZING (RECIRCULATING FILTERS)

Vegetated recirculating gravel filters have been used as a "vertical flow wetland" alternative in North America, mainly in cold-climate applications, where surface flooding or spray irrigation creates operational problems in the winter. Because surface flooding is a much simpler means of influent distribution, it is preferred where thermal considerations allow. Because these systems operate as unsaturated flow filters, the vegetation used often falls into the facultative category (see Chapter 2), so these systems can only nominally be classified as "wetlands" from the standpoint of the vegetative community, which does not play a significant role in the treatment process. At the present time, there are approximately 35 systems of this nature operating in Canada, and about 140 systems operating in the United States. The application of these systems ranges from single-family homes (Wallace and Higgins, 2001) to dilute runoff streams in excess of 1,500 $m^3$/d.

These systems operate as gravel filters, which is an old treatment technology dating back to 1889 (Grady *et al*., 1999). The degree of treatment depends on the influent mass loading, recirculation ratio, media type, and air exchange (oxygen transfer). At the present time, designs are typically based on empirical methods (Grady *et al*., 1999) presented in standard sanitary engineering textbooks.

The most common design approach is to size these systems as recirculating gravel filters and ignore the vegetation component from a treatment perspective. The overall footprint of the system is usually based on a prescriptive mass

loading scaling factor. BOD loading rates of 10 to 40 g/m$^2$·d are often used, with most designs using loading rates of <25 g/m$^2$·d (Crites and Tchobanoglous, 1998).

The hydraulic loading and recirculation must also be considered because the goal of these systems is not only to provide frequent dosing (to keep the bed media moist) but also to minimize the dose volume to promote unsaturated flow and facilitate air exchange (and oxygen tran sfer) within the wetland bed. Doses of 48–120 doses per day are common, which typically require storage tanks in the recycle loop with the capacity to retain the average daily (forward) flow (Crites and Tchobanoglous, 1998).

This technology can reliably achieve secondary treatment for BOD that has received primary treatment. Nitrification and denitrification are possible but depend on the influent mass loading rate and degree of recycle; current design tools are empirical in nature (NRC, 1946; Galler and Gotas, 1964).

## 20.6 BIOSOLIDS WETLANDS FOR SLUDGE DEWATERING

At present, information on the sizing of biosolids wetlands is based on mass loading scaling factors. These have been developed based on the cool temperate climate of Denmark. Scaling factors are <60 kg/m$^2$/yr for waste activated sludge (WAS) and <50 kg/m$^2$·yr for a combination of primary sludge and WAS (Nielsen, 2002).

This system utilizes the *ET* properties of *Phragmites* as an aid in sludge dewatering and stabilization, coupled with gravity drainage and microbial stabilization. As a result, the system is highly dependent on the loading and resting of individual beds. The overall wetland area is subdivided into beds to facilitate this mode of operation. A minimum of 8 beds are required for facilities that produce up to 500 tons of dry solids per year; ten beds are the minimum for 500–1,000 dry tons per year, and 12–14 beds are needed for >1,000 dry tons per year. (Nielsen, 2002).

The typical loading intervals last four to ten days, the remainder of the operational sequence being devoted to resting the individual bed. Shorter loading periods and longer resting intervals are the preferred operational strategy, making the number of beds an important design consideration.

## 20.7 SECONDARY CONSIDERATIONS

It is assumed that at this stage the designer has implemented an appropriate sizing method (loading charts or the *P-k-C** model) and cross-checked performance forecasts against existing performance data and biogeochemical constraints. The final stage of the sizing process is to consider other factors that may influence the overall wetland sizing. The "definitive list" of final sizing parameters is inherently project specific; here, we will consider two commonly encountered situations that may influence the final design of a HSSF wetland.

### Seasonal Impacts of the Biomass Cycle

As discussed previously in this Chapter, the annual biomass cycle can impose constraints on wetland performance. However, short-term seasonal effects of plant biomass can further influence system performance (see Figures 9.11–9.13, Chapter 9). If we take the case of a typical European HSSF wetland sized at 5 m$^2$/PE (ATV, 1998), the equivalent nitrogen loading is 2.4 g/m$^2$·d (73 g/m$^2$·month). Inspection of the biomass cycle (e.g., Figure 9.13) indicates that all of the influent nitrogen can be assimilated into plant biomass during the period of maximum growth (June and July in the northern Hemisphere). These short-term effects can be important when the system has a frequent regulatory compliance interval (e.g., weekly or monthly).

### Thermal Energy Balance Limitations

The preceding design examples have considered wetland sizing independent of thermal considerations; thus the inherent assumption of these examples is that "bigger is better," e.g., more wetland area equals a desirable outcome in terms of better treatment performance. There are obvious limitations to this assumption, which are most likely to be encountered in extreme environments; the two most common are the following:

In water-scarce environments, water quantity may be more important than water quality; hence, the effluent is too valuable to waste and is required for reuse. In these situations, a wetland designer may choose to minimize the wetland area (and associated treatment performance) to maximize the effluent volume available for reuse. In these situations, utilization of the sequential, tank-by-tank, variable flow model (see Tables 20.3, 20.6, 20.8) can greatly facilitate the design compromise between treatment efficiency and the volume of water available for reuse.

## SUMMARY

This chapter has integrated the elements of preceding chapters into a sequential approach to designing and evaluating SSF treatment wetlands. Sizing is the first step in design, and loading charts, scaling factors, and the *P-k-C** model have all been presented for comparable design examples.

The designer is cautioned that there is nothing about loading charts, scaling factors, or the *P-k-C** model that acknowledges the limitations of wetland biogeochemical cycling. Therefore, this chapter also discusses the cycling of biomass cycling and other constraints of the wetland ecosystem to ensure there are no unrealistic expectations of the nutrient, oxygen, and carbon supplies of the ecosystem. Rate coefficients must be adjusted if the presumed capacities of the ecosystem are being exceeded. Loading charts are a method of understanding where a particular design is positioned compared to the behavior of existing systems. Designs that fall outside the range of the existing data envelope will require further justification (such as pilot-scale studies) to ensure system performance.

# 21 Implementation of SSF Wetlands

The purpose of this chapter is to provide information that will help ensure successful outcomes for projects using horizontal and vertical subsurface flow (SSF) wetlands (or biosolids wetlands) by discussing the internal configuration of these systems. Common construction pitfalls and start-up errors are also discussed.

Implementation of SSF wetland systems consists of the following three stages:

1. Physical design (specification of internal components)
2. Construction of the wetland
3. Start-up (commissioning)

The sizing of the system can be done using different sizing tools, including loading charts, scaling factors, and first-order modeling. The pros and cons of these methods have been discussed in Chapter 20.

The first implementation stage, physical design, involves making decisions as to the number of cells, site grading, aspect ratio, bed depth, internal piping, media size, hydraulics, water level control, insulation, etc. The configuration of these components is then typically documented in a set of technical drawings (engineering plans) and written specifications.

Construction of the system consists of preparing bidding documents, retaining a contractor, and physically building the wetland. This is the most critical phase of the implementation because construction of SSF wetlands is essentially a "one-way street." Problems with site grading and elevations become difficult and expensive to correct once the liner (if any) is in place. Problems with the liner become next to impossible to correct once the bed media is installed. Because it is so difficult to undo construction problems, the wetland designer is often retained in some advisory capacity to observe and document the construction work.

The final stage, commissioning, includes introducing the flow and pollutant loading into the wetland, as well as managing water levels in the wetland in a manner consistent with vegetation establishment and regulatory compliance.

The overall implementation process may seem deceptively simple, but it is not. Determining the wetland size is not the same as designing the system. Mistakes made in the technical drawings and specifications will lead to serious problems down the road. Mistakes made during construction may be extremely difficult to fix, and repairs are likely to cost many times more than the original components. Failure to understand how the wetland is supposed to operate leads to start-up problems. Any of these situations is likely to lead to the intervention of regulatory authorities.

Characterization of the influent waste stream and general site assessment issues have been previously discussed in Chapter 16. Procedures for sizing the wetland (determining the necessary wetted area) have been reviewed in Chapter 20. The next stage in the implementation process is deciding how the wetland should be configured, how internal components should be placed, and how large they are. Those issues are discussed in more detail here.

## 21.1 SITING

General conditions of the potential site will have been considered during the establishment of the basis of design. There will remain a number of possibilities for the location of the system within the overall site confines. These factors have been previously discussed in a general way in Chapters 16 and 18 for FWS wetlands; these also apply to SSF wetlands. This chapter considers additional factors that often come into play when siting SSF wetlands. These systems are typically smaller than FWS wetlands and, consequently, are often constructed in or near existing infrastructure.

### Construction Access

Although the as-constructed footprint area of an SSF wetland may be small, the designer must keep in mind that these wetland cells will be constructed with earth-moving equipment such as backhoe excavators. The size of this equipment requires a clear perimeter area around each wetland cell; the track size of the equipment will define the minimum separation distance between the wetland cell, the site boundary, and additional wetland cells. Large excavators are often preferred by contractors because the long reach of these machines facilitates placement of bed media during construction. An example of a construction-imposed separation distance is shown in Figure 21.1.

Typical separation distances are in the range of 5–7 m around the perimeter of each wetland cell to allow access by construction equipment. Designers should keep in mind that devices such as cranes (Figure 21.2) may be required to set primary treatment devices such as settling tanks, so overhead vertical clearance (from obstacles such as power lines) may be another construction access issue. Excavations for tanks, pipes, wetland basins, and water level control structures raise another access issue. Clearly, there must be an adequate location on the site to temporarily store excavated soil. With deep excavations (especially trenches), the excavation may have to be braced, or the sidewalls may have to be stepped back to avoid the risk of cave-in. This greatly increases the amount of site area and access needed during

**FIGURE 21.1** Separation distance between these two vertical flow wetland cells was dictated by the need for access by construction equipment at The Preserve, Minnesota. The use of such a large excavator was desirable to place gravel media in the wetland cells. Alternate means of gravel placement, such as an extendable conveyor, would decrease this separation distance.

the construction period. This is especially important in sandy soils that have a low angle of repose and thus require large excavation widths.

It should be noted that heavily wooded sites will require clearing and grubbing, as discussed in Chapter 18, and remote sites may necessitate the construction of access roads, adding to the overall construction cost.

### Slopes

SSF wetlands require the construction of level beds. On sloping sites, this will necessitate terracing of the areas where wetland beds are to be constructed. On steeply sloping sites, this will require substantial cut (earth removal) on the uphill side and substantial fill (earth placement) on the downhill side; this additional earthwork can far exceed the volume of the wetland basin itself. Consequently, steeply sloping sites are often not preferred construction areas, unless no other alternative is available.

It should be noted that completely flat sites may also require substantial earthworks if gravity flow through the treatment process is desired. Sites with 1–3% slopes are often the easiest to work with in terms of establishing a hydraulic profile that flows by gravity.

### Existing Utilities

SSF wetlands are often used for homes and villages that have previously lacked wastewater treatment. Because the wetland (and any associated collection system component) is often the last utility in the ground, there is always the risk of hitting and damaging other underground utilities, such as water pipes, gas lines, electrical power lines, or telephone wires. Most utilities in North America have a "one-call" telephone number to dispatch an individual to locate these utilities. Obviously, sites with known utility conflicts should be avoided, or provisions to reroute the affected utilities must be incorporated into the design process.

**FIGURE 21.2** Installation of settling tanks at The Preserve, Minnesota. Note that construction access is needed for four different components: (1) the truck and trailer used to deliver the tanks, (2) the crane used to set the tanks, (3) the excavation itself, and (4) the area needed to stockpile the excavated soil. Thus, the total area needed for construction is far greater than the tanks themselves.

Biosolids wetlands are generally constructed to support sludge management at existing mechanical treatment plants and are often constructed in close proximity to these treatment works. Again, knowledge of existing utilities is a critical component of the design process.

### Floodplains

Siting of wetland systems in floodplains and floodways has already been addressed in Chapter 18. It should be noted that most flood events result in considerable sediment deposition as flood waters recede. Free water surface (FWS) wetlands are much more tolerant of this sediment load than SSF wetlands, where the additional sediment could create potential clogging issues in the wetland bed. As a result, locating SSF wetlands in floodplains requires careful consideration of the expected frequency and severity of flooding in the project area.

Biosolids wetlands will contain organic sludge with varying degrees of pathogens, depending on the age of the biosolids and level of stabilization. Because the potential to export pathogenic material exists during a flood event, a decision to locate such a facility in a floodplain would have to be carefully evaluated.

### Regulatory Issues

Regulatory requirements are often a major factor in the selection of SSF technology over FWS wetlands. For instance, in the United States, approximately 25% of homes rely on onsite (single home) septic systems (U.S. Census Bureau, 1990). There are considerable health risks associated with exposure to raw sewage (or sewage exiting the septic tank). As a result, there is a large body of prescriptive codes that require the treatment and disposal of the sewage *without surface exposure of the wastewater* (U.S. EPA, 2002c). Thus, wetlands such as FWS and surface-flood vertical flow (VF) systems cannot be used in these applications, and the regulations force the designer to use HSSF wetlands or VF wetlands with buried distribution piping so the water will not be exposed.

Another example of regulatory requirements that dictate the wetland selection process is airports. In cold climates, ice must be removed from the airplanes prior to take-off, and the associated de-icing chemicals generate stormwater runoff that is high in organic (glycol) contaminants. Constructed wetlands can remove this chemical oxygen demand (COD) load. However, because there is a potential for bird–aircraft strike hazard (BASH), open water bodies such as ponds and FWS wetlands are often discouraged or prohibited from being constructed near airport runways (FAA and U.S. Department of Transportation, 2004). For this reason, SSF wetlands (VF or HSSF) are preferred for treating de-icing runoff.

Siting of wetlands is also influenced by required separation distances from homes, water bodies, and other landscape features. These separation distances are usually prescriptive in nature and dictated by local, state, and provincial regulations. In the United States, these range from approximately 3 m to over 300 m, depending on the applicable regulations and the size of the treatment system. In situations where there are limited choices for siting the wetland, these separation distances may end up not only dictating the location but also the shape of the wetland, as illustrated in Figure 21.3.

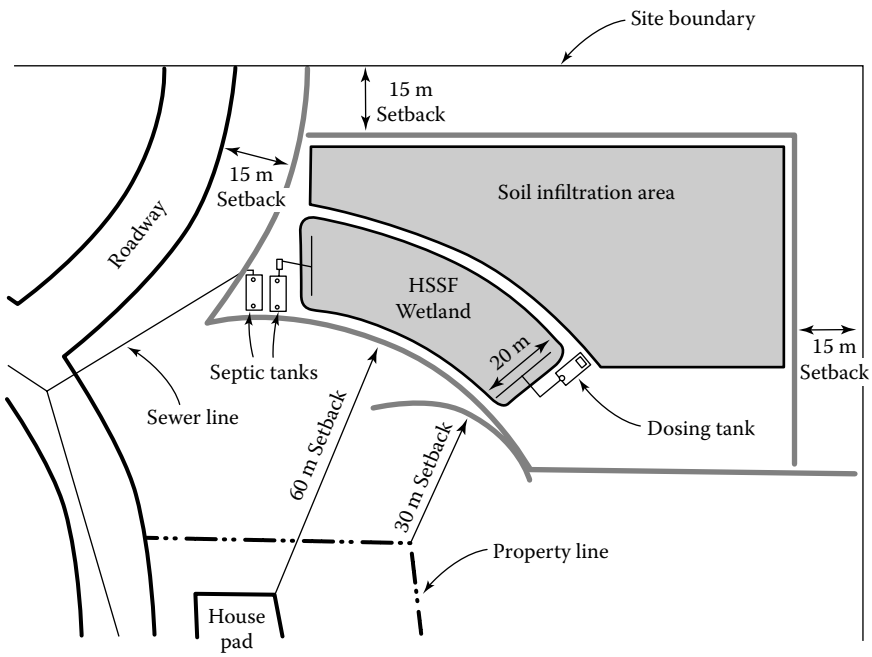

**FIGURE 21.3** The shape and location of this HSSF wetland bed in Lake Elmo, Minnesota, were dictated by regulatory setback requirements.

## 21.2 LAYOUT AND CONFIGURATION

Once the wetland area and location have been selected, the designer must then make a number of decisions regarding the layout and configuration of the wetland. These include

- The number of parallel flow paths
- The number and type of wetlands in each flow path
- Clogging dynamics
- Cell configuration (aspect ratio and bed depth)
- The hydraulic profile of the wetland system
- The internal configuration of the wetland cells (flow distribution, bed depth, media size and type, the need for insulating mulch, the water level control structures, the liner selection and type, etc.)

### Number of Flow Paths

The decision to design the wetland system with two or more parallel flow paths depends on several operational factors:

- The need to provide operational flexibility
- The need to provide treatment redundancy
- The need to operate the system on a load-and-rest basis

### Operational Flexibility

When there are multiple flow paths, one treatment train can be taken out of service for maintenance and the flow diverted to the other parallel wetland cells. This flexibility is a desirable attribute in a wetland treatment system, but it comes at the added cost associated with extra berms, liner, water level control structures, and earthwork. These added costs become especially significant for very small treatment systems. Let us consider the example of a single home horizontal subsurface flow (HSSF) wetland sized 300 $m^2$, where a 5-m perimeter is needed for construction access. The overall site area needed is approximately 35 m × 22 m, or 770 $m^2$. The results of splitting this wetland into two parallel beds is 40 m × 22 m, or 880 $m^2$. In the first case, the wetland occupies 39% of the required site area; with the two parallel beds, the wetland occupies 34% of the site area, an influent splitter structure is necessary, and the outlet control structure(s) must regulate two water levels.

Although the split-bed approach illustrated offers more operational flexibility, it comes at the cost of additional area, liner, and control structures. The added costs of these components must be weighed against the alternate methods to provide operating flexibility. For instance, many single-home septic tanks provide approximately three days of hydraulic retention time, so one means of taking the system out of service for maintenance or repairs would be to simply pump the septic tank. This would give the operator about three days to complete the necessary work, and if additional time is needed, the tank could be pumped again. This alternate approach to flexibility is less expensive than the split-bed system, and for this reason, single-home HSSF wetlands in the United States are commonly single-bed designs.

As the size of the system increases, the added cost of parallel flow paths becomes a progressively smaller component of the overall construction cost, and providing alternate means of flexibility (such as pumping of septic tanks) becomes progressively more expensive. Therefore, for larger projects, two or more parallel flow paths become the preferred design approach. For small community wastewater projects, systems with a design flow greater than 35 $m^3/d$ would typically have two parallel flow paths, and for larger projects, additional parallel flow paths may be warranted. For instance, the HSSF wetland used to treat aircraft de-icing runoff in Edmonton, Alberta, consists of six parallel flow paths, with two cells in each flow path (Figure 21.4).

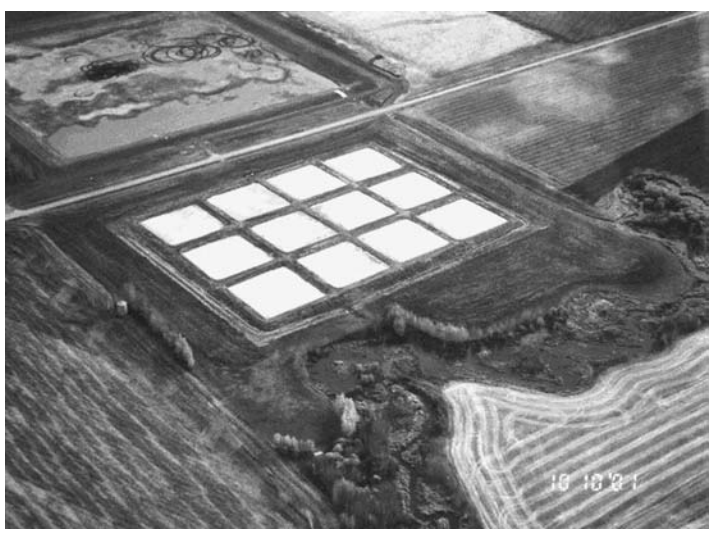

**FIGURE 21.4** HSSF wetland for treatment of aircraft de-icing runoff, Edmonton, Alberta. This particular system consists of six parallel flow paths, with two treatment cells in each flow path.

### Treatment Redundancy

Many regulatory authorities require wastewater treatment systems to be designed to treat more than the stated design flow and load. For treatment systems in the upper midwestern United States, a commonly used redundancy requirement is that the treatment system must be able to treat 75% of the influent flow and load, with one treatment train (flow path) out of service (Great Lakes UMRB, 1997). It should be noted that this redundancy requirement was developed for mechanical wastewater treatment plants treating raw municipal wastewater and may or may not be appropriate for treatment wetlands, depending on the type and intended function of the wetland.

With a redundancy requirement, two parallel flow paths are the minimum. If the designer selects two flow paths, each wetland flow path must be designed to treat 75% of the flow and load, and the wetland must be designed to treat 150% of the design ($2 \times 75\%$). In certain cases, adding a third flow path may be advantageous. With three flow paths, two treatment trains will be in operation when one is out of service, so the two trains in service must each be able to treat 37.5% (one half of 75%) of the design flow and load. So, the overall wetland is sized to treat 112.5% of the design ($3 \times 37.5\%$). The designer must then evaluate whether the savings in wetland area is sufficiently justified, given the added cost of the extra berms and control structures.

### Loading and Resting

Some treatment wetlands require a loading and resting regime to function properly. For these types of systems, the loading and resting sequence will determine the number of the parallel flow paths required.

Most VF wetlands are pulse-loaded at a rapid rate to flood the surface of the bed. In between pulses, water drains from the wetland and air is drawn into the wetland bed (see Chapter 2). This air movement reoxygenates the microbial biofilms and maintains aerobic conditions within the wetland bed. Particulate organic matter is deposited on the surface of the bed, and microbial populations are greatest in the upper regions of the bed, where the organic loading is the highest (Langergraber *et al.*, 2006b) As the loading period progresses, this leads to the development of a clogging mat on the surface of the bed (unless very low organic loadings are utilized). This clogging mat blocks the movement of air into the bed, promoting anaerobic conditions and ponding of the bed surface (Platzer and Mauch, 1997; Hyánková *et al.*, 2006).

Loading and resting are used as means to avoid clogging of the bed and associated surface ponding (EC/EWPCA Emergent Hydrophyte Treatment Systems Expert Contact Group and Water Research Centre, 1990; Platzer and Mauch, 1997; Molle *et al.*, 2004a). The need for resting intervals becomes increasingly important as the organic loading on the VF wetland is increased. For instance, in France many VF wetlands are fed with raw sewage (no primary treatment); to operate successfully, three VF beds in parallel are needed in the first stage (Molle *et al.*, 2004a). One bed is fed with raw sewage while the other two are rested (Figure 7.31). Thus, the loading and resting operating regime of these French systems dictates that the first stage of the treatment process must consist of at least three parallel flow paths.

## 21.3 NUMBER AND TYPE OF WETLANDS IN EACH FLOW PATH

Once the number of parallel flow paths has been decided, the next question facing the wetland designer is how many cells to put in each flow path. There are several scenarios that would lead the designer to consider multiple cells in series:

- There is a need for greater treatment efficiency (and hence greater hydraulic efficiency) to increase the number of *P*TIS through the use of two or more cells in series.
- There is sufficient slope to the site that breaking the flow path into multiple cells is advantageous from a civil engineering and an earthwork perspective.
- There is a desire to use more than one wetland type in the overall treatment process (e.g., vertical flow to horizontal flow, or vice-versa).
- There is a desire for staged treatment, with different treatment reactions occurring in different wetland cells.

### Greater Treatment Efficiency

The first case is a situation where the designer wishes to increase the overall treatment efficiency of the process—or to provide the same level of treatment in a smaller area. By combining two wetland cells in series, the number of tanks in series (*N*TIS) is theoretically increased. The decreasing length-to-width ratio for each physical compartment means that *N*TIS is not doubled. The relaxed parameter, *P,* accounts for both hydraulic effects (*N*) and effects of pollutant weathering; so a decision to increase *P* must be based on the pollutant under consideration and the best professional judgment of the designer. In any case, the advantage of cells in series for HSSF wetlands is not large unless the design contemplates a close approach to *C**.

As discussed in Chapter 6, compartmentalization becomes a significant aspect of the wetland sizing process when the goal is a very high level of treatment. The case of providing two wetland cells in series (instead of one cell) was previously explored for biochemical oxygen demand (BOD) removal in Tables 20.7 and 20.8. In that particular example, there was not a dramatic reduction in the required area because the design goal (94.4% reduction in mass load) allowed an effluent concentration significantly above (double) the assumed *C** value.

However, as the target effluent quality gets closer and closer to *C**, the hydraulic efficiency *N* (and hence *P*) becomes an extremely important part of the sizing process, because bypassing of untreated effluent in the TIS model has

**TABLE 21.1**
**COD Reduction for One Wetland Cell, *P*TIS = 2**

| Input Parameters | | Calculated Values | |
|---|---|---|---|
| Flow rate, $Q$ | 137.1 $m^3/d$ | Volume per tank | 547.2 $m^3$ |
| Precipitation, $P$ | 2.2 mm/d | Area per tank | 1,200 $m^2$ |

| | | Piping required | 1,200 m |

| Calculated Values | | System In | Exit Tank 1 | Exit Tank 2 | System Out |
|---|---|---|---|---|---|
| Net flow | $m^3/d$ | 137.1 | 139.6 | 142.0 | 142.0 |
| Precipitation | $m^3/d$ | 5.280 | 2.640 | 2.640 | — |
| $ET$ | $m^3/d$ | 0.312 | 0.156 | 0.156 | — |
| Infiltration | $m^3/d$ | 0.024 | 0.012 | 0.012 | — |
| HLR, $q$ | m/d | 0.057 | 0.116 | 0.118 | 0.059 |
| Nominal HRT | days | 7.98 | 3.92 | 3.85 | 7.70 |
| Concentration, $C$ | mg/L | 120.0 | 21.5 | 11.2 | 11.2 |

a large impact on the effluent quality. Here, we will consider a scenario where the wetland process must deliver an effluent quality very close to $C^*$, where there are very large impacts of compartmentalization on the wetland size.

Tables 21.1 and 21.2 consider the case of an aerated subsurface flow wetland (saturated flow) to remove COD from hydrocarbons. Because of the internal mixing induced by aeration ($N = 3$) and pollutant weathering, the wetland is assumed to function as 2 *P*TIS (aerated wetlands are addressed in more detail in Chapter 24). The spatially variable flow *P-k-C** model previously introduced in Chapters 17 and 20 is utilized here. The influent COD is assumed to be 120 mg/L, the regulatory compliance limit is 20 mg/L, and $C^*$ is assumed to be 10 mg/L. However, because of variability in the wetland performance, an effluent quality of 11.2 mg/L is targeted as the design objective so that the system will meet the 20 mg/L regulatory limits on a consistent basis (90% of the time). The lower targeted effluent concentration is not a safety factor and has nothing to do with treatment redundancy.

Further, it is assumed that there will be significant weathering of the COD mixture as it approaches $C^*$, so the two wetland cells in series are represented by $P = 3$ instead of $N = 6$.

As the target effluent concentration is so close to $C^*$, any bypassing of untreated water (low *N*TIS and therefore low *P*TIS) has a very large impact on treatment performance. In Table 21.1, the required wetland area is 2,400 $m^2$; in Table 21.2, the required wetland area is 1,500 $m^2$. So, in this particular example, there is a large benefit in terms of size reduction (35%) if the wetland is constructed as two cells in series, even though the "benefit" of the second cell has been reduced by pollutant weathering effects.

## Dividing Wetland Cells Based on Slope

On sloping sites, there will be earthwork cut-and-fill costs associated with terracing the site for wetland basins. However, wetland designers should be aware that dividing the wetland into multiple segments may potentially have impacts on treatment performance (as explored in Tables 20.8, 20.9, 21.1, and 21.2). If there are large topographic changes between wetland cells, this can provide the opportunity for creative design elements, such as cascade waterfall aerators (Burka and Lawrence, 1990), if these are advantageous from a process design standpoint.

## More Than One Wetland Type

Another obvious situation to divide the flow path into multiple cells is when there is a desire to use more than one wetland type along the flow path. This subdivision of the treatment process into unique process elements dates back to the original work of Seidel (Seidel, 1966), which is discussed in Chapter 15. Her work eventually led to the development of the current "hybrid" wetland systems,

**TABLE 21.2**
**COD Reduction for Two Wetland Cells in Series; *P*TIS = 3**

| Input Parameters | | Calculated Values | |
|---|---|---|---|
| Flow rate, $Q$ | 137.1 m³/d | Volume per tank | 228 m³ |
| Precipitation, $P$ | 2.2 mm/d | Area per tank | 500 m² |
| $ET$ | 0.13 mm/d | Influent flow, $Q_i$ | 137.1 m³/d |
| Infiltration | 0.01 mm/d | Effluent flow, $Q_o$ | 140.2 m³/d |
| $P$TIS (system) | 3 | Average flow, $Q_{avg}$ | 138.7 m³/d |
| Area, $A$ | 1,500 m² | Influent mass load | 16,452 g/d |
| Porosity, ε | 0.38 | Effluent mass load | 1,563 g/d |
| Bed depth | 1.2m | Mass % reduction | 90.5% |
| $C_i$ | 120 mg/L | Nominal HLR | 0.091 m/d |
| $C$* | 10 mg/L | HLR based on $Q_{avg}$ | 0.092 m/d |
| $k$ | 356 m/yr | HLR based on $P$TIS | 0.093 m/d |

| HLR, $q$ | m/d | 0.091 | 0.276 | 0.278 | 0.280 | 0.093 |
| Nominal HRT | days | 4.99 | 1.65 | 1.64 | 1.63 | 4.88 |
| Concentration, $C$ | mg/L | 120.0 | 34.0 | 15.3 | 11.2 | 11.2 |

which typically employ a combination of vertical–horizontal flow wetland cells (Urbanc-Bercic and Bulc, 1994; Cooper and Green, 1995; Platzer, 1996; O'Hogain, 2003; Obarska-Pempkowiak *et al.*, 2004; Vymazal, 2005), or a combination of the horizontal–vertical flows (with recirculation) (Brix, 1998; Laber *et al.*, 1999). Combination wetland systems of this nature are discussed in more detail in Chapter 24.

### Staged Treatment

Another situation where a designer may elect to use multiple wetland cells along the flow path is when each wetland cell is intended to provide a different treatment function. In many situations, these wetland cells will be different types of wetlands, as discussed previously and in Chapter 24.

However, in certain applications, the same type of wetlands may be linked together solely based on treatment function. A good example of this approach is the two-stage VF wetland systems in France (Molle *et al.*, 2005a). The first stage of the treatment process is often three pulse-fed VF beds that are alternately loaded and rested. The primary function of these beds is BOD and total suspended solids (TSS) removal. The second stage of the treatment process is typically two parallel pulse-fed VF beds that are also alternately loaded and rested. These second-stage cells are intended primarily for BOD polishing and nitrification.

## 21.4 CLOGGING DYNAMICS

Both horizontal and vertical flow SSF wetlands rely on the movement of water through a porous media for proper functioning. Both systems are susceptible to bed clogging, which restricts the flow of water through the bed media. In some instances, this restriction in flow will create flooding and will be considered to be a "failure" of the wetland treatment process. However, the definition of *failure* is qualitative and is often based on the perception and expectations of local regulators, government officials, system operators, and nearby residents.

### Defining Failure in SSF Wetlands

Because *failure* is a subjective term in the treatment wetland field, it is useful to define what the expectations of the regulators, owners, and users of the system might be. Several cases concerning hydraulic failure help to illustrate this point.

- In Denmark, soil-based HSSF wetland technology was adopted early and spread rapidly throughout the country. Although the design intent was subsurface flow, these systems did not have sufficient hydraulic conductivity, and overland flow occurred instead (Brix, 1998). However, the treatment performance of these systems was satisfactory and the overland flow mode was tolerated.
- In the United States, regulations for single-home septic systems prohibit the surface exposure of

wastewater because of public health concerns (U.S. EPA, 2002c). HSSF wetlands that have clogged inlet zones and overland flow (even for a small percentage of the wetland bed) are thus deemed "failed," and considerable effort and expense have gone into maintaining these wetlands to eliminate overland flow, even when treatment performance was satisfactory. A similar situation exists in the United Kingdom (Cooper *et al.*, 2006a).

- VF wetland systems in France are highly loaded with BOD and TSS (raw sewage) in the initial treatment stage (Molle *et al.*, 2004a). A large component of the initial treatment is physical filtration and deposition of organic matter on the surface of the beds. In other words, the beds are designed to clog. However, these high loads can only be tolerated for a short time; so, a loading and resting regime (at least three parallel beds in the first stage) is utilized so that there is sufficient resting interval to recover from the clogged condition via drying and cracking of the cake (Figure 7.31). Therefore, in these systems, clogging does not equate to failure because there is a routine operational program to address the clogging issue.
- However, other VF wetlands have clogged and failed. This occurs when there are insufficient beds to allow adequate rest intervals. When these beds clog, water ponds on the surface and air movement into the bed ceases, resulting in poor treatment (Platzer and Mauch, 1997; Cooper *et al.*, 1997). In extreme cases, ponded water may essentially fill the entire basin, requiring the entire wetland to be bypassed.

Thus, it can be seen that the definition of *hydraulic failure* depends on the regulatory requirements, degree of treatment flexibility, operational regime, and local expectations. These definitions of failure may or may not involve treatment efficiency issues. For design purposes in this book, the following conditions are assumed to constitute a failure mode:

- An inability to meet treatment standards on a consistent basis based on the regulatory compliance interval.
- For HSSF wetlands, the flow should be kept within the wetland bed. When clogging occurs in the inlet region, any overland flow path should be kept to a required minimum. This may be zero exposed water, or some minimal length that may be considered an inlet distribution zone. This defines failure based on length of overland flow, not the area of the bed that is clogged.
- For VF wetlands, the inability of the system to hydraulically pass the design flow. This will require sufficient beds to allow adequate resting periods to resist clogging.
- For biosolids wetlands, not having sufficient beds to allow adequate resting periods to stabilize the applied sludge.

## Clogging in HSSF Wetland Beds

The aspect ratio (L:W) of each wetland cell is an important design decision for HSSF wetlands. Longer and narrower beds increase the organic loading applied to the cross-sectional area of the bed. High cross-sectional loadings will result in a greater length of the bed operating as an overland flow system due to the clogging mechanisms described in Figure 7.25, Chapter 7. This is likely to be unacceptable from a regulatory standpoint in the United States, and if the overland flow channelizes, treatment performance will be compromised.

At the present time, there is considerable interest in determining whether or not a sustainable balance between solids deposition and solids decomposition/resuspension can be reached in the inlet zone of HSSF wetlands. This issue is of profound design importance. If a steady-state criterion can be identified, then HSSF wetlands can be designed with a sufficiently conservative inlet loading criteria so as to preclude the need for bed-media maintenance or replacement. If bed clogging is inevitable (and merely delayed by lower inlet loading rates), then the need for scheduled bed cleaning/replacement in the inlet zone becomes an integral part of HSSF wetland technology operation and lifecycle costs.

To achieve a steady state in the inlet region, the deposited inlet-suspended solids and the microbial biomat generated by particulate/soluble organic matter must be in equilibrium with the combined rate of organic solids decomposition and the rate of particulate matter resuspension. This implies that the rate of accumulation, $A$, in the inlet zone is zero. This condition can be represented (using terms previously presented in Equation 7.16, Chapter 7) as indicated in Equation 21.1:

$$G + S = D + R \tag{21.1}$$

where

$G$ = generation rate, g/m$^2$·d
$S$ = settling rate, g/m$^2$·d
$D$ = decomposition rate of transportable solids, g/m$^2$·d
$R$ = resuspension rate, g/m$^2$·d

Reduction in the hydraulic conductivity of the inlet zone can be attributed to a variety of mechanisms, including

1. Accumulation of mineral (biologically inert) sediments associated with influent TSS
2. Accumulation of particulate organic matter (subject to biodegradation) within the inlet zone
3. Formation of chemical precipitates within the wetland bed
4. Generation of microbial biofilms in response to the combined load of the particulate and soluble organic matter

These materials combine to form a mixture that is here termed *biosolids*, and the degree of biosolid accumulation depends on all four mechanisms. Because a significant portion of the incoming organic load in domestic wastewaters is present as

decomposable particulate organic matter, depositions of this particulate organic matter may result in organic loadings tenfold higher in the inlet region as opposed to the rest of the wetland bed (Puigagut *et al.*, 2006). This has profound effects in biosolid formation in the inlet zone. Reductions in the hydraulic conductivity from biosolid accumulations are a function of the media size, as discussed in Figure 7.24, Chapter 7.

### Short-Term HSSF Inlet Zone Clogging

At the present time, there is insufficient knowledge to quantify the generation $G$, decomposition $D$, and resuspension $R$ rates within HSSF wetland beds. This is largely due to the difficulties encountered when doing *in situ* sampling of HSSF systems, as previously discussed in Chapter 7. Without the ability to quantify the terms $G$, $D$, and $R$, the alternative is to extract design information from the performance of existing HSSF wetlands, as shown in Figure 21.5.

Data illustrated in Figure 21.5 suggests that HSSF wetland beds should be configured such that the cross-sectional area (orthogonal to the flow) results in a BOD loading of <250 g/m$^2$·d for bed medias with a $d_{10} > 4$ mm. BOD has been selected as the influent loading parameter in this case because (1) the majority of degradable organic matter in municipal effluents is present as particulates, (2) soluble organic matter also contributes to inlet zone biosolids formation, and (3) chemical precipitates (as represented by the difference between COD and BOD) occur more uniformly in the HSSF bed and are likely not restricted to the inlet zone.

There are drawbacks to limiting performance information to BOD, as illustrated in Figure 21.5. First of all, a HSSF wetland with a high inlet flow of nonorganic (mineral) TSS may plug at organic loads much lower than those indicated in Figure 21.5. Secondly, the nature of the organic material must be considered. Some waste streams contain organic matter that is much more degradable than others. HSSF wetlands treating soluble, rapidly degradable organic material can reasonably be expected to have a shorter clogged inlet zone.

### Long-Term HSSF Inlet Zone Clogging

Systems illustrated in Figure 21.5 generally have an operational performance history less than ten years. Although reducing the cross-sectional organic loading may have short-term benefits in reducing bed clogging, the long-term viability of HSSF hydraulic conductivity remains uncertain. Two factors argue against the ability to stabilize long-term hydraulic conductivity of HSSF beds. These include

- Not all organic matter deposited in the inlet zone is biodegradable. The refractory (nondegradable) component represents a long-term accumulation of organic TSS.
- A certain component (variable between HSSF systems) of influent TSS consists of nondegradable (mineral) material. This inert material is efficiently removed from the water column through the particulate settling/filtration/interception mechanisms discussed in Chapter 7. Because these removal mechanisms are very efficient in HSSF beds, most of the TSS reduction occurs in the early stages of the wetland bed (see, for example, Figure 7.26). Long-term loading of inert TSS results in an ongoing reduction of the hydraulic conductivity in the inlet zone.

The current understanding of HSSF wetland design does not allow a quantitative determination of the region of inlet

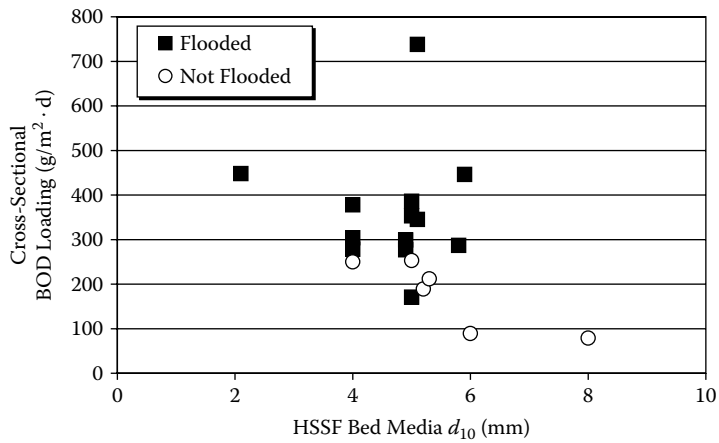

**FIGURE 21.5** Flooding status of HSSF wetlands as a function of cross-sectional organic loading and bed media size. (Data from Steinmann *et al.* (2003) *Water Research* 37: 2035–2042; Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia; Puigagut *et al.* (2006) *Size distribution and biodegradability properties of the organic matter in horizontal subsurface flow constructed wetlands*. Kröpfelová (Ed.), Paper presented at the 6th International Workshop on Nutrient Cycling and Retention in Natural and Constructed Wetlands, 31 May–4 June 2006; Trebon, Czech Republic.)

clogging (biosolids penetration distance), although this is believed to be related to the size of the bed media, as indicated in Figure 21.5. The $d_{10}$ of the media is often used to approximate the pore volume, as only 10% of the bed media is smaller than this size.

Studies on sand clogging indicate that the clogging distance $D_c$, can be related to the $d_{10}$ of the media: $D_c \approx 150\ d_{10}$ within the range of $5 \times 10^{-3}$ mm $< d_{10} < 3{\times}10^{-2}$ mm (Blazejewski *et al.*, 1994). Because this $d_{10}$ is much smaller than the media sizes used in most HSSF wetlands, the usefulness of this relationship is limited to soil-based HSSF systems. Blazejewski *et al.* (1994) suggested a clogging thickness of 3 cm for fine-grained HSSF beds.

Bavor *et al.* (1989) noted that clogging within a series of long, narrow HSSF trenches (L:W ratio of 25:1) was remedied by excavating the first 5 m of the bed and replacing with coarse rock. Kadlec and Watson (1993) provided evidence from the Benton, Kentucky, system that the farthest biomat-penetration distance stretched 100 m into a 300-m bed. But this type of information does not help in design unless couched in terms of organic loadings and decomposition rates.

Based on the information currently available, it appears that bed clogging (as evidenced by overland flow length) is reduced, or at least delayed, by minimizing the cross-sectional loading, and using coarser bed materials in the inlet zone.

However, based on the current state of the art, there is no available evidence that argues against the phenomenon of long-term bed clogging ($A > 0$), even if short-term clogging pitfalls are avoided. Long-term performance information from the United Kingdom (Cooper *et al.*, 2006b) indicates that HSSF systems will require some degree of inlet zone media replacement or cleaning during the course of their operational lives. Whereas the frequency of this maintenance is dependent on the bed clogging factors described in this book, it appears that even well-designed, well-operated HSSF wetlands will require inlet zone maintenance approximately every ten years to avoid the development of large regions of overland flow. At the present time, media replacement is the most common (and most expensive) method of maintenance (Wallace and Knight, 2006) although trials using hydrogen peroxide as a cleaning agent have shown promising results (Hanson, 2002b; Behrends *et al.*, 2006).

### Clogging in VF Wetland Beds

VF wetlands are also subject to solids accumulation, which can fill the pore volume within the upper region of the wetland bed, potentially leading to ponding and hydraulic failure. Equations describing clogging of VF wetland beds have previously been presented in Equations 2.58–2.61 in Chapter 2.

The organic loading applied to the VF wetland appears to play a large role in the clogging process. For a soil/sand VF wetland at Merzdorf, Germany, Platzer and Mauch (1997) observed a log-linear decrease of hydraulic conductivity as a function of the cumulative applied organic load. With resting intervals, the hydraulic conductivity of the bed was restored to the original values.

At the present time, there are two operating regimes to address the clogging of VF wetland beds:

1. Systems that are continuously operated without resting. These VF wetlands are loaded at relatively low organic loads to minimize biosolids accumulation and associated clogging of the bed.
2. Systems that employ multiple beds in a load-and-rest regime. These VF wetlands are designed to clog during the loading phase; hydraulic conductivity is restored during the resting phase.

Because clogging and organic loading appear to be intimately related, it is not possible to specify an organic loading rate for a VF wetland system without also specifying the resting sequence associated with that loading, as previously discussed in Chapter 20.

Approximately 180 VF wetlands in North America have been designed as recirculating systems, which are functionally very similar to recirculating gravel filters (Crites and Tchobanoglous, 1998). Recirculation ratios vary depending on design goals, but ratios of 3 to 12 times the inlet flow rate are common.

An array of distribution pipes results in a nonuniform application of influent TSS and organic matter. This loading is concentrated at the discharge orifices of the distribution pipes. Biosolids then preferentially form at each discharge orifice in a zone about 30 cm in diameter. In extreme conditions, these biosolids will plug the upper layer of the wetland bed because recirculating wetlands operate at hydraulic loadings that are much higher than the inlet flow reductions in bed porosity and loss of hydraulic conductivity can rapidly lead to flooding of the wetland bed. An example is shown in Figure 21.6.

Operational experience in the United States indicates that the organic loading (as represented by BOD) should be less than 15 g/d per orifice for buried pipes to avoid biosolids clogging with bed media greater than 4 mm. The equivalent BOD loading in the biosolids clogging region at the orifice is approximately 200 g/m$^2$·d.

The uniformity of application is increased and the organic loading is reduced if there is a secondary redistribution of the influent by splashing or spraying. Figure 21.7 shows a cold-climate method of achieving this. Perforated pipes are placed in infiltration chambers that are then buried in the upper portion of the wetland. Water sprays out of the distribution orifices up into the infiltration chamber, where it splashes around and undergoes secondary distribution. Orifice shields (resembling plastic pipe caps) are commercially available for this purpose.

## 21.5 CELL CONFIGURATION

As discussed in the previous section, clogging dynamics will often determine the number of wetland treatment cells and, for HSSF wetlands, the aspect ratio (L:W) will be a function of the cross-sectional loading if delaying or minimizing the

**FIGURE 21.6** Example of biosolids clogging in a small recirculating VF wetland. This system in central Minnesota experienced rapid hydraulic failure in response to extremely excessive BOD loadings from illegal drug manufacturing.

overland flow is a design goal (see Figure 21.5). Even if the cell dimensions are governed by clogging considerations, there are still a number of design decisions. Several factors of SSF wetland bed design warrant further consideration at this stage; these include

- The length-to-width (L:W) ratio of the wetland cells
- The depth of the wetland cells
- The types and sizes of the bed media that will be placed in the wetland cells
- The overall size of the wetland cells

### Length-to-Width Ratio

For VF and biosolids wetlands, the aspect ratio (L:W) is relatively unimportant, because these wetland beds are top loaded. For HSSF wetlands, the aspect ratio is critically important, because this determines the cross-sectional loading and flow velocity and, to some extent, the *N*TIS value.

When working with HSSF wetlands, the designer is faced with two mutually contradictory design goals:

- The desire to spread the influent over a very wide planar area. (This delays the time to clogging.)
- The desire to spread the influent as uniformly as possible over the vertical cross section. (This improves flow distribution.)

Spreading the influent over wide areas presents a number of hydraulic challenges, especially for small systems, where the flow rate is close to zero. One approach, which has been implemented in Denmark, is to divide the inlet chamber into two or more segments that can alternately be loaded to gain

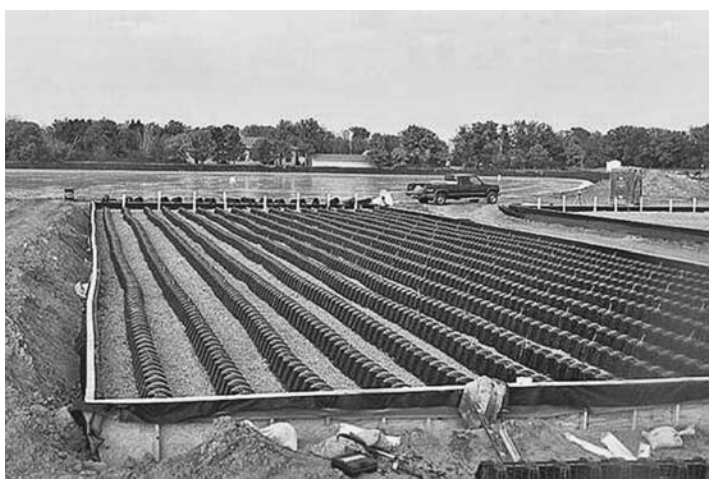

**FIGURE 21.7** Recirculating VF wetland under construction at The Ponds, Minnesota. The black infiltration chambers are used as a means of secondary flow distribution to reduce the organic loading at the distribution orifice. (This photo was taken at an intermediate stage of construction; additional gravel was later placed to bury the influent distribution chambers.)

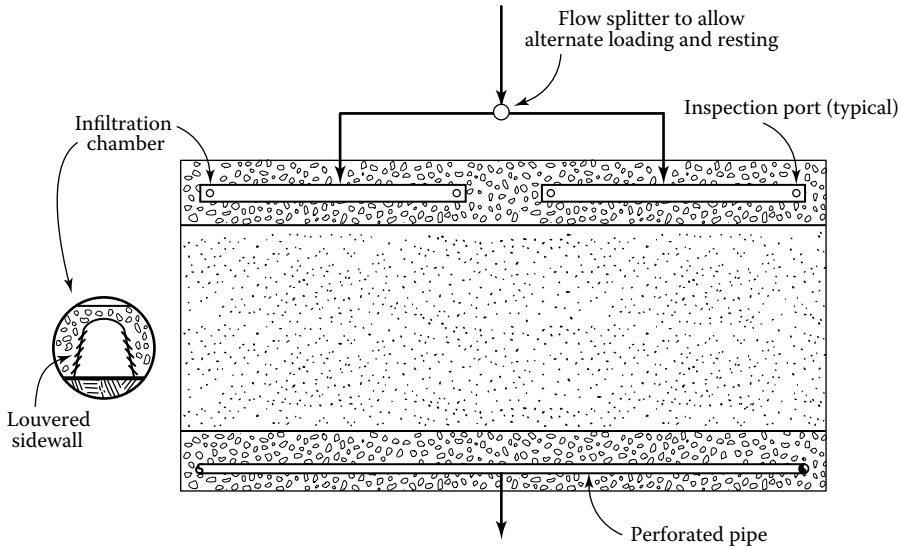

**FIGURE 21.8** Layout and design factors for a HSSF wetland utilizing an influent flow split to enhance flow distribution. (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

better control of the flow distribution (Brix, 1998). A schematic of this is shown in Figure 21.8.

For small-scale wetlands, flow-splitting approaches use weirs, stoplogs, or rotating elbows if flow balancing is an operations goal. All such flow-splitting devices require periodic maintenance to remove accumulated solids that may interfere with the flow split, especially for small-scale systems with low flows.

An alternate approach is to split the flow two ways using a central effluent collection pipe with influent distribution channels on either side of the wetland. An example of this design strategy is presented in Figure 15.5, Chapter 15.

## Wetland Cell Depth

HSSF wetlands were originally designed with a depth of 60 cm based on the belief that this was the maximum depth that *Phragmites* root systems would penetrate (Kickuth, 1977). However, analysis of many HSSF wetlands has indicated that the root systems of emergent wetland plants grow preferentially in the upper region of the bed; this concept is illustrated in Figure 3.4 in Chapter 3, with the zone of root penetration typically being only about 30 cm. Thus, deeper beds often have a lower region without plant roots, and water flows preferentially along the bottom of the wetland bed. This lower region is typically associated with more reducing conditions and less efficient treatment.

For HSSF wetlands, the designer is faced with choosing the bed depth. Some observations include the following:

1. Deeper beds promote vertical stratification of flow, as discussed in Chapter 2. This allows bypassing of the flow below the plant root zone (Fisher, 1990; Pilgrim *et al*., 1992; Marsteiner *et al*., 1996; Garcia *et al*., 2004b), with adverse impacts on treatment performance.
2. Shallower beds often result in better treatment (see Tables 8.14 and 9.33 for BOD and ammonia, respectively).
3. Deeper beds provide a greater cross-sectional area, which reduces cross-sectional loading (see Figure 21.5). This theoretically reduces the flow velocity (in the absence of vertical stratification), resulting in less head loss through the wetland bed, which makes maintaining a uniform water surface profile easier.
4. Deeper beds speculatively provide additional volume for storage of refractory and nondegradable (mineral) sediments. This added storage volume would presumably decrease the time intervals between clogging and associated bed maintenance.
5. A deep bed speculatively allows for some ice formation at the top while still passing the water underneath the ice within the bed.

From a treatment standpoint, the additional cost of the extra bed depth (e.g., 60 cm versus 30 cm) appears to add zero or negative value to a fixed area of wetland, but there is no quantification across multiple systems. Control of head loss is better done through aspect ratio and media size. If sediment storage is a design consideration, more bed depth may be warranted. Ice formation can be adequately controlled via a variety of other insulation techniques. To date, virtually all HSSF wetlands have been designed with beds between 30 and 60 cm deep. But, controlled field-scale research studies indicate that shallower depths provide better treatment.

VF and biosolids wetlands are typically constructed to a prespecified bed depth, 50–80 cm for VF wetlands and 50–60 cm for biosolids wetlands.

### Type and Size of Bed Media

Whereas HSSF beds almost always use coarse stone in the inlet and outlet regions, a variety of materials are used for the main bed media.

The original HSSF beds utilized sand in the Max Planck Institute Process (MPIP) system (Seidel, 1966) and soil in the root zone method beds (Kickuth, 1977). Many more of the root zone method systems were constructed, despite significant problems with the hydraulic conductivity and associated problems of overland flow (Brix, 1998).

The response to the overland flow problem was to design HSSF beds with coarser materials so that the water could flow through the wetland bed. Different countries took various routes in the development of HSSF wetland technology, and there are regional differences in the size and type of the bed media. Perusal of Table 10.14, Chapter 10, will provide an indication of the wide variety of bed medias that have been evaluated. In certain cases, the use of media with specific chemical properties, such as phosphorus sorption or a high cation exchange capacity (for ammonia retention), may be desirable. Examples of bed media and size gradations that have been used in HSSF wetlands are summarized in Table 21.3.

Finer materials have a greater surface area for microbial biofilms and may result in better treatment, as indicated in Table 9.33, Chapter 9, for ammonia. Finer materials are more prone to clogging and associated hydraulic problems, as illustrated in Figure 7.23, Chapter 7. The use of coarser material in the first part of the HSSF wetland bed and finer material closer to the outlet has been proposed as a compromise between these two competing design objectives (Wallace and Knight, 2006). The type of wastewater may also be a factor, because biosolids production and/or distribution appears to be a function of the organic loading. With lower organic loadings, finer bed medias could conceivably be used without clogging for the same time period as coarser materials with higher loadings, as proposed in the Austrian design guidelines (ÖNORM B 2505, 2005) and summarized in Table 21.3.

Economics, availability, and local design practices typically dictate what material will be preferred for the wetland bed. To date, medias in the size range of 8 to 16 mm have been most commonly used in HSSF wetlands (IWA Specialist Group on Use of Macrophytes in Water Pollution Control, 2000).

VF wetlands typically use a layered approach to the bed, with fine material (typically sand) at the top of the wetland bed and progressively coarser materials lower in the bed—down to the drainage layer. It has long been recognized that the composition of the sand layer is critical; the material must be fine enough to trap TSS on the surface of the bed but coarse enough to allow water movement without clogging (Cooper, 2003). Depending on the level of pretreatment, finer bed media may be warranted; the French systems use coarser bed material in the first VF stage (which treats raw sewage) and finer bed material in the second VF stage, which provides COD polishing and nitrification (Molle *et al.*, 2004a).

Biosolids dewatering wetlands typically have a fine layer (sandy loam or sand) with an underlying drainage layer (Nielsen, 2002). However, it has been noted that it is important to maintain continuity of capillary suction to facilitate flow through the various drainage layers; otherwise, the result will be "hanging water" as evidenced by a lack of sludge dewatering (Nielsen, 2004). So, large differences in the size range between adjacent drainage layers should be avoided.

Different bed media and layering for VF wetlands are summarized in Table 21.4.

**TABLE 21.3**
**Examples of Bed Materials Used in HSSF Wetlands**

| | Main Bed Media | | | Inlet/Outlet Regions |
|---|---|---|---|---|
| **Source** | **Media Size** | **Material** | **Hydraulic Conductivity** | **Media Size** |
| EC/EWPCA (1990) | 3–6; or 5–10 mm | Gravel | 86 m/d | 50–200 mm stone |
| TVA (1993) | 3–6 mm | Gravel | 2,600 m/d (secondary effluent)<br>260 m/d (primary effluent) | 50–100 mm stone |
| ATV (1998) | 0.2–1.0 mm | Soil/sand | $k = \frac{(d_{10})^2}{100}$<br>where $k$ is in m/s and $d_{10}$ is in mm | |
| U.S. EPA (2000a) | 20–30 mm<br>5–20 mm top layer | Gravel | 100,000 m/d<br>10,000 m/d inlet region | 40–80 mm stone |
| IWA (2000) | 8–16 mm | Gravel | $k = 12{,}600\ D_P^{1.9}$<br>where $k$ is in m/d and $d_{10}$ is in cm<br>use 10% of this value in the inlet region | 75–100 mm stone |

| Wallace and Knight (2006) | >4 mm | Gravel | 260 m/d | 25–50 mm gravel |

**TABLE 21.4**
**Summary of Bed Materials Used in VF Wetlands**

| Source | Wetland Type | Layer | Thickness | Media Size | Material |
|---|---|---|---|---|---|
| EC/EWPCA (1990) | Pulse-fed | Surface layer | 8 cm | — | Sharp sand |
| | | Second layer | 15 cm | 6 mm | Pea gravel |
| | | Third layer | 10 cm | 12 mm | Round gravel |
| | | Drainage layer | 15 cm | 30–60 mm | Round gravel |
| ATV (1998) | Pulse-fed | Main layer | >80 cm | 0.2–1.0 mm | Soil/sand |
| Molle *et al.* (2004a) | Pulse-fed (First stage) | Surface layer | >30 cm | 2–8 mm | Fine gravel |
| | | Second layer | 10–20 cm | 5–20 mm | Gravel |
| | | Drainage layer | 10–20 cm | 20–40 mm | Coarse gravel |
| Molle *et al.* (2004a) | Pulse-fed (Second stage) | Surface layer | >30 cm | $0.25 < d_{10} < 0.4$ mm | Sand |
| | | Second layer | 10–20 cm | 3–10 mm | Gravel |
| | | Drainage layer | 10–20 cm | 20–40 mm | Coarse gravel |
| ÖNORM B2505 (2005) | Pulse-fed | Surface layer | 10 cm | 8–16 mm | Gravel |
| | | Second layer | >50 cm | 0–4 mm | Sand/gravel |
| | | Third layer | 5–10 cm | 4–8 mm | Gravel |
| | | Fourth layer | Separation fabric | — | 2.5-mm mesh |
| | | Drainage layer | 20 cm | 16–32 mm | Gravel |
| NAWE (2006) | Recirculating | Main layer | 75 cm | 12–15 mm | Gravel |
| | | Drainage layer | 15 cm | 16–40 mm | Coarse gravel |
| Nielsen (2002) | Biosolids dewatering[a] | Surface layer | 5–10 cm | — | Sandy loam |
| | | Second layer | 15 cm | | Sand |
| | | Third layer | Separation fabric | | — |
| | | Drainage layer | 30–45 cm | | Pebble gravel |

[a] Sludge dewatering effectiveness is dependent on maintaining continuity of the capillary suction under unsaturated flow. Therefore, large transitions in the size range of adjacent drainage layers should be avoided, especially between the overlying biosolids material and the top layer of the filter (Nielsen, 2006).

### SSF Wetland Cell Size

Another factor enters into the design process when determining the footprint area of individual wetland cells, specifically the construction equipment that will be used to place the bed media. Even large excavators have a maximum reach of approximately 10 m (see Figure 21.1). Therefore, SSF wetland cells greater than about 20 m wide cannot be filled with standard excavators, and the remaining construction options consist of

- Allowing equipment to operate inside the wetland basin (typically, skid-steer loaders for small basins, or bulldozers for large basins)
- Using a specialized piece of equipment, such as an extendable conveyor, to place the bed media

The pros and cons of these different approaches are discussed under the SSF wetland construction section of this chapter. However, the designer should give thought to construction methods and the type of construction equipment locally available when determining the dimensions of individual wetland cells.

## 21.6 SSF WETLAND HYDRAULICS

Once an overall size has been determined for the wetland system, and decisions about the number of flow paths and wetland cells have been made, the next stage in the design process is to determine the hydraulic profile of the system.

There are a number of hydraulic aspects that must be considered when designing SSF wetlands. Generally, these will include the following elements:

- The overall hydraulic profile for the treatment process, including frictional losses within the wetland bed
- Distribution of the influent flow
- Collection of the effluent flow
- Water level control

Gravity flow through the treatment process is the preferred situation from an operations and reliability standpoint. Pumping of the flow is less desirable because of the reliability, maintenance, and power consumption issues associated with wastewater pumps. On very flat sites, grading the site to achieve the "stair-step" configuration needed for gravity

flow must be weighed against the construction and operations costs of pumping. For countries with a high level of infrastructure support, such as the United States, pumping is perceived as less expensive than extensive earthwork during construction. For developing countries, the inverse may be true.

The hydraulic profile for a wetland system results from a number of different calculations. Major components of the hydraulic profile for SSF wetlands typically include:

- The driving head needed to distribute the influent flow
- Frictional losses (head loss) in conveyance piping
- Elevation differences between different stages of the treatment process
- Frictional losses in the wetland bed (HSSF wetlands)
- If the bed is intended to completely drain, the depth of the bed
- The elevation and hydraulic characteristics of water level control devices such as weirs or standpipes

Separate calculations are made for each unit process, resulting in a stair-step diagram describing the relative elevations of the water surface profile (and for pumped systems, the hydraulic grade line). Typically, calculations are made at different flow rates, such as the average daily flow, the minimum flow rate, and the peak daily or hourly flow rates. The peak flows should include the capture of water from rainfall events; often a 10-year or 25-year storm event is used for this purpose, depending on the regulatory jurisdiction.

For very small wetland systems, the low flow at night will be zero due to the diurnal fluctuation in water use patterns. This can create a number of design challenges in terms of flow distribution and, in very cold climates, freezing of pipes. Specific design challenges for small-scale wetland systems have been addressed in the literature (Wallace and Knight, 2006).

Generally speaking, the larger the system, the more important detailed hydraulic calculations become. For SSF wetlands, these calculations must also address anticipated phenomena such as bed clogging (see Chapter 7). The preferred design practice for SSF wetlands is to make each bed completely drainable and also to have a discrete elevation drop between cells (often, a minimum drop of 0.3 m is desirable, unless the site cannot support this elevation change or hydraulic calculations indicate that this differential is insufficient).

## Hydraulics of HSSF Wetlands

For HSSF wetlands, the water surface profile within the wetland bed is assumed to be governed by frictional losses within the wetland bed. If flow is within the laminar range, a simple relationship such as Darcy's law can be used to compute the frictional loss (Equation 2.40, Chapter 2), restated here as Equation 21.2.

$$u = -k\frac{dH}{dx} \tag{21.2}$$

where
$H$ = elevation of the water surface, m
$k$ = hydraulic conductivity, m/d

This is the one-dimensional version of Darcy's law. It is restricted to the laminar flow regime. At higher flow velocities, there will be a turbulent component to the flow, which must also be considered (see Equations 2.44, 2.46, 2.47, Chapter 2). The use of these friction-loss equations are only the start of the hydraulic design process, because what is of most use to the wetland designer is the longitudinal depth profile. This is typically a nonuniform profile due to changes in the flow rate (gains or losses from precipitation, infiltration, and ET) and hydraulic conductivity of the wetland bed. Calculation procedures have been previously established in Equations 2.48–2.54, and the results of such calculations are illustrated in Figure 2.26.

These calculations are typically performed by dividing the wetland bed into subunits (each with its own hydraulic conductivity) and calculating the head loss across each subunit. The standard procedure is to start at the effluent end of the bed (the tailwater condition) and work backwards to the inlet.

Here, we explore the effects of design parameters on the water surface and its relation to the media surface. The goals of hydraulic design for HSSF wetlands are to convey the design flow within the wetland bed without surfacing while providing an acceptable hydrologic environment for the survival of emergent wetland plants. Two philosophies may be used to achieve these goals:

1. A management-intensive scheme, in which operators compensate for hydraulic upsets through operational adjustments
2. A design-intensive scheme, in which the design is made sufficiently conservative so as to eliminate the need for most operational adjustments

In either case, the overall wetland footprint area is presumed to be set from the treatment requirements as previously discussed in Chapter 20.

Normally, the requirement for treatment performance will provide a specification of either the hydraulic loading rate or detention time. In turn, these combine with the required volumetric flow rate to determine either the volume of water in the bed or area of the bed. However, it must be recognized that many wastewater sources create flows that vary considerably on both diurnal and seasonal time scales. Neither the minimum nor the maximum anticipated flow should cause hydraulic failure.

The requirements for stable water depth and controllable water flow for creating proper vegetation conditions serve to further restrict the geometry of the bed and the size of the media.

These requirements can be summarized as

1. Anticipated design flows must pass through the bed without overland flow or flooding.
2. Anticipated design flows must pass through the bed without stranding the plants above water; i.e., there must not be protracted, excessive headspace that results in desiccation and die-off of wetland plants.
3. Operation should remain acceptable in the inevitable event of changing hydraulic conductivity, especially in the inlet zone. As the bed clogs with roots and microbial biofilms it should not flood.
4. The bed should be drainable.
5. Water levels within the system should be fully controllable through the use of inlet and outlet structures.
6. The configuration must fit within the available site area in terms of project boundaries and hydraulic profiles.

There are often serial and parallel arrangements of individual wetland cells within a system. In the present discussion, attention is restricted to individual cells and to simple rectangular geometries. The variables that may be chosen to satisfy these considerations are: length ($L$), bottom slope ($S_b$), and the media ($D$ or $k$). Bed depth ($\delta$) is usually in the narrow range of 30–60 cm and is therefore set by the desire for plant root penetration within the HSSF bed rather than hydraulics. *The width of the system is scaled by the need to carry the full design flow and by clogging concerns.*

There is no theoretical need for a slope to the top of the bed. If water level control is to include the ability to totally inundate the bed for vegetation management, then a top slope is detrimental.

Because the media is likely to undergo significant changes in hydraulic conductivity, its frictional resistance cannot be relied upon for control of the water depth. This implies that the conductivity of the media must be large enough, or the water travel distance short enough, to sustain a nearly level pool condition controlled by the elevation of the wetland outlet control structure.

In certain cases, it may be desirable to be able to drain the HSSF wetland bed. In this case, the bottom slope should be set to provide for complete bed drainage. Normally, a few centimeters of elevation differential allows for this requirement. The wetland bottom slope cannot be considered as the design driving force for water movement. The reason is that designs based on bed slope are excessively sensitive to changing conditions of flow and hydraulic conductivity. Dry-out or flooding are virtually certain to occur with such designs.

### *Headspace Considerations*

Under conditions of very low flow, the water surface will be a horizontal level pool controlled by the elevation of the outlet structure. It is necessary that this condition should not create a dry zone of excessive depth (headspace, $f$) (Figure 21.9), which would occur due to a tilt of the upper bed surface. If the top and bottom of the HSSF wetland are both sloped, it creates a condition very conducive to overland flow within the system, as illustrated in Figure 21.10.

However, many old HSSF systems have been built to specifications that require uniform bed depth and a significant bed bottom slope. Indeed, early design guidance documents recommended high bottom slopes: 0.5–2.0% (TVA, 1993); 1–5% (Cooper *et al.*, 1996). Another early guideline was established for Danish systems, namely, restricting the bed surface slope to no more than a 30-cm drop, thereby ensuring that plant roots could reach water even under level pool conditions (Johansen, 1994).

The effect of bed slope is seen in Figure 2.26, Chapter 2, for the Benton, Kentucky, system. There, a 0.1% bed slope over 334 m ($\Delta B$ = 33 cm) results in a drained bed water elevation that is not compatible with the hydroperiod needs of emergent wetland plants at low flow conditions. The result was unsuitable water conditions for the target wetland plant species (*Scirpus validus*).

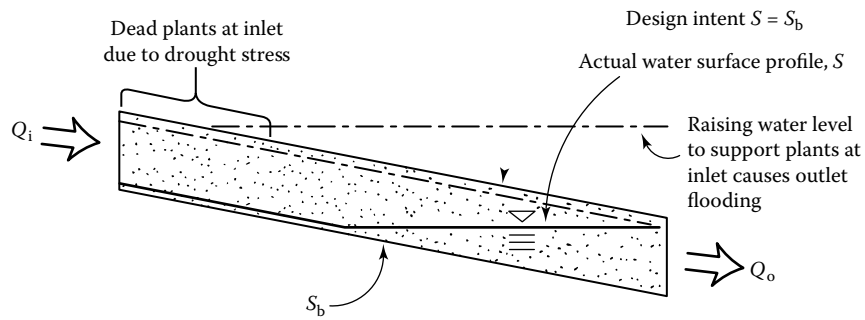

**FIGURE 21.9** Water level problems occurring in sloped HSSF wetland beds under conditions of low flow. (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

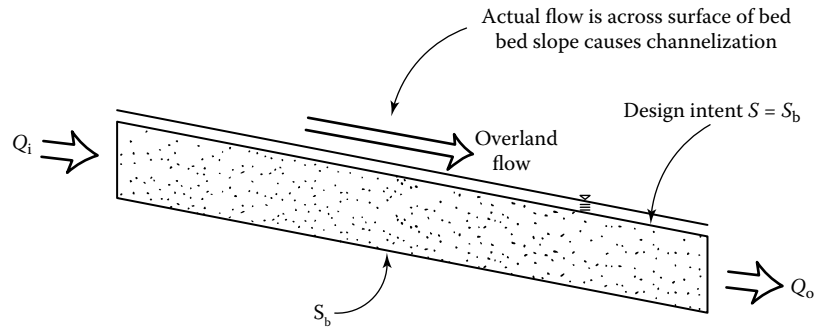

**FIGURE 21.10** Overland flow problems resulting from HSSF beds with high flow and/or low hydraulic conductivity. (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

Under conditions of high flow, the headspace concern moves to the outlet end of the system. When the outlet water level is lowered to prevent inlet zone flooding, the result may be excessive freeboard at the outlet. Emergent wetland plants cannot tolerate this hydrologic regime, and the vegetation will become terrestrial (Figure 21.11).

If the drop in the water level is extreme enough, desert-like landscapes sometimes result at the wetland outlet, because the target wetland plants may not tolerate this hydroperiod (Figure 21.12). Neither for the low flow or high flow scenario, the maximum allowable headspace should exceed plant tolerance for the depth to the water surface. As a conservative (safe) rule of thumb, headspace should be limited to about a third the maximum rooting depth, or about 10 cm:

$$f < 10 \text{ cm} \tag{21.3}$$

If there is little or no slope to the bed surface, using a media with a sufficiently high hydraulic conductivity will prevent these design pitfalls.

### *Hydraulic Loading Considerations*

Equations 2.47–2.52, Chapter 2, provide the framework for determination of the allowable flow rate per unit width that may be passed through a given media of specified length, without creating excessive headloss. Based on prior considerations, the case of interest is a level bottom and a level top to the bed. The datum may then be chosen as the bed bottom, and therefore $h = H$. Hence, the simplification of Equation 2.54 results, which, on substituting a mean depth, describes a quadratic relation between depth and flow:

$$h_i^2 = h_o^2 + 2\frac{L}{W}\frac{Q}{k} \tag{21.4}$$

A nonlinear relation of this type has been reported by many investigators (Kadlec *et al*., 1981; Hobson, 1989; Ranieri, 2003). Headloss is exacerbated by high length-to-width (aspect) ratios and high flows, or low conductivity. Equation 2.56 may be rearranged for use in conceptual design to determine the maximum allowable flow to a specified media and geometry:

$$Q < \frac{k}{2}\left(\frac{h_i^2 - h_o^2}{L/W}\right) \tag{21.5}$$

The allowable headloss ($h_i - h_o$) would typically be restricted to about 5 cm. The outlet depth would be set about 10 cm below the bed surface to allow for headloss and moderate rain events without flooding. As an example, for a 60-cm bed depth, this gives $h_o$ = 50 cm and $h_i$ = 55 cm. The two

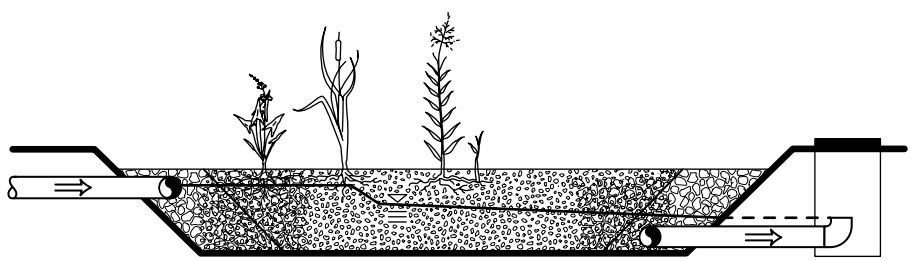

**FIGURE 21.11** Lowering of the outlet control to prevent inlet zone flooding. In extreme cases, this can exceed the hydrologic tolerances of the wetland vegetation (see Figure 21.12). (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

**FIGURE 21.12** A desiccated zone of the Columbus, Mississippi, HSSF treatment wetland.

remaining design choices are the media conductivity (size) and the aspect ratio (*L*:*W*).

The literature abounds with advice on aspect ratio. TVA (1993) suggests that cells should be made as long and narrow as possible, and gives examples with $4 < L/:W < 28$. Reed *et al.*, (1995) pronounce an aspect ratio of 2:1 if site conditions permit. U.S. EPA (2000a) provides methods that generally result in $0.5 < L/:W < 1.0$. Treatment effectiveness may not depend strongly on aspect ratio (Bounds *et al.*, 1998), but hydraulics definitely do. Selection of a bed configuration that does not take into account subsurface flow hydraulics, or does not factor in the effects of bed clogging, will lead to flooding problems.

The literature also abounds with advice on hydraulic conductivity. TVA (1993) prescribes 3- to 6-mm washed gravel, which is presumed to have a conductivity of 260 m/d. Measured whole-bed conductivities were typically in the range of 4,000 to 8,000 m/d (Watson and Choate, 2001), so a sizeable safety factor is associated with the TVA approach. U.S. EPA (2000a) concludes that size does not matter much for treatment and suggests 20–30 mm smooth stone, for which a bare stone conductivity of 100,000 m/d is assumed. However, a safety factor of 100 is used to account for clogging in the inlet zone, resulting in a design $k = 1{,}000$ m/d.

As an example, consider the EPA (2000a) recipe of $k = 1{,}000$ m/d and $L{:}W = 1.0$. The maximum allowable flow would be

$$Q < \frac{1{,}000\ \text{m}^3/\text{d}}{2}\left(\frac{(0.55\ \text{m})^2 - (0.50\ \text{m})^2}{1.0}\right) = 26.25\ \text{m}^3/\text{d}$$

The water surface profile associated with this limiting condition is nearly a straight line. It is noteworthy that this constraint applies without regard to the size (area) of the wetland. If the maximum design flow is more than this limit, the wetland would need to be replicated at $L{:}W = 1.0$.

The foregoing illustrative analysis is based on a uniform bed, with no spatial variation from inlet to outlet. But this is clearly not often the case owing to preferential inlet zone clogging. It is excessively conservative to assign a worst-case (low) conductivity to the entire bed. A two-zone approach is preferred, as has been suggested by U.S. EPA (2000a), with a low conductivity in the inlet zone and a higher value in the outlet zone (see Figure 2.22, Chapter 2). Because there is a factor difference of ten or more in these, the headloss in the outlet zone is considerably less than in the inlet zone. It becomes useful to consider a two-piece headloss formula:

$$h_i^2 = \left(h_m^2 + 2\frac{L_i}{W}\frac{Q}{k_i}\right) = \left(h_o^2 + 2\frac{L_o}{W}\frac{Q}{k_o} + 2\frac{L_i}{W}\frac{Q}{k_i}\right) \tag{21.6}$$

where

$k_i$ = inlet zone hydraulic conductivity, m/d
$k_o$ = outlet zone hydraulic conductivity, m/d
$L_i$ = inlet zone length, m
$L_o$ = outlet zone length, m
$h_m$ = depth at end of inlet zone, m

There are now two conductivities and an inlet length to be chosen. To illustrate, the approximate Richmond, New South Wales, Australia, observation was $Q = 24$ m$^3$/d, $W = 4$ m, $L_i = 20$ m, $L_o = 80$ m, $k_i = 2{,}000$ m/d, and $k_o = 30{,}000$ m/d. For $h_o = 0.45$ m, this results in $h_m = 0.48$ m and $h_i = 0.56$ m. Thus, most of the headloss occurs in the inlet zone.

Only a small amount of quantitative information is available for the two-zone model. The Fisher (1990) and Watson and Choate (2001) data suggest a ten-fold decrease in conductivity in the inlet zone (see Figure 2.27, Chapter 2). The size of the inlet zone is approximately 20–30% of the bed length.

There are steps that may be taken to alleviate inlet zone clogging, including limiting the TSS and BOD loading to the

inlet zone and distributing such loads over the entire inlet area (see Figure 21.5). In this design approach, the cross section of the wetland bed is determined by the organic loading and is often overdesigned hydraulically. Wallace and Knight (2006) suggest limiting the cross-sectional BOD loading at the wetland inlet to less than 250 g/m$^2$·d.

### Hydraulics of VF and Biosolids Wetlands

As discussed in Chapter 2, water movement in VF wetlands is a complex mixture of saturated and unsaturated flow processes. However, in terms of laying out the hydraulic profile, a more simplified procedure can be used. Here, we will consider the case of pulse-fed, VF wetlands as commonly employed in Europe. The hydraulic profile consideration then must consider two major points:

- Is there enough driving head to uniformly distribute the flow?
- Is the bed drainable?

If we assume that the VF wetland will be fed via a siphon (one of the simplest methods to gravitationally release large volumes of water in a short time) and that 1 m of driving head is needed to activate the siphon (and overcome frictional losses in the distribution piping), we have established the driving head criteria. If the VF wetland is 1 m deep and must completely drain, that is an additional 1 m of elevation change. So, in this example, if the designer assumes that he/she must reserve 2 m of elevation drop (1 for the siphon and 1 for draining the bed), then the constraints of the hydraulic profile should be met.

As the VF wetland is loaded, the hydraulic conductivity may change over time as a result of the cumulative organic load (Platzer and Mauch, 1997). This effect is dealt with either by using low organic loadings or a load-and-rest operational strategy, as discussed in Chapter 20.

Biosolids wetlands are typically governed by the rate of organic matter application (kg/m$^2$·yr), not the rate of hydraulic application. Underdrain piping is usually overdesigned from a hydraulic standpoint, because one of the major functions of these pipes is to aerate the wetland bed. As a result, most hydraulic issues with biosolids wetlands are likely to be related to pumping sludge to the wetland beds. As the solids content of the biosolids increase, so does the viscosity of the fluid (in a very nonlinear manner). Pumping of viscous fluids is outside of the scope of this book, and designers are encouraged to consult standard wastewater engineering textbooks and the guidance of equipment manufacturers in this regard.

## 21.7 FLOW DISTRIBUTION AND MANAGEMENT

Each type of SSF wetland presents different challenges in terms of flow distribution. Major design issues regarding flow distribution are discussed in this section. The fundamental design goal in all cases is to distribute the flow (and associated organic loading) as uniformly as possible across the wetland.

### HSSF Wetlands

The design goal for influent flow distribution in HSSF wetlands is the ability to distribute the flow as uniformly as possible across the cross section of the wetland bed. This was done initially using castellated or V-notch weirs in the United Kingdom; these proved to be maintenance-intensive devices due to solids accumulations, which interfere with the flow distribution, and are no longer recommended (EC/EWPCA Emergent Hydrophyte Treatment Systems Expert Contact Group and Water Research Centre, 1990).

In North America, the initial means of influent distribution was perforated pipes buried within the inlet region (TVA, 1993). Experience with perforated pipes led to a realization that the organic loading gets concentrated at the distribution orifice and the zone immediately adjacent to the orifice is very susceptible to clogging. This has led to a switch to infiltration chambers (see Figure 21.27) as a means of influent distribution, as the louvered sidewalls of these chambers allow a more uniform distribution of the organic load than perforated pipes (Campbell and Ogden, 1999; Wallace and Knight, 2006).

Pipes with rotating tees or elbows have also been used to distribute flow. The advantage of this method is that the elevation of each discharge point can be individually adjusted to achieve uniform flow distribution. The disadvantage of this method is that the primary effluent is exposed during the treatment process, which would lead to regulatory problems in the United States and northern Europe. As well, such exposed distribution systems can freeze in cold climates.

As knowledge of the certainty of clogging of the influent zone within HSSF wetlands has advanced, there has been a realization that the influent distribution works must have a multi-functional purpose—not only to distribute the influent flow, but to distribute organic load throughout the wetland bed, to delay flooding as long as possible, and also to provide access for bed maintenance activities and influent sampling. One approach has been to arrange the influent distribution into a "T" arrangement to reduce the organic loading at the influent zone, as indicated in Figure 21.13. This header arrangement using infiltration chambers would speculatively be advantageous from a load distribution standpoint, but hydraulic studies (at least in the startup phase) indicate that flow distribution is unequal (Muñoz *et al.*, 2006).

In any case, designers should consider the need for operator access to influent distribution works, in order to visually inspect the influent flow, collect samples, or conduct bed maintenance activities (Figure 21.14).

### VF Wetlands

Most VF wetlands are pulse-fed. The design goal of pulse feeding is to rapidly apply the influent flow such that the bed is rapidly flooded and that uniformity of application is ensured (see Figure 2.33, Chapter 2). Typically, pulse feeding

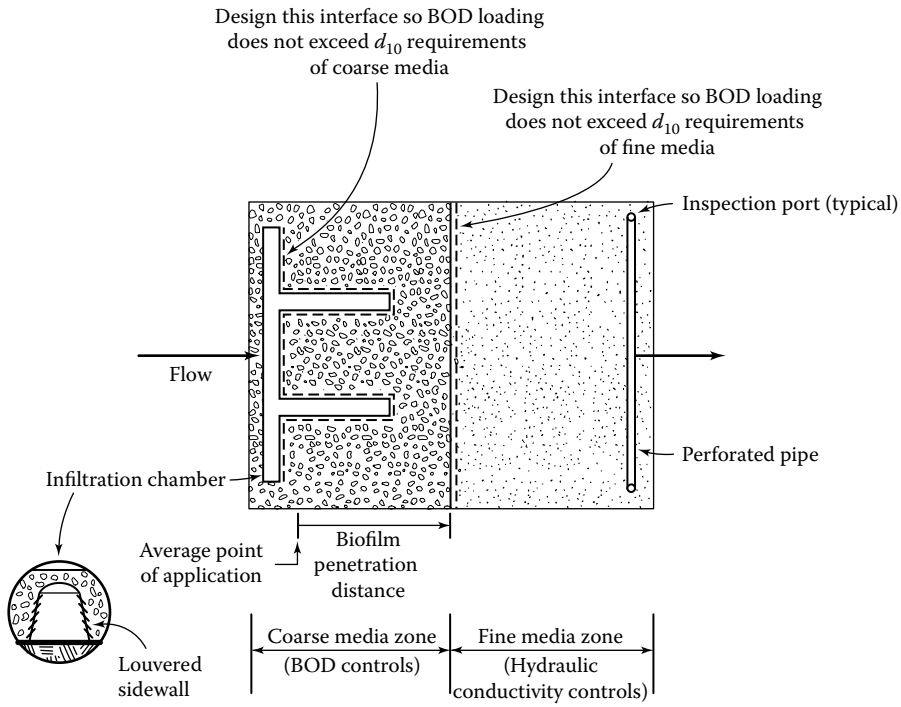

**FIGURE 21.13** HSSF influent header using a "T" layout to reduce the organic cross-sectional loading. (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

is by storing influent water and then rapidly dosing it onto the surface of the bed, either through the use of pumps or, if there is an adequate drop across the site, by gravity drains or siphons (Molle *et al.*, 2004a), as indicated in Figure 21.15.

Siphon dosing can be accomplished by sink and float "swimmer" siphons, as illustrated in Figure 21.15, or by air-bell siphons. Regardless of the method of pulse feeding, the design goal is to rapidly flood the bed in less than 15 min (ÖNORM B 2505, 2005), and the shorter dose intervals in the 5–10 min range are more desirable. Water then infiltrates through the VF wetland bed through the mechanisms of air entrapment and unsaturated flow, as described in Chapter 2.

A variety of piping methods have been used to distribute the influent flow. One of the most common methods is a series of perforated influent distribution pipes placed on the surface of the wetland bed (Cooper, 2003); an example of this approach for a small-scale VF wetland is shown in Figure 21.16.

Other distribution arrangements have been used, such as spray irrigation (similar to Figure 18.23, Chapter 18), but this creates problems under freezing conditions (Figure 21.17). Perforated distribution pipes laid on top of the bed is one of the most common distribution methods. In France, suspended self-draining distribution pipes are common (Molle

**FIGURE 21.14** Influent distribution channel for a tertiary treatment HSSF wetland. This open channel is a preferred design approach of Severn Trent Water in the United Kingdom because it allows easy operator access for cleaning. (Photo courtesy P. Cooper.)

**FIGURE 21.15** VF wetland dosing siphon, Rousillion, France. This is a "swimmer siphon," which alternately sinks and floats during the dosing cycle. At the time of this photo, the dosing chamber was in the "fill" phase, and the siphon assembly was floating.

**FIGURE 21.16** Perforated distribution piping for a pilot-scale VF wetland in Israel. The photo was taken during the feeding phase of the cycle to illustrate the desired effect of temporary bed flooding. Pipe spacing is approximately one meter.

**FIGURE 21.17** Ice formation around an influent spray distributor, Connell, Washington.

*et al.*, 2004a). In addition, very simple point-source distribution methods have also been used in the United States (see Figure 2.33, Chapter 2).

At the present time, there is not a rational design method for the number of square meters per distribution point. If the distribution rate is fast enough (e.g., well in excess of the hydraulic conductivity of the bed media), temporary flooding of the bed will occur, ensuring a good redistribution of the flow and load across the bed surface.

Similarly, there is not a rational design method for the volume per dose. In the original Max Planck Institute Process (MPIP) system of Seidel, the design criterion was a hydraulic loading rate of 1 m/d, and hourly dosing (EC/EWPCA Emergent Hydrophyte Treatment Systems Expert Contact Group and Water Research Centre, 1990), which equates to a flooding depth of approximately 4 cm/dose.

Recirculating VF wetlands have sometimes been employed in North America (Figure 21.7) (Wallace and Hallahan, 2005; García-Pérez *et al.*, 2006). In cold climates, these system often have a distribution system below the surface of the bed to combat freezing (Lemon *et al.*, 1996).

Pumping of the flow is required for flow recirculation. These systems typically employ perforated pipes to distribute the flow, which is much higher than the influent flow rate, in order to achieve the flow/pressure demands for even flow distribution across the VF wetland bed. One hydraulic design procedure is to calculate hydraulics based on the terminal end of the distribution lateral with an assumed residual head (typically 0.3 m). Orifice size, spacing, and pipe diameters are adjusted with the design goal so that there is less than a 10% differential in the orifice discharge rate between the beginning and end of the perforated distribution lateral. These calculations are best performed on a computer spreadsheet.

Water must be stored in a tank or sump for the recirculation pump to draw from. The volume of this storage tank is typically sized to provide between 12 and 36 hours of hydraulic retention time (based on forward flow), with 24 hours being a common design value (Crites and Tchobanoglous, 1998).

### Biosolids Wetlands

The inherent design challenge with biosolids dewatering wetlands is not necessarily distribution of *flow*, but rather, distribution of *solids load*. Because sludge is a viscous material, it will not flow across the bed and distribute itself in the same way as water would. Early sludge bed designs utilized piping along the sides of the wetland cells in conjunction with tees and splash plates to apply sludge to the basins. This approach has largely been abandoned. Modern design practice tends to utilize standpipes (with splash plates) within the wetland bed to more uniformly distribute the influent load. Figure 1.20, Chapter 1, illustrates a biosolid wetland cell being dosed by the standpipe method.

Both the rate of application and the area per distributor are important in order to ensure uniform application of sludge across the wetland cell. The general guidelines are that the sludge application system (typically pumps) must be able to apply 15 cm of liquid over one hour and the sludge distribution standpipes should cover no more than 250 $m^2$ per distributor (Nielsen, 2002). Facilities that do not comply with these design guidelines will result in preferential deposition of sludge near the distributor pipes, resulting in localized overloading and nonuniform application of the sludge layer (Nielsen, 2003).

Organic loadings, feed intervals, and the recommended number of beds for these systems are discussed in Chapter 20.

### Effluent Flow Collection

Collection of the effluent flow in SSF wetlands depends on the process objectives for each type of wetland. For HSSF wetlands, flow collection may be as simple as a perforated pipe with minimal concerns about clogging. For VF and biosolids wetlands, the situation is more complicated, because a second primary purpose of the effluent piping is aeration in addition to flow collection.

For HSSF wetlands, flow collection is relatively straightforward, and can be as simple as a perforated pipe extended across the width of the wetland cell, as indicated in Figure 21.8.

The situation is more complicated for VF and biosolids wetlands, as the collection system is typically overdesigned to allow passive aeration of the wetland bed. For biosolids wetlands, the effluent collection system is typically overdimensioned, with 10-cm perforated pipes spaced every 3 m (maximum) in the wetland bed (Nielsen, 2002). The primary purpose of these pipes is aeration, not drainage, as indicated in Figure 1.7 in Chapter 1.

The section of the drainage/ventilation pipes that passes through the filter layers of the bed should not be perforated to avoid short-circuiting of flow. The elevation of the ventilation cap should be above the maximum flooding level of the bed for the same reason.

### Water Level Control

The operator has control over water levels in HSSF wetlands. The general water level control objectives in HSSF wetlands are the following:

- Maintain the water level below the surface of the wetland bed.
- Manage the water level such that it remains within the root zone of the emergent wetland plants.

This is most easily done with a control structure that has a wide range of adjustability, as indicated in Figure 21.18. For small-scale systems, flexible hoses, as indicated in Figure 23.11, Chapter 23, or rotating elbows are commonly used.

Water level control is essential to the establishment of plants in HSSF wetlands. The minimum-cost alternative to Figure 23.11, Chapter 23, for small-scale wetlands is a fixed standpipe with removable extensions, as implied in Figure 21.18. For large-scale systems, adjustable weir

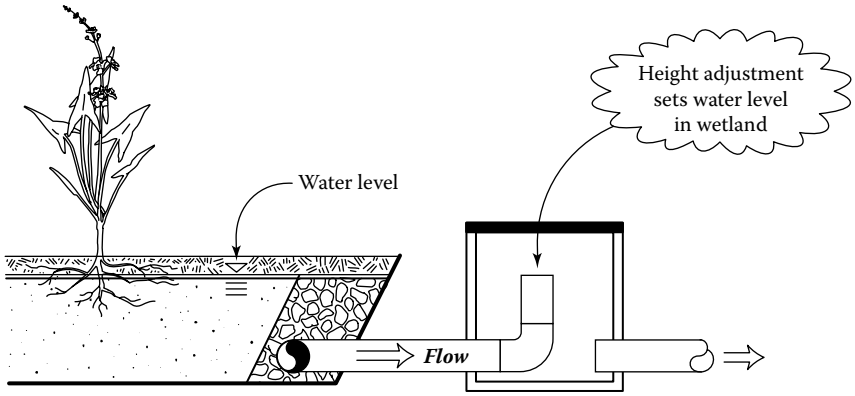

**FIGURE 21.18** Water level control structure for a HSSF wetland. (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

gates are preferred. In the intermediate range, stacking-plate designs such as the one illustrated in Figure 18.27, Chapter 18, are often cost-effective choices, provided that the plates achieve a leak-free seal, which almost invariably means that premanufactured units must be used.

VF and biosolids wetlands are most commonly designed as free-draining systems; water level control may be desirable, but is not mandatory for these systems.

## 21.8 LINER SYSTEMS

Various synthetic and clay liner systems have already been discussed in Chapter 18 for FWS wetlands; the same considerations apply also to SSF wetlands. In North America, one-piece factory-seamed PVC liners (0.76 mm) are commonly used on small wetland basins (<1,000 $m^2$). Larger projects typically use HDPE liners in the 1.1–1.5 mm thickness range; these liners are shipped to the project site in rolls. Individual liner panels are fusion-welded together after placement to create a water-tight liner system. In some regulatory jurisdictions, leak testing of the liner may be required (see Figure 2.7, Chapter 2).

If some infiltration out of the wetland basin is acceptable, then the expense of a synthetic liner system is likely not warranted. If the local soil has sufficient clay content, compaction of this material may adequately seal the basin; amendments such as bentonite or lime can also be used to enhance the sealing properties of the soil.

The choice of a liner system often is a function of the local economy and the materials that are commonly available. For instance, ethylene propylene diene monomer (EPDM) roofing membranes (1.5 mm) and geosynthetic blankets (bentonite enclosed in geotextile) have been successfully used in SSF wetland projects.

### Thermal Considerations

The most obvious example is in cold climates; small and on-site HSSF wetland systems must be designed to operate in subfreezing environments, because winter influent storage is usually not an option.

For HSSF wetlands, cold climate design typically involves burying all the distribution piping and conducting energy balance calculations to determine if an insulating layer of mulch is warranted to prevent freezing of the bed; procedures for this type of thermal analysis are discussed in Chapter 4.

In VF wetlands, ice formation on top of the bed may be an operational concern, and distribution piping must be designed to self-drain between dosing events. In extreme cold climates, the pulse-fed, surface flood method of distribution common in Europe may have to be replaced with designs using buried distribution piping (see Figure 21.7 for example).

For biosolids systems, freezing is generally seen as beneficial because it lyses the cell walls within the sludge material, which aids in dewatering (Reed *et al*., 1988). Some modification of the distribution piping may be needed in very cold climates; for instance, compressed air may be required to purge the dosing standpipes to prevent freezing damage.

## 21.9 SSF WETLAND CONSTRUCTION

Construction of SSF wetlands includes preparing bid documents (if necessary), hiring the services of a construction contractor, and physically building the wetland. This is a critical phase of the implementation process. Because of the nature of SSF wetlands, errors made in the early stages of construction become almost impossible and very expensive to correct after the bed media is installed. As a result, a clear understanding and correct execution of the design documents are essential.

In most areas, there are not a sufficient number of treatment wetland construction projects to allow a contractor to specialize in this type of construction. The construction contractor will likely be unfamiliar with treatment wetlands and often will not have a good understanding of how the system is supposed to function. Contractors on treatment wetland projects will come from backgrounds such as single-home (onsite) septic systems, general civil construction, or

mechanical wastewater treatment plants. Each of these disciplines bring their own history and bias to wetland construction. For instance, septic contractors may understand the purpose of the system as wastewater treatment, but they may be unfamiliar with the level of workmanship and detail necessary to implement a treatment wetland. Civil contractors will likely understand the earthwork and elevation aspects of the project very well, but are unlikely to be familiar with wastewater treatment. Mechanical contractors will be skilled at installing pipes and equipment such as pumps, but are unlikely to understand how a treatment wetland is supposed to "work." In addition to these three disciplines, a specialty subcontractor is often involved to install the liner and do any seaming or associated work. Generally speaking, the construction process is most successful when the wetland designer acts as the bridge to integrate these different construction backgrounds via construction and start-up supervision.

### Elevations and Grading

The basic earthwork process for excavation and grading of SSF wetlands is essentially the same as for FWS basins, which has been previously discussed in Chapter 18. Basic tools, such as Equation 18.1, can be used to estimate earthwork volumes, but for larger projects, 3-dimensional computer modeling is often employed.

The basic objective is to excavate a level basin (or a flat basin with a constant bottom slope). On small projects, this may be done with an excavator (similar to the unit shown in Figure 21.1). Larger projects often use bulldozers or skid-steer loaders to facilitate the basin leveling process.

The setting of the correct elevation of each basin, pipe, and control structure is one of the most fundamental and critical aspects of the construction process, because mistakes made in this regard become almost impossible to fix later on. This usually involves the establishment of a local benchmark of known elevation on the project site. The distance and elevation of the different process components are then measured against this relative benchmark. Generally, these types of measurements are made for two purposes:

1. To confirm that the individual process component is at the correct elevation.
2. To confirm that the earthwork meets the specified degree of flatness (tolerance of at least ±5cm).

Laser levels are increasingly used as a quick and easy means to check elevations, although basic hand levels or water levels can provide acceptable results if used properly. For large projects, the services of a surveyor with specialized equipment are often employed, and the location and elevation of project components are measured using a total station. As-built confirmation of the rough grading is recommended.

### Liners

Various liner systems have been previously discussed in Chapter 18 for FWS wetlands, and those same considerations apply to SSF wetlands. The primary disadvantage of PVC is that seaming material in the field requires the use of adhesive mastic or tape; consequently, most PVC liners are factory-seamed and delivered to the job site. This generally limits their use to small wetland basins (<1,000 $m^2$). Even factory-seamed liners need to be checked in the field, as errors in factory seaming are not uncommon, and pipe penetrations through the liner still need to be sealed, usually with mastic adhesive.

Larger projects will require field seaming; the liner is delivered to the job site in rolls. Having an organized plan for liner placement greatly facilitates field seaming. Figure 21.19 shows one method of liner placement using a tracked excavator and manual labor.

On project sites with stones or other material that may damage the synthetic liner, a protective layer of sand is often

**FIGURE 21.19** Use of a chain and hoist assembly to facilitate liner placement in a HSSF wetland basin, Delft, Minnesota. Sandbags are used to hold the liner pieces in place prior to seaming.

placed on the wetland basin prior to liner placement. After the liner is installed, factor seams must be inspected, and on larger projects, field seaming will commence. Liner seaming is typically done by subcontractors who specialize in this work.

## Berms

The basic elements of berm design have been discussed in Chapter 18 for FWS wetlands. Berm design is generally less complicated for SSF wetlands, because SSF wetlands do not have to contend with wave action or damage by wildlife and require less freeboard. One critical aspect of berm construction is the installation of the liner, with an effective and easy way to anchor the liner edge.

### Earthen Berms

Edge treatment in SSF wetlands is often the earthen berm; the basic cross section for this construction system is shown in Figure 18.18, Chapter 18. Berm construction appears deceptively simple; in reality, the berm/liner interface is a common source of construction mistakes. The design and construction of berm systems must take into account a variety of factors, including

- The angle of repose of the native soils at the project site
- The anchor trench to secure the edge of the liner
- Grading of the outside edges of the berm to prevent stormwater runoff from entering the basin
- The surface treatment of the inside berm face

Wetland designers often assume that a prescriptive side slope (3:1, for example) can be constructed; however, this is dependent on the angle of repose of the soil. Designers should verify that the specified side slope is actually constructable at the project site.

Anchoring the liner edge is often a source of construction problems. Liner placement is greatly facilitated if the berm face is smooth, uniform, and level. Construction of the anchor trench is best done with a chain trencher. Figure 18.24, Chapter 18, is an example of good grading and liner installation. This level of detail in site grading requires a skilled heavy-equipment operator and cohesive soils. If the berm is not uniform, or poorly graded, liner installation is much more complicated and prone to construction errors. Figure 21.20 shows a poor job of berm grading that has resulted in an uneven top elevation and numerous bulges in the liner. The exterior grading outside the berm is insufficient to protect the wetland from the intrusion of stormwater runoff and associated sediment.

In some instances, it may be acceptable to leave the liner exposed on the inside of the berm face, or the liner may be covered with a protective fabric, as illustrated in Figure 21.21. In other applications, it may be desirable to provide more protection to the liner. This is commonly done through the use of rip-rap, as indicated in Figure 21.22.

**FIGURE 21.20** Example of poor berm finishing, liner installation, and site grading. Stormwater runoff is carrying sediment into the HSSF wetland basin.

**FIGURE 21.21** VF wetland in St. Thomé, France. Inside face of the berm consists of liner covered with a protective fabric. The pipes against the berm face are drainage pipes with ventilation caps.

If a decision is made to leave the liner exposed, textured liner material should be used on the berm face. Standard liner materials are very slick when wet (Figure 21.23) and can present a considerable safety hazard; it is not possible to climb out of a wetland basin under these conditions if the berm slope is at 3:1 or steeper. That includes animals, such as dogs, cats, etc.

### Vertical Sidewalls

An alternative to earthen berms is the use of vertical sidewalls. Sidewalls require additional material to construct and are quite expensive, but offer the advantages of greater space efficiency and much easier liner installation. Vertical sidewalls can be constructed out of plywood, concrete block, or cast-in-place concrete. Figure 21.24 shows an example of plywood construction. This type of wall system is also shown in Figures 21.1, 21.26, and 21.28. The plywood wall system is not structurally free standing; both the outside and inside of the wall must be filled in equal lifts to hold the wall in place. It is anticipated that over time the wood will decay, leaving the liner in place.

In many areas of the world, the concrete block is a common and relatively inexpensive construction material when vertical sidewalls are advantageous. The interior cavities of the concrete block are typically poured with concrete, and reinforcing steel is added for structural strength; Figure 21.25 is an example of this type of sidewall construction. The third alternative is cast-in-place concrete walls (see Figure 1.15, Chapter 1). This is the most expensive method of construction, but offers

**FIGURE 21.22** HSSF wetland divider berm armored with rip-rap, Albuquerque, New Mexico.

**FIGURE 21.23** HSSF wetland berm in southern Israel. A light rain has made this surface extremely slippery because smooth high-density polyethylene (HDPE) was used on the berm face.

**FIGURE 21.24** Example of vertical sidewall construction using plywood, Prinsburg, Minnesota. The inside wall face has a 5-cm-thick extruded polystyrene (XPS) board for thermal insulation and also to minimize wear on the liner.

**FIGURE 21.25** HSSF wetland with concrete block sidewalls, Akumal, Mexico.

the greatest structural strength. This method of construction is sometimes used for biosolids wetlands, because, when the basin is unloaded, removal vehicles such as skid-steer loaders can push directly against the concrete wall.

### Influent and Effluent Piping

After the liner installation, the next major step in the construction process is the installation of the influent distribution piping and effluent collection piping. For VF wetlands, the drainage pipes are installed prior to placement of the various layers of bed media (Figure 21.26) and the influent distribution piping is typically installed on top of the bed (see Figure 1.14, Chapter 1, for an example), although biosolids wetlands that use the riser pipe approach shown in Figure 1.20, Chapter 1, may have the influent distribution pipes installed prior to placement of the bed media. HSSF wetlands have the influent and effluent piping installed at either end of the bed prior to placement of the bed media (Figure 21.27).

### Bed Media Placement

Placement of the bed media is one of the most critical aspects of SSF wetland construction. This is especially true for VF and biosolids systems, which rely on stacked layers of filter material that often has to meet a fairly tight grain-size distribution. One of the major decisions during SSF wetland construction is how the bed material will be placed into the wetland cell. From the perspective of the construction contractor, there are three major choices, each of which has pros and cons:

- Utilization of a general construction machine, such as a tracked excavator
- Allowing equipment within the wetland cell to spread bed material (typically skid-steer loaders or small bulldozers)
- Use of a specialty device, such as an extendable conveyor, to spread the bed material

The lowest-cost alternative for most construction contractors will be to use a general purpose machine such as an excavator (see Figure 21.1). This type of equipment can (1) excavate the basin, (2) facilitate liner placement, and (3) place the bed material once the liner is installed. The drawback to this approach is that most excavators have a reach less than 10 m, which implies that 20 m is about the maximum width the wetland cell that can be constructed with this method. Also, the use of such large excavators for media placement will likely impose greater construction-access separation issues on the overall wetland project.

If direct placement of the bed media by an external piece of equipment is not feasible, the next lowest-cost alternative is to allow tracked vehicles within the wetland cell. In HSSF wetland cells, this is somewhat easier, as the placed bed media can be "pushed" forward in a manner that the construction equipment does not have to travel directly on the liner.

**FIGURE 21.26** VF wetland perforated drainage pipes and nonperforated ventilation risers prior to bed media placement, Lake Elmo, Minnesota. Apparatus in the rear corner of the wetland cell is for leak testing of the liner (see Figure 2.7).

**FIGURE 21.27** HSSF wetland influent distribution chamber, Cambridge-Isanti School District, Minnesota. The white PVC pipe inside the chamber is perforated to distribute the flow from a dosing pump. The white PVC pipe to the right is an aeration header.

The situation is more complicated for VF and biosolids wetlands; if construction vehicles are allowed within the basin for these systems, they must travel directly over the effluent collection piping (Figure 21.28). Even if the ground-bearing pressure of the tracked vehicle is acceptable, wetland designers should keep in mind that the shear forces associated with turning tracked vehicles can easily break the underdrain piping, and considerable care must be taken in placing bed media in this manner.

There are situations where the wetland basin will be too large (or too small) to allow cost-effective access by construction vehicles such as those illustrated in Figure 21.28. One solution is an extendable conveyor system that can minimize the need for secondary releveling.

### Installation of Control Structures

For small SSF systems, control structures are likely to be simple standpipe units (see Figure 23.11, Chapter 23, for example) or stacking-plate designs (see Figure 18.27, Chapter 18).

The primary design challenge is that the control structures must be designed in a way that allows for efficient and safe operator access.

**FIGURE 21.28** Example of drainage material being placed over effluent collection piping in a VF wetland in Lake Elmo, Minnesota. Gravel is being placed by the excavator outside the basin; secondary re-leveling is done by the skid-steer loader inside the basin.

In the United States, entry into confined spaces is subject to considerable federal regulatory requirements, which, at a minimum, requires the testing of the ambient atmosphere (to check for breathable or explosive atmospheres). If wetland designers can create "open access" controls, this is strongly encouraged because it will greatly simplify operator use of the facility.

## 21.10 COMMISSIONING AND START-UP

One of the most important aspects of the start-up and commissioning of SSF wetland systems is vegetation establishment. Plant establishment is a process of planting the wetland vegetation combined with appropriate water level control. Various methods of plant establishment are discussed in this section.

### Plant Selection

The selection of plant species in SSF wetlands is often a product of cultural and regulatory constraints. SSF wetlands tend to be heavily loaded compared to "agronomic" FWS wetlands, so the influence of the plant geochemical cycle often is not as important. Also, the aboveground plant canopy does not interact with the water column in the same way. In FWS wetlands, the emergent plant detritus falls into the water column, providing surface area for microbial biofilms and a degradable carbon source for treatment processes such as denitrification (see Chapter 9). At the present time, there is not sufficient knowledge to recommend a single species as being able to conclusively improve treatment over a mixed plant community.

In Europe, common reed (*Phragmites* spp.) is used almost exclusively as the plant of choice and often forms monocultures in SSF treatment wetlands; HSSF systems in the Czech Republic often use a combination of *Phragmites* and reed canary grass (*Phalaris arundinacea*) (Vymazal, 1998). Both species are considered invasive in the United States, and their use is often discouraged by natural-resource managers.

In North America, the primary emphasis in HSSF wetlands has been on *Typha* spp., *Schoenoplectus* spp., and *Carex* spp. There is an emerging body of information showing that the root zone oxygen transfer of these species is different (Stein *et al*., 2006b), especially in the dormant season, but to date there is insufficient knowledge to translate this into design guidance.

For single-home SSF systems, the aesthetic benefits of the plant community is often an important design consideration. Plants such as *Asclepias incarnata*, *Solidago rigida*, *Canna* spp., *Iris* spp., and *Cyperus alterniflorus* have been used successfully in North America (Wallace and Knight, 2006) depending on the climate, although the aesthetic quality of the plant community typically requires some "gardening" from the system owner to maintain the best visual presentation.

In tropical countries, locally available species of *Phragmites* and *Typha* have been the most common choice to date.

Cold climates offer a different set of selection choices. If the wetland is insulated with a mulch layer, this creates a permanent unsaturated zone that shifts the competitive advantage away from the obligate wetland plants towards facultative plants (Chapter 2). *Schoenoplectus* (*Scirpus*) species such as *Scirpus atrovirens* and *Scirpus fluviatilis* have proven to be good choices in the cold climates of North America (Wallace *et al*., 2001).

The selection of a plant species (or suite of plant species) is generally a function of two factors:

1. The degree of rhizome spread and, hence, the ability to achieve plant canopy and crowd out unwanted invasive species
2. The development of more belowground root biomass and depth of root penetration, which benefits wastewater treatment

Qualitative observations in Minnesota indicate that *Phalaris* is very effective in Factor #1, but poor in #2; hence, project specifications often include a one- to two-year maintenance contract to promote the development of a *Schoenoplectus* plant community over the initial colonization pressure of *Phalaris*. Contact herbicides are routinely used in this regard.

The cost of the initial plantings of SSF wetland systems is discussed in Chapter 23.

### Vegetation Establishment

#### Planting Wetland Vegetation

Planting in SSF wetland treatment systems is done by hand. Rhizomes and similar rootstock are planted directly into the SSF bed media. The water level is typically lowered temporarily to facilitate planting. After planting, the water level is immediately raised so that the rhizomes do not dry out.

For mulch-insulated wetlands, the procedure is slightly different. After planting, the water level is typically raised above the top of the SSF bed so as to subirrigate the mulch layer. If potted or bare-root plants are used, the mulch is firmly packed around the plant for stability, protection, and to ensure good water contact with the roots, as shown in Figure 21.29.

For soil-based SSF systems, extreme care must be taken to avoid compaction of the soil; in these applications, workers typically use pieces of plywood to distribute their weight and minimize impact to the media (Kickuth, 2002). Owing to the repetitive nature of the work, laborers quickly adapt tools to the task. One of the most commonly used tools for planting is a military entrenching tool.

#### Successful Plant Establishment

For plant establishment in a treatment wetland to be successful, the plant material (seed, tuber, rhizome, pot, etc.) must

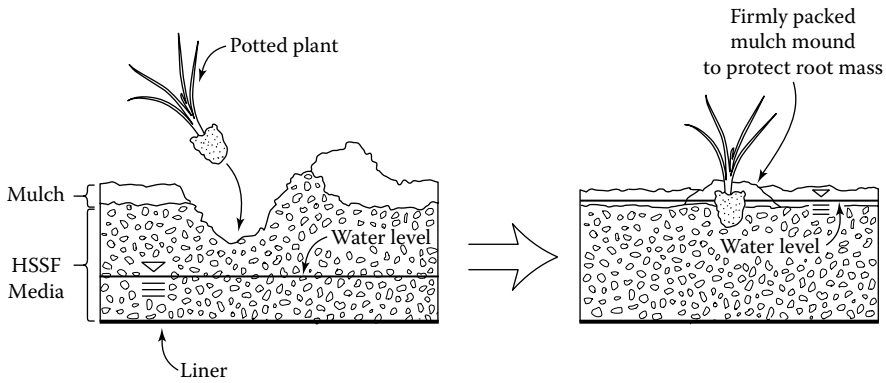

**FIGURE 21.29** Potted-plant installation procedure for a mulch-insulated HSSF wetland. (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

be viable at the time of planting. This may require provisions such as the shading and watering of the planting stock at the project site so that it does not dry out and die before it can be planted. After planting, water level management during the start-up phase must be compatible with the needs of the plants.

Wetland plants are adapted to a hydric environment and have very little drought tolerance. If the plants are allowed to dry out during the establishment phase (where there is very little root network available from which the plants can draw water), widespread mortality can occur.

For SSF wetlands, the water level should be raised up to the level of the bed for nonmulched systems and about 1 cm above the gravel bed (so that the mulch is subirrigated) for mulched systems. The goal is to provide a continuous flooding of the plant root zone during establishment. Figure 21.30 shows a HSSF wetland with *Solidago rigida* during the plant establishment phase and the resulting established plant community at the end of one growing season (Cross, 2001).

Design specifications for vegetation establishment in constructed wetlands should clearly delegate responsibility for plant maintenance from the time of initial planting through plant establishment. Successful establishment requires periodic inspections to document water level, plant survival, and plant growth. The frequency of these inspections is project-specific, but must be often enough to deal proactively with potential problems (see Figure 18.36, Chapter 18).

HSSF wetland beds are often filled with clean water before planting. As this clean water is displaced by the influent flow, pollutant loads gradually increase. This is a preferred

(a) (b)

**FIGURE 21.30** Newly planted (a) and established (b) mulch-insulated HSSF wetland in Anamosa, Iowa. (Photos courtesy C. Cross.)

approach, as it does not expose workers to potentially harmful substances in the wastewater during planting and provides a time window for the vegetation to adapt to the pollutant loadings.

VF wetlands are designed to operate as free draining systems and, as a result, may require a supplemental water supply during start-up to assist in vegetation establishment. The dosing interval must be sufficient to maintain moisture in the root zone to keep the plants alive, typically, once or twice per day, at a minimum. The use of portable sprinklers to spray irrigate water during the establishment phase has been used in recirculating VF systems because newly installed plant material typically cannot reach the buried distribution piping.

For biosolids systems, it is desirable to apply a thin layer (5 cm) of sludge across the surface of the basins (Nielsen, 2003).

Planting densities vary based on the plant spreading rate, desired time to canopy coverage, and growing season. For cool temperate climates, planting densities between 2 and 6 plants per square meter are recommended (ATV, 1998; Nielsen, 2003); this will typically achieve complete plant coverage in approximately two growing seasons, depending on the climate. Expansion of the plant coverage is primarily through lateral runners (see Figure 3.12 for example).

## SUMMARY

The physical design of SSF wetlands requires numerous decisions concerning siting and layout. The compartmentalization and number of flowpaths as well as the aspect ratios of the cells must be determined. Because of competing objectives, designers must often compromise between the number of cells, flow paths, aspect ratio, bed depth, and the size of the bed media.

VF and biosolids wetland systems will require the selected loading rate that can be matched with a load-and-rest regime that allows the system to function without short-term clogging problems.

Based on the information that is currently available, it appears that clogging of HSSF wetlands can be delayed by minimizing cross-sectional loading. However, there is no information to indicate that clogging of HSSF wetlands will not occur over the long term, and it is likely that HSSF wetland beds will require periodic maintenance about every ten years to maintain hydraulic conductivity, especially in the inlet zone. Although this chapter explores the design and construction of SSF treatment wetlands, the guidelines presented herein are by no means a definitive checklist for implementation of treatment wetland projects, as the physical, climatic, and political landscape of each project will be unique.

# 22 Management, Operations, and Maintenance

As discussed in the preceding chapters, most treatment wetlands are designed and constructed to require infrequent operational control or maintenance. Through conservative design and simple, low-maintenance mechanical controls, many free-water surface (FWS) wetland treatment systems will experience minimal ecological changes and will continue to meet final effluent limits for a long period of time. The situation is more problematic for horizontal subsurface flow (HSSF) wetlands, which will require periodic bed maintenance throughout the lifetime of the system, and for vertical flow (VF) wetlands, which are dependent on loading-and-resting regimes to maintain hydraulic conductivity, unless lightly loaded.

Monitoring and adjustment of flows, water levels, water quality, and biological parameters are the principal day-to-day activities required to achieve successful performance of these low-tech treatment wetlands. Other operations and maintenance activities in treatment wetlands, such as repair of pumps, levees, and water control structures; vegetation management; pest control; and removal of accumulated mineral solids, typically must be attended to at much less frequent intervals.

This chapter provides guidance on the appropriate level of operational monitoring necessary for the control of wetland treatment systems. Typically, these are natural systems with low hydraulic and constituent loadings. Ecological integrity therefore requires minimal attention, unless a particular preconceived plant mix has been mandated. Hydraulic balance and hydropattern control may require infrequent attention. Compliance monitoring is driven by the permit conditions, but often a modest amount of extra monitoring is useful in optimizing operations. Emphasis should be placed on the avoidance of unnecessary operational and maintenance activities, including the management of nuisance species when this achieves no measurable compliance goals.

## 22.1 START-UP

It should be fairly obvious that a newly built wetland is not in a condition to perform the functions that will ultimately prevail in the system. Yet, there have been many misunderstandings resulting from start-up conditions that do not meet long-term expectations. Start-up transients are not necessarily brief, because it can take considerable time for the wetland biology to develop. Several processes occur during start-up, importantly including:

- Plants increase in density and areal coverage.
- Senesced plant parts form a litter layer.
- Newly placed soils either release constituents if initially loaded or absorb constituents until they are fully loaded.

Because plants form part of the "biomachine" that accretes phosphorus and other chemicals, and because plant detritus forms the sites for periphyton and bacterial assemblages, it is expected that removal will be enhanced by grow-in. One pattern of start-up is typified by the rapid vegetation of a bare soil wetland after an initial planting. If that planting is sparse, the start-up period will be characterized by the time for plant fill-in plus the time for litter development. That can be relatively brief, especially in warm climates. At the Orlando Easterly Wetland in Florida, the start-up duration was approximately 24 months, during which considerable change in the ecosystem took place. Figure 10.21 shows two of the principal variables: vegetation density and phosphorus rate constant. Note the close parallel between the amount of vegetation and the rate constant during the first two years. After that period, the vegetation density levels off, and the rate constant drops to its long-term average value of 13.5 m/yr. The phosphorus requirement for building the new standing crop of biomass leads to a peak uptake rate constant, that is, roughly double the long-term average value.

An interesting feature of the unvegetated wetlands is the absence of a carbon source to fuel the conventional heterotrophic denitrification. That process would conventionally require a supply of carbon of approximately equal mass to that of nitrogen lost (Ingersoll and Baker, 1998). A newly constructed wetland does not have the carbon source created by litter decomposition, unless the system is mulched initially with carbonaceous material.

Algae are an opportunistic first-colonizer in new wetlands, because the canopy is not yet extensive, and sunlight is available, perhaps accompanied by copious nutrient supplies (see Figure 3.1). Although this initial vegetative cover develops rapidly, it utilizes only a small fraction of the nutrients in the system and temporarily creates a pond environment.

### Antecedent Conditions

The initial soils and sediments may contain extra nutrients or contaminants, or they may possess an initially high sorption capacity. The antecedent load of pollutants should be assessed to determine if there is treatment liability that must be accommodated before the incoming water can be treated. The same processes that will eventually provide treatment

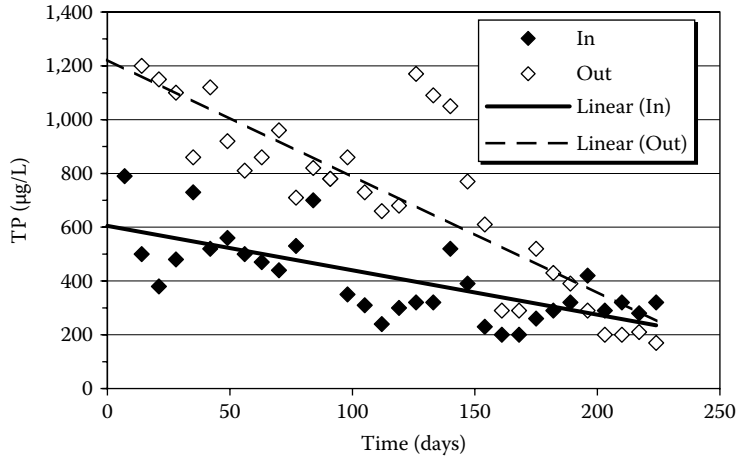

**FIGURE 22.1** Start-up of a FWS wetland near Orlando, Florida. The antecedent soils were laden with labile phosphorus, which was released to overlying water during start-up. This initial load was absorbed and flushed over the first 200 days of operation.

for incoming water can also remove and immobilize such antecedent pollutants. However, if the water flow is immediately commenced, then the wetland can temporarily serve as a "source" of contaminants. If unanticipated, such releases can create regulatory problems. For instance, a wetland treatment system in Orlando, Florida, released phosphorus and nitrogen from antecedent land uses and conditions, during a start-up in the flow through mode (Figure 22.1). Despite the improvements to performance that ultimately resulted in phosphorus removal, the regulatory expectation was that removal should occur "from day one." Very large fines were levied just as the wetland came out of start-up, causing closure of the facility.

The keys to avoiding such start-up problems are an understanding of potential treatment liability and a plan to avoid discharges until the wetland has "settled down" to a post-start-up condition. However, it is difficult to forecast the direction or magnitude of potential start-up releases. Accordingly, a regulatory framework has been developed in South Florida for start-up of FWS wetland systems. Three periods in the (early) life of a treatment wetland are identified:

- *Start-up phase.* The permittee shall manage water depths in the treatment cells to facilitate the recruitment of marsh vegetation in accordance with an Operations Plan, which may include recirculating waters within the system. The start-up test for an individual flow-way begins when the previously mentioned samples demonstrate, over a four-week period, a net reduction in the target pollutant (phosphorus for the STAs) occurs. Discharge/flow through operations, from an individual flow-way that has passed the start-up test, may commence once documentation and all supporting data and analyses are submitted. The intent of this phase is to prevent flow through operation until it can be demonstrated that the project is producing net benefit.
- *Stabilization phase.* Once flow through discharges from a flow-way begin, the permittee shall initiate water quality monitoring for that flow-way consistent with the monitoring program. Performance during this period is not expected to be optimal because the wetland is not yet fully developed. The stabilization test is met when the long-term criteria for the facility are met, i.e., the concentration limits are being met. If, after the two years of full flow through operation, the facility has not met this stabilization test, the permittee is to submit a report evaluating reasons for not meeting the stabilization test.
- *Routine operations phase.* During the routine operations phase, the wetland is deemed in compliance if the permit effluent limitation is being achieved.

In general, the South Florida projects have achieved start-up and stabilization in periods ranging from a few weeks to more than two years, which is typical of warm climates. In cold climates, a grow-in period of approximately two growing seasons may be anticipated, depending of the planting density and rate of vegetation propagation (see Figure 3.12).

It is generally a bad idea to initiate the development of a wetland with large flows of high-strength wastewater. Newly planted vegetation is susceptible to destruction if exposed to high-oxygen stress or high concentrations of some chemicals such as sulfur compounds. Therefore, a "ramp up" from fairly good quality water to the strong influent is often used. For instance, the Saginaw, Michigan landfill leachate treatment wetland anticipated source water of several hundred mg/L of ammonia nitrogen. The wetland was developed, including litter and plants, using rainwater and a potable water supplements. The system was placed on large recycle and the introduction of leachate commenced. The raw leachate was thus diluted with treated water. This start-up strategy was successful. As a counterexample, the potato water

treatment wetland at Connell, Washington, was started-up with an abrupt transition from clean irrigation water to full-strength process water (anaerobic). Large populations of purple sulfur bacteria developed, and the wetland developed sulfides in excess of 40 mg/L (Burgoon *et al*., 1999). Very strong odors were generated and inlet vegetation suffered. These were fortunately only start-up problems, which have not continued beyond the commission phase.

## Vegetation Start-Up

Design specifications for vegetation establishment in constructed wetlands should clearly delegate responsibility for plant maintenance from the time of planting until system start-up. This task may be the responsibility of the contractor or planting subcontractor, the engineer, the owner, or some combination of these parties and should be carefully described in the planting specifications (see Table 22.1). The key requirements for healthy wetland plant propagules to succeed are water, soil, nutrients, and light. The first two components must be controlled to some extent by the engineer and the contractor, and nature generally provides the other requirements for plant growth. The establishment of vegetation is usually a task of a planting contractor and not the facility operator.

Water level control is of primary importance during the plant establishment phase. Therefore, clear lines of responsibility need to be spelled out: who is required to supply start-up irrigation water, and who is responsible for watering the new plants? Failure to supply water in appropriate amounts can result in planting failure (see Figure 18.35). Generally, there are three phases to water level adjustment during this phase:

- *Phase 1:* Decreasing the water level to expose the rooting media (mud flat) for the initial planting or for replanting.
- *Phase 2:* A gradual increase of the water depth as emergent plants become established. The emergent shoots should be above the water surface at all times to give the plants access to sunlight and oxygen. Water level adjustments should be less than 2 cm/d during this time. Typically, the higher the oxygen stress on the plants (high organic and/or nutrient loads), the smaller the incremental adjustment should be.
- *Phase 3:* Setting the water level at the design depth after plants are established.

Basic procedures for establishment of wetland plants for SSF wetlands have already been provided in Chapter 21.

If there is significant failure during the initial planting, these steps may need to be repeated. Initial plant inspection should examine the viability of the planted propagules, whether seeds, seedlings, or field-harvested mature plants. If plants were planted in rows on specified centers, the surviving plants in a subset of these rows can be counted to determine the survival rate. When counting surviving plants, each of the original seedlings or plant clumps should only be counted once, and any daughter plants that may have arisen from rhizomes should not be counted. If seeds were used, then random plots can be used to estimate germination success. Planting success can be compared to planting specifications based on these plant counts. In some cases, a contractor may have to fill in some areas with new plants to comply with the requirements of the planting specifications.

Inexperienced contractors and inexperienced engineers writing specifications and providing construction supervision have often killed their wetland plants through insufficient soil moisture, excessive water depths, inadequate soil preparation, damaged plant material, inadequate plant spacing, inappropriate planting methods, and bad timing. Success is highly probable as long as a contractor understands the growth requirements of the desired wetland plants and uses information available to most horticulturists.

Once emergent plants are well established, replanting is usually not necessary unless the system is overwhelmed by

**TABLE 22.1**
**Example of Contractual Responsibilities for Plant Establishment**

**3.2 Maintenance of Stand**

**A. Maintenance**

The planting contractor shall make arrangements and bear all costs of providing adequate water for initial planting and plant maintenance. Treatment effluent from the existing facultative lagoon can be used, if desired by the contractor, as long as off-site runoff is controlled. The planting contractor shall be responsible for maintaining the plants to ensure optimum growing conditions until accepted by the Owner. Initial water depth in the wetlands shall be increased gradually from 0 inches to maximum depth in 2-inch increments over a period of two months following completion of planting. All planting shall be done in moist soil without standing water. Maintenance may include watering or dewatering of the wetlands cells to ensure optimum growing conditions.

**B. Inspection**

Sixty days after the completion of the planting, the Owner or Engineer will make an inspection to determine if satisfactory stands of cattail and bulrush, have been produced. A satisfactory stand is defined as one in which: (1) spacing between planted seedlings averages 3 feet or less; (2) the seedling survival averages at least 80 percent; and (3) no areas of greater than 100 contiguous square feet with a seedling survival rate of less than 50 percent. If satisfactory stands have not been established, another inspection will be made after the planting contractor has corrected any deficiencies and provided the Owner or Engineer with written notice that the stands are ready for inspection.

rodents or waterfowl, which can destroy the emergent plant community if left unchecked. In cold climates, grazing pressure in the winter and early spring is a significant operational concern during the plant establishment phase, and wetland designers should anticipate replanting and/or exclusion activities (Wallace *et al.*, 2001).

## 22.2 MONITORING

All wetland treatment systems should be monitored for at least inflow and outflow water quality, water levels, and indicators of biological condition. Following proper design and construction, monitoring is the next most important factor in successful operation of treatment wetlands. Monitoring information is essential to the ability to anticipate the need for operational changes and should be collected accurately and consistently, and frequently reviewed by a knowledgeable operator. Changing the character or function of the wetland ecosystem takes considerable time and operator investment. The appearance of the wetland is not necessarily representative of what it is doing for water quality, because many wetland functions do not tie strongly to the abovewater canopy. Consequently, it is water quality and quantity data that are the primary indicators of wetland operational status. There are few controls for Type *A* wetlands (the ones that are passively designed) but more for Type *B* systems (the ones with added controllable features). Water level control is possible for all types. Added possibilities may include flow control (fill and drain), recycle, bypass, added streams with supplemental constituents, and aeration, as discussed in Chapter 24. Alteration of the ecosystem is also possible for all types, but usually is a drastic step, to be avoided if possible. Dredging of sediments or soils, bed media replacement, new plantings, or removal of plants by mechanical or chemical means can all be accomplished but at considerable expenditure of time, money, and loss of treatment potential. In all cases, appropriate diagnostic information is a prerequisite to initiating maintenance or control steps.

### Water Quality

Continuous flow wetlands will require compliance monitoring of a specified list of chemical constituents and inflow rate, because most operate under some kind of discharge permit. The sampling locations can vary from project to project, and usually include some or all of the wetland inflow and outflow points. However, some projects may require internal monitoring points in the treatment wetland, and in some cases, monitoring of the receiving water body. The locations, types, and frequency of compliance sampling are spelled out in the individual permits, as are the averaging periods and limits for the various regulated constituents. Laboratory protocols for chemical analysis are also officially prescribed and include a variety of established methods, as defined in Standard Methods (APHA, 2005) or by U.S. EPA, for example.

However, the methods for acquiring wetland water samples are neither well defined nor standard. There is no apparent difficulty with obtaining samples at inlet and outlet structures, yet there can be serious anomalies related to sampling methodology. For instance, either autosamplers or grab sampling may be employed. The autosampler can be set to flow-proportion, and thus (hopefully) produce flow-weighted concentrations for use in mass balances. It is instructive to see what happens when both procedures are used over a long period of record (Figure 22.2). Not only do the sampling methods yield much different results, there is an apparent bias of the autosamplers to give higher results. Speculatively, the reason is that autosampler intake tubing may "suck mud" if the intake strays from its optimal position.

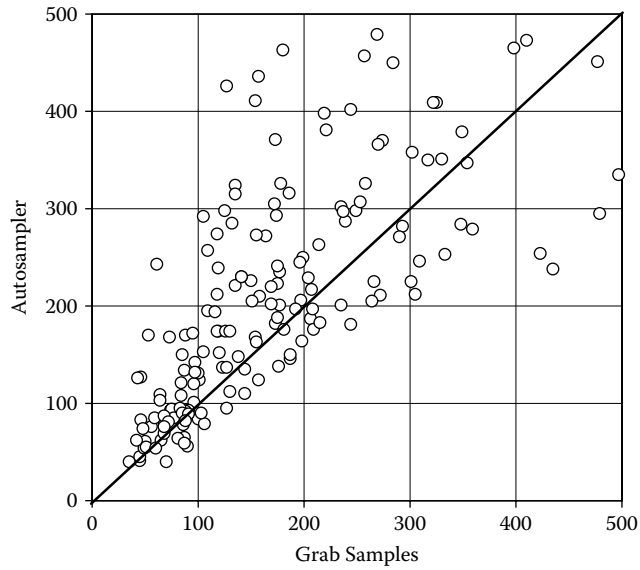

**FIGURE 22.2** Autosampler versus grab samples for total phosphorus for one of the inlet structures of STA2 of the Everglades Protection project. Data span eight years of operation. Note that the autosampler results are generally higher (mean = 223 μgP/L) than grab sample results (mean = 149 μgP/L).

Acquiring representative internal wetland water samples in a FWS environment is very difficult. Floating materials, such as *Lemna*, can often be excluded by careful sampling. Water depths may be quite shallow, and there can be large amounts of readily suspended materials in the vicinity (see Figure 7.9). The inclusion of particulates in a dipped sample will not be representative of the particulates that move with water in the undisturbed environment. The local velocities created by the sampling activity resuspend an abnormally high amount of total suspended solids (TSS). That solid material can bias the lab analyses for total amounts of contaminants such as total phosphorus or total Kjeldahl nitrogen (TKN). The intense vertical gradients in water quality near the wetland bottom can also create anomalous results. In very shallow water, the sample can contain some or all of pore water, which usually has much different (higher) concentrations from surface waters (see Figure 10.5, for example). All of these factors create a need to avoid disturbance in the act of sampling and to avoid very shallow depths that may involve pore water. In the various Everglades sampling

**FIGURE 22.3** Effluent grab sampling using a portable peristaltic pump at a HSSF wetland in Scandia, Minnesota. Considerable care must be taken with the sample tubing to obtain representative samples.

activities, depths less than 20 cm are not bottle-dip sampled for these reasons. However, carefully aspirated samples may be acquired at smaller depths.

Similar problems exist in sampling SSF wetlands, especially because dedicated sample ports must be used to extract *in situ* samples, which may or may not representative of the flow path. Figure 7.1 illustrates a typical sample port assembly for SSF wetland systems.

Peristaltic pumps are often a preferred sampling device for SSF systems, as shown in Figure 22.3. Considerable care must be taken in the placement of the sampler tubing to obtain a representative sample; poor tubing placement will disturb biofilms and/or suck sludge from the bottom of control structures or sample ports. Dedicated sample tubing that is permanently installed is often used at facilities where routine sampling is conducted.

### Sampling and Analyses in Support of Mass Balances

Compliance monitoring may not be enough to gain an understanding of wetland function, because it is focused upon measuring the variables that may affect the receiving waters, and is commonly restricted to outflows. A fuller understanding of wetland performance rests upon constituent mass balances, which in turn depend upon the water mass balance for the wetland.

### Water Flows

The water budget has been described in detail in Chapter 2. The principal inflow is usually the water to be treated, which is augmented by rainfall, evapotranspiration, and seepage before forming the wetland outflow. Rainfall records may be kept at the site or procured from a nearby weather station. Evapotranspiration may be derived from weather bureau pan evaporation or from governmental irrigation services, as discussed in Chapter 4. Therefore, the primary monitoring requirements are usually the wetland inflow rate and outflow rate. Both are required if there is significant seepage, so that the seepage may be estimated by difference.

Flow measurement can be accomplished using any one of several techniques. For pumped inflows, either pump-hours plus the pump-discharge curve may be used or a turbine meter can be installed. For small flows, a calibrated weir, possibly with continuously recording head, is a common choice (Figure 22.4). Most large inlet and outlet devices that operate with a measurable head loss can be calibrated to determine flow from headwater and tailwater elevations. For large inflows without a calibratable structure, devices such as Doppler flow meters or ultrasonic velocity meters have been employed. It is noteworthy that virtually every type of

**FIGURE 22.4** A V-notch weir, with recorded head, is a user-friendly method of measuring small inflows and outflows. Photo from the Duck Spring wetland system near Alcoa, Tennessee.

**FIGURE 22.5** This small HS flume is used in conjunction with an ultrasonic head to record influent flows for a HSSF wetland in Delft, Minnesota.

flow measurement relies upon clean conditions and periodic recalibration. Any of the measurements are prone to being somewhat in error with field accuracies on the order of ±15%. For any of the devices that include sensors and data logging, frequent manual cross-checks are recommended.

Low flows in small systems will be zero (no flow). This has several design implications. Most notably, there will be an insufficient flow to create scouring velocities in household plumbing and gravity sewer pipes. During intermittent flow, solids will "hop" down the pipe, moving only when the flow and depth exceed certain limits. Solid particles accumulate into dams, partially obstructing the invert of the pipe. When flow pulses occur, water accumulates behind the dam and pushes the solids along the pipe (Littlewood and Butler, 2003). This "sliding dam" mechanism of movement is the dominant form of solids transport in small treatment systems.

Conventional weirs or upflow-splitting devices are generally not used as primary flow control elements for small wetland systems unless the solid material has been removed in a primary treatment process. Due to the low flow, toilet paper and other solids will inevitably get caught on one of the overflow weirs because there is insufficient velocity to remove the material. All flow will go to the other outlet, until it, too, clogs with solid material. Flow will switch back and forth between the outlets in an unpredictable manner and create problems for the operations staff.

Accurate flow measurement for a small collection network is difficult to obtain for many reasons. Use of an overflow weir as the primary control element (combined with an ultrasonic head or other sensing device) can present an ongoing problem for maintenance personnel due to solids accumulation. Magnetic flow meters have a minimum flow velocity threshold of about 6 cm/s for accurate flow determination. For small-scale applications, this generally requires "necking down" the piping to 25 or 50 mm to get the necessary low-flow accuracy. This is generally not a viable option unless solids have been removed from the wastewater in a settling tank.

Small flumes, such as H or HS types (as shown in Figure 22.5), offer acceptable accuracy at low-flow rates (Grant and Dawson, 1997) but may not achieve scour velocity, leaving the flumes susceptible to solids accumulation. If a flume is used after a solids removal device (such as a settling tank), the velocity at low flow will allow the growth of a biofilm on the flume surface. For this reason, bubbler units are not recommended as a sensing device because biofilm growth will rapidly plug the air tube. Noncontact devices, such as ultrasonic heads, are recommended for use with flumes as shown in Figure 22.5. Tipping buckets offer very accurate low-flow measurements, but the corrosive atmosphere present in sewage systems precludes the use of mechanical counters. Also, tipping buckets can become "pinned" under high flows, so it is important to determine the suitability of the tipping bucket assembly at peak flow.

Due to the reasons cited in the preceding text, elapsed time meters are often used as a means of flow measurement on systems that receive a pumped influent, even though this may result in lower accuracy flow determinations.

In pumped systems, the flow will be stagnant (zero velocity) in pressure mains most of the time. To prevent freezing problems in cold climates, pressure mains must be installed below the frost line. If this is not possible, the pipe should be sloped to drain and provisions for a drainage outlet should be made at the pump end as well as at the discharge point.

In the long term, water storage changes in the wetland are almost always negligible in comparison to other flows. However, water depth is a very useful parameter for other purposes than the water budget, and hence water stage in each cell is a desirable data set. Staff gages should be installed in each cell of the wetland and surveyed for vertical control at the time of start-up (Figure 22.6). When combined with a topographic survey of the wetland, stage measurements provide a quantitative tool for assessing the average, maximum, and minimum water depths in the wetland and the frequency with which these depths occur. These data are essential for

**FIGURE 22.6** A staff gage provides valuable information on the water depth and volume in the wetland. Photo from the Lake Nebagamon, Wisconsin, treatment wetland system, in the exit deep zone. The screen box covers the intake for the effluent siphon.

interpreting tracer measurements of hydraulic residence time and for assessing any detrimental hydroperiod effects on biota. A variety of water level measuring instruments (e.g., analog chart recorders, ultrasonic, pressure-sensor, and capacitance-sensor units) are available for continuously recording water levels at various key points within the wetland.

### Constituent Concentrations

Table 22.2 summarizes an example of monitoring program in support of operation of a municipal wastewater-polishing wetland treatment system. This list includes measurements of the water quality of all major inflows and outflows associated with the treatment wetland. Inflows include the sources of pretreated wastewater entering the wetland as well as natural inflow streams that may have a significant effect on the water quality or the hydrologic budget of the natural wetland treatment system. As described in Table 22.2, the parameter list to be tested at all major inflows and outflows at least monthly includes all regulated pollutants and integrative measures such as $BOD_5$, TSS, pH, dissolved oxygen, water temperature, conductivity, $NO_2$-N + $NO_3$-N, ammonia, nitrogen, TKN, total phosphorus, chloride, and sulfate. The frequency of operational monitoring for system control is dictated by the size and capacity of the system, the sophistication of the owner's staff and sampling equipment, and site-specific factors related to influent quality variability and climatic factors.

Inflow and outflow stations may also be monitored less frequently for selected heavy metals or organics that might be present in the wastewater and for whole effluent acute and chronic toxicity. If water quality characteristics are highly variable for any of the inflow or outflow locations, or if there are weekly or monthly permit limits, sampling should be more frequent than monthly or quarterly.

These water quality data as well as water-budget parameters should be organized and recorded in computerized spreadsheets for visual analysis of variability and trends. The constituent loadings may be compared to design criteria to ascertain if the system is being operated according to design. The constituent mass balances are easily constructed from system data on such a spreadsheet and may be used to determine if design conditions are being achieved, and whether the system is performing as expected.

Table 22.2 reflects the example of municipal wastewater treatment, but constructed wetland systems are used for a wide

**TABLE 22.2**
**Example of Monitoring Requirements for Operation of a Large FWS Wetland Treatment System**

| Monitored Parameters | Sample Locations | Sampling Frequency |
|---|---|---|
| Flow | Inflows and outflows | Daily |
| Rainfall, pan evaporation, and air temperature | Adjacent to wetland | Daily |
| Water stage | Within wetland | Daily |
| **In the Field** | | |
| Water temperature, dissolved oxygen, pH, and electrical conductivity | Inflows and outflows | Weekly |
| Plant cover (dominant species) | Near inflow, near outflow | Annually |
| **In the Laboratory** | | |
| $BOD_5$, TSS, $Cl^-$, $SO_4^{2-}$, $NO_2$+$NO_3$–N, $NH_4$–N, TKN, TP, and pathogens | Inflows and outflows | Monthly |
| Metals, organics, and toxicity | Inflows and outflows | Quarterly |

*Note:* Some of these are needed for permit reasons, others for mass balancing.

variety of other purposes, including animal waste treatment, groundwater remediation, and urban and agricultural stormwater. Each of these applications generates a similar requirement for a strategy to promote understanding. All are based upon knowledge of the water budget, but the suite of chemicals of interest may change, depending upon the application.

### Biological Monitoring

Biological monitoring within a wetland treatment system provides information, concerning the structural integrity (health) of the vegetation and fauna. Protection of this biological integrity is important from an environmental habitat perspective and because of the biota's control of wetland operational performance. It has been suggested that every component of the wetland ecosystem should be monitored, including sediments, water, vegetation, benthic invertebrates, fish, amphibians, reptiles, birds, and mammals (Ecological Services Group, 1996; Wren *et al*., 1997). This concept originates from the fact that some of these ecological components have been routinely found to be above pristine background for some contaminants, as expected for a treatment system.

However, there have been no ecological disasters associated with the thousands of treatment wetlands over the thirty-plus years of the technology, and thus the question involves (possibly) impaired wetland ecology, not acute problems for wildlife. Therefore, biological studies fall in two categories: monitoring needed to foster the design water quality functions, and research needed to more fully define impacts of less-than-perfect water on various organisms that may inhabit the treatment wetland. There is usually an important distinction between constructed wetlands and natural wetlands as recipients of wastewater: the former are usually not subject to intensive biological monitoring but the latter may be in some states (e.g., Florida).

A compromise is typically put in place with some facet of biological monitoring or research being conducted in addition to the requisite compliance and mass balance monitoring. Typical categories are bird, mammal, and fish studies. Broad-scale potential for ecological problems is commonly assessed by examining or forecasting the concentrations of specific chemicals or toxins. For instance, great care is used in the arid regions of the United States because of the known acute effects of selenium that has impacted wildlife wetlands (e.g., Kesterson, California).

Wetlands designed for ancillary benefits can have nontreatment goals and requirements. Trends in use of the treatment wetlands by plant and wildlife species may indicate needed changes in system management to support those nontreatment goals. Surveys for rare or threatened species may also be conducted when appropriate.

### Monitoring Vegetation

Cover estimates and observations concerning plant health should be a routine part of operational monitoring in a constructed wetland treatment system. Because plants grow slowly and are important for maintaining the performance of wetland treatment systems used for water quality treatment, problems must be anticipated and prevented before they are serious or have progressed too far. Reestablishing a healthy plant community in a constructed wetland is a slow process when the plants have been harmed because of operator neglect.

Plant growth is monitored by estimating percent cover and average plant height. These nondestructive techniques are used to ascertain the status of plant development before and during wetland treatment system operation. Plant cover is an estimate of the percentage of the total ground area covered by stems and leaves. This parameter can be estimated by walking through or next to a plant stand and visually determining a cover category for the plants. Typically, seven cover categories are sufficient for this visual estimation method: (1) less than 1%, (2) 1–5%, (3) 6–10%, (4) 11–25%, (5) 26–50%, (6) 51–75%, and (7) 76–100%.

Cover estimates can be made on a finer scale by using a frame to delineate specific areas. Cover estimates should be made at enough locations in the constructed wetland to provide reasonable statistical averages for comparison between cells and between dates.

Ground-level photography may be used to provide archival information about vegetation. Photos at identified specific locations give a visual time series of potential succession in the system. For instance, a rodent eatout may be documented (see Figure 19.6 for example).

Aerial photography is an excellent supporting tool that can provide estimates of the type and percent cover of vegetative communities in treatment wetlands. Figure 22.7 illustrates the vegetative patterns for one of the constructed treatment wetlands at the Des Plaines River site near Wadsworth, Illinois. The various areas of different vegetation are clearly visible, but ground-truthing is required to establish which plants are growing in the zones.

## 22.3 WATER LEVEL AND FLOW MANAGEMENT

There are not many controls on the operation of a treatment wetland, especially Type *A* systems that mimic passive, natural wetlands. Water depth and water flow rate are the two principal controllable features.

### Flow Management

For many continuous flow FWS treatment wetlands, there is not a choice of the amount of water that reaches the wetland on a daily basis. However, there are choices for some stormwater systems and for lagoon-wetland combinations. For larger continuous flow systems, there are multiple flow paths and hence decisions on how much water to allocate to these parallel paths. Any system may incorporate recycle, which will be under the control of the operator.

### Flow Balancing

In the case of multiple parallel paths, the operator has the choice of how much of the incoming flow to apportion to each flow path. Often, the adjustment of the proportion is

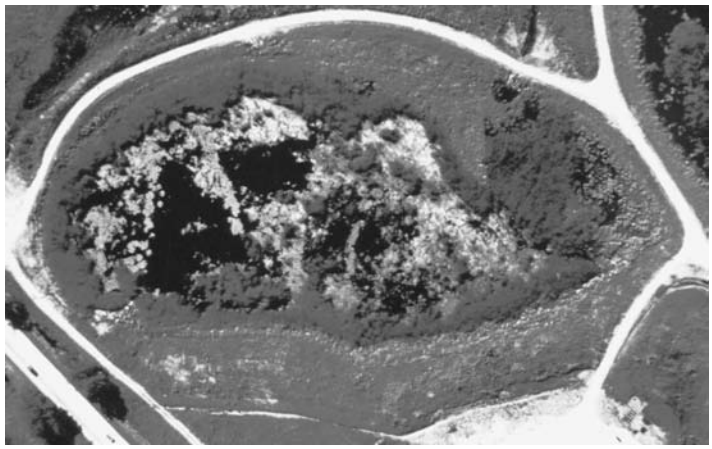

**FIGURE 22.7 (A color version of this figure follows page 550)** Wetland EW3 at the Des Plaines River site near Wadsworth, Illinois. The fringe zone is vegetated by cattails and bulrushes, whereas the interior has submerged aquatic vegetation and floating-leaved plants. Open water shows as the dark areas on this false color infra-red photo.

not physically easy but rather involves opening and closing of multiple valves or structures. The performance of each flow path depends upon the amount of water it receives, with the optimum occurring when the hydraulic loadings to the various flow paths are equal, so that no one flow path is underworked or overworked. It is informative to examine the sensitivity of the over all system performance to the flow split or potential imbalanced loading. To do so, consider a hypothetical example of a system with two flow paths of equal area in parallel, both of which perform according to the *P-k-C** model.

For the conditions indicated in Figure 22.8, if the equal fractions of the flow are sent to each of the two paths, the inlet concentration is reduced by about 80%, from 100 to 19.3 mg/L. As more water is diverted to path 2, its performance starts to decline, until the extreme when all the water goes to path 2, doubling its hydraulic loading compared to design. At that extreme, the outlet concentration is about double the design value at 39.3 mg/L (about 60% reduction). Of course, path 1 becomes underloaded, and its performance increases. The combined outflow from the system shows that imbalance as well. But interestingly, a modest amount of imbalance is not particularly harmful. For the hypothetical example, a 60–40 split is forecasted to raise the outlet concentration to 20.1 mg/L, about 5% higher than design.

The extreme of shutting down one flow path may be necessitated by a need for unusual maintenance activities. For instance, flow paths in STA1W of the Everglades protection project have suffered hurricane damage, requiring shut down of a parallel path for vegetation reestablishment. To the extent that such events may be anticipated, allowance can be made in design. Water may be diverted elsewhere for

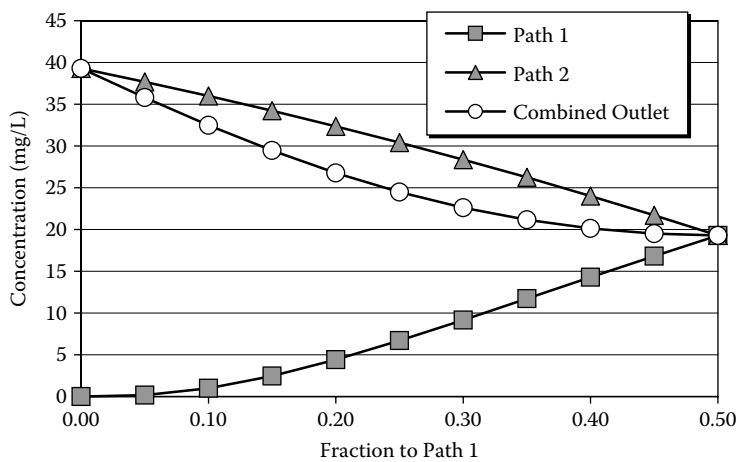

**FIGURE 22.8** A hypothetical example of flow imbalance between two parallel paths in a treatment wetland, for the conditions shown in the corresponding table. Path 1 is overloaded at the expense of Path 2.

| | |
|---|---|
| Total Flow $Q$ = 5,000 $m^3/d$ | $C_i$ = 100 mg/L |
| Path 1 Area = 100,000 $m^2$ | $C^*$ = 0 mg/L |
| Path 2 Area = 100,000 $m^2$ | $k$ = 20 m/yr |
| Wetland Area = 200,000 $m^2$ | $P$ = 3 TIS |

treatment if such alternatives exist, or extra area and paths may be included in anticipation of path shutdowns.

### Systems with Storage

Flow management is an important part of those systems that involve seasonal or event storage because the stored water may be discharged according to any of several schedules (see Chapter 17). In all of these systems, the overriding goal is to bleed down the stored water in a timely fashion to make room for the next event or for the next storage season.

In small-scale systems with winter storage, cost considerations will usually lead to storage that does not much exceed the volume of inflow over the cold season. In spring, the operator is faced with selecting the program of withdrawals from storage to be sent to the treatment wetland. Such withdrawals may be limited by pump capacities, which would also be constrained by cost considerations, or if gravity discharge is possible, the withdrawal rates may be much less constrained. For instance, the Houghton Lake, Michigan, system has a wetland discharge season extending from May 1 to October 15 (170 days), but the transfer pump is capable of transferring the water over about 100 days. Therefore, the operator has discretion over which days there is inflow to the wetland, just so long as the storage is at its minimum level at the end of the wetland-operating season. Strategies ranging from paced uniform discharge to fast emptying followed by minimum pond level maintenance have been used (see Chapter 17).

The discharge of municipal wastewater treatment lagoons is in some circumstances constrained by the ability of receiving waters to maintain acceptable water quality. Such cases occur when the volume of the discharge is significant compared to a receiving stream flow. In that situation, the stream may become dominated by the effluent, especially at times of low recipient flow. It may then be desirable to vary the discharge of treated effluent to avoid unacceptable water quality in the combined flow downstream of the discharge. The ability to vary discharges is in turn conditioned on the ability to store water during periods of low acceptable discharge. The flows in the recipient dictate the magnitude of allowable discharge, and hence this strategy is termed *hydrograph controlled release* (HCR; Kadlec and Pries, 2004).

Stormwater systems may be preceded by flow-equalization reservoirs to prevent the low degree of treatment that accompanies large event flows. Examples of this are currently under design and construction in South Florida, where vast (5–10,000 ha) reservoirs will collect stormwater runoff before passing it through the comparably vast stormwater treatment areas (constructed wetlands), many of which are already built. These are likely to be HCR systems, serving the water-quantity needs of the downstream-receiving systems, which are the Florida Everglades. Operating protocols are currently under development.

### Bypassing

It is often not feasible, for hydraulic reasons, to treat large event flows in stormwater wetlands. If the hydraulics allow, treating all the water would generally result in the greater load removal, but will pass higher concentrations to receiving waters for the large events. Hydraulic integrity often requires that extreme flows be avoided or else damage to the wetland may result. Therefore, the design of such systems typically allows for bypass. However, this is usually accomplished by the design of control structures rather than by any overt operator action. Exceptions are the STAs of South Florida, most of which have operator-controlled bypass structures.

### Depth Management

It has been shown that depth is not a crucial factor in the areal removal rates of many wastewater parameters (see Chapters 9 and 10, for example). The extra detention time of deeper water does not foster a higher removal, and in many cases, shallower water shows better removals. It is much more important to manage water depth for the health and vigor of the plant community, which is typically sensitive to water depth.

#### Depth Controllability

In very large FWS wetlands, the hydraulic resistance of the vegetation creates a dilemma for operations. The water depth is not controllable by changes in outlet structure settings, except for a small region near the outlet (see Chapters 2 and 18). Over most of the system, the water flow rate and the vegetation resistance will control the water depth. Therefore, it is important to distinguish between wetlands that can have depth control via outlet structures and those that cannot. In the latter case, depth control is unavoidably linked to flow control and vegetation management, and not to any modification of structure settings.

As an illustration, consider the two hypothetical FWS wetlands for which different level scenarios are calculated in Figures 22.9 and 22.10. Both have the same hydraulic-loading rate of 5 cm/d, and both are presumed to have the same (high) vegetation resistance to flow. First consider a modest size 1-ha wetland with $L{:}W = 4$. If operation is at an exit weir setting of 0.5 m, then there is essentially a zero gradient in the water surface (level pool). If the exit weir is then lowered to 0.15 m, the water level goes down everywhere, with only a few centimeters of head loss forecast (Figure 22.9; 18.9 cm down to 15.0 cm). The average depth is lowered to 17.1 cm. Next consider the long, narrow wetland with $L{:}W = 25$. When the outlet weir elevation is 0.5 m, the inlet elevation is 3.9 cm higher and the mean depth is 0.52 m. For this system, when the outlet elevation is lowered to 0.15 m, there is not a drawdown of the entire wetland (Figure 22.10). The inlet depth drops only to 0.48 m, and the mean depth is reduced only to 36.5 cm. For the specified flow, the vegetation is holding back the water and lowering the outlet level cannot change that.

Design should be such that water depth control is at the outlet structure or else the operator has no option for depth control except to lower the flow rate. For HSSF wetlands, the hydraulic profile will be governed by both Darcy's Law and the outlet weir setting. Again, outlet control is the preferred method of regulating the water level (see Figure 21.11). This will require a conservative bed design with a high hydraulic conductivity.

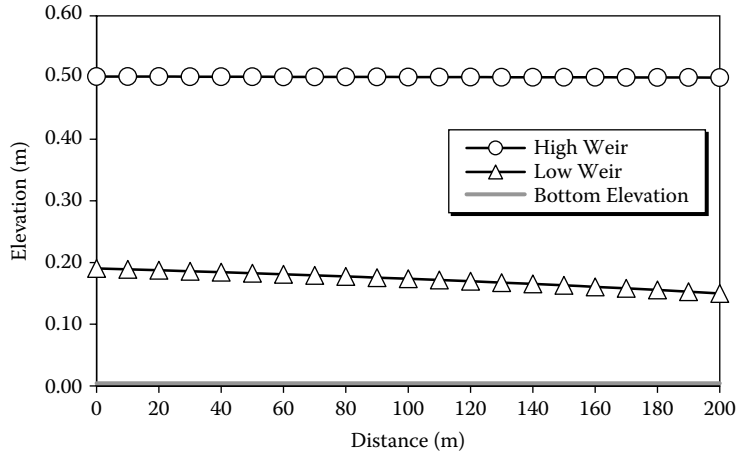

**FIGURE 22.9** Effect of lowering the outlet weir setting on the water depth in a small, moderate aspect ratio wetland.

| $Q$ = 500 m$^3$/d | $Q$ = 0.006 m$^3$/s | |
| $q$ = 0.050 m/d | HLR = 5.00 cm/d | High Weir Inlet Depth = 0.500 m |
| $a$ = 1.00E +07 m$^{(1-b)}$/d | $\Delta x$ = 10 m | High Weir Outlet Depth = 0.500 m |
| $b+1$ = 3 | $\Delta hB$ = –0.002 m | Low Weir Inlet Depth = 0.189 m |
| $c$ = 1 | d$B$/d$x$ = 0.000010 m/m | Low Weir Outlet Depth = 0.150 m |

## Water Depth, Plants, and Nutrient Loadings

Water depth is an important variable in the survival of wetland vegetation. In mitigation and habitat wetlands, it is coupled with a hydropattern to provide the desired growth conditions for any particular species. The depth that may be tolerated for continuous inundation is less than that which can be withstood for brief periods of time (Table 22.3). Some of the more robust plants, such as *Typha*, can withstand prolong periods of drought, lasting many months, and can temporarily be completely submerged. At continuous flooding water depths of 1 m or more, emergent plants in treatment wetlands can no longer survive.

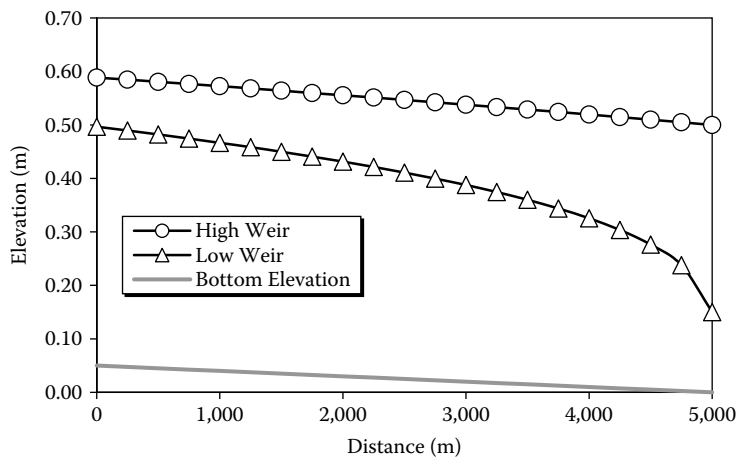

**FIGURE 22.10** Effect of lowering the outlet weir setting on the water depth in a large, high-aspect ratio wetland.

| | | |
|---|---|---|
| $L$ = 5,000 m | $A$ = 1,000,000 m$^2$ | |
| $W$ = 200 m | Aspect = 25.0 | |
| $Q$ = 5,000 m$^3$/d | $Q$ = 0.058 m$^3$/s | |
| $q$ = 0.005 m/d | HLR = 0.50 cm/d | High Weir Inlet Depth = 0.539 m |
| $a$ = 1.00E +07 m$^{(1-b)}$/d | $\Delta x$ = 250 m | High Weir Outlet Depth = 0.500 m |
| $b+1$ = 3 | $\Delta hB$ = –0.050 m | Low Weir Inlet Depth = 0.447 m |
| $c$ = 1 | d$B$/d$x$ = 0.000010 m/m | Low Weir Outlet Depth = 0.150 m |

**TABLE 22.3**
**Water Depths for Common Treatment Wetland Plants**

| Common Name | Scientific Name | Best Depth (cm) | Flood Depth (cm) |
|---|---|---|---|
| Bulrush | *Scirpus californicus* | 30–60 | 120 |
| Soft-stem bulrush | *Scirpus validus* | 15–30 | 60 |
| Broadleaf cattail | *Typha latifolia* | 30 | 60 |
| Narrowleaf cattail | *Typha angustifolia* | 30 | 60 |
| Common reed | *Phragmites australis* | 30–60 | 90 |
| Arrowhead | *Sagittaria* spp. | 3–8 | 30 |
| Yellow flag | *Iris pseudacorus* | 3–8 | 45 |
| Pickerel weed | *Pontederia cordata* | 8–15 | 30 |
| Soft rush | *Juncus effusus* | 8–15 | 25 |
| Woolgrass | *Scirpus cyperinus* | 3–15 | 30 |

*Source:* Adapted from Pineywoods RC&D (2001) *Constructed Wetlands in East Texas* (4 volumes). Pineywoods Resource Conservation and Development Council, Nagodoches, Texas.

For SSF wetlands, the situation is different because there is an unsaturated region within the wetland bed. For HSSF wetlands, this unsaturated region is a result of the water level control regime and the desire to keep flows within the wetland bed. If insulating materials such as mulch are used, this will increase the thickness of the unsaturated rooting zone. In VF wetlands, unsaturated conditions will occur throughout the wetland bed on a periodic basis due to pulse-feeding and the load-and-rest operating regimes typically used in these systems.

The net result of such unsaturated conditions is to shift the competitive advantage away from plants that require submerged root zones. SSF wetlands are more likely to be dominated by plants that enjoy wet but not submerged root zones. Plants in the genera of *Phragmites*, *Schoenoplectus*, and *Phalaris* are commonly used in such systems (Vymazal *et al*., 1998; Wallace and Knight, 2006; Stein *et al*., 2006a).

There are many sources of recommendations for water depths and associated hydroperiods for the common wetland plants (for example, Hotchkiss, 1972; Niering, 1985; Dressler *et al*., 1987; Boon and Groe, 1990; Thurnhorst, 1993; Eggers and Reed, 1997; Pineywoods RC&D, 2001; Shaw and Schmidt, 2003). Hydrologic tolerances of wetland plants are further discussed in Chapter 3. The treatment wetland operator should understand the allowable depth and hydroperiod ranges for the plants at a particular site.

As noted in Chapter 3, floating mats are prone to form under excess depth conditions in FWS wetlands. For instance, if a good growth of cattails (*Typha* spp.) develops under shallow water conditions, it will likely have a shallow, interlocked rhizosphere. This root mat has an inherent buoyancy created by various gas-generating processes (such as methanogenesis). If water depths are then raised, the entire mat may tear loose from the rooting media and form a floating mat. If the mat covers the entire wetland cell, then it can function effectively in treatment. But if floating islands develop, they are subject to wind-driven motion and severe disruption of the wetland. This happened in Cell 2 of the Everglades Nutrient Removal Project (ENRP), with disastrous impairment of treatment. Removal of the plants was necessary.

### Seasonal Depth Adjustments

Although shallow water fosters plant growth and is effective in promoting treatment in FWS wetlands, it can be problematic in winter due to ice formation. In densely vegetated wetlands, the plant stems hold the ice layer in place. If water levels subsequently drop, the ice layer generally drops with it, although an air gap can form under the ice at some localities within the wetland if the ice sheet is held up by plant stems. However, this anchoring of the ice layer can create severe damage if water levels are subsequently raised. The ice layer floats and tears out embedded vegetation as it moves upward. If the ice layer becomes thick enough, under-ice flow is impeded, which can lead to over-ice flow (Kadlec, 1987). Water flows upward through holes or cracks, emerges, and flows downgradient over the ice and under the snow. For example, this mode of flow is experienced each winter at the Frank Lake, Alberta, treatment wetland.

It is possible to provide more space for flow under the ice by raising water levels prior to ice formation. However, care must be taken that such increased water depths do not entirely submerge the plants, because the oxygen transfer necessary for their survival is primarily obtained via the standing dead stalks and their airways (see Chapter 5). Indeed, an effective method of destroying cattails is to cut them and overflood the stubble. This procedure of water level increase was used effectively at the Listowel, Ontario, FWS wetlands (Herskowitz, 1986) and is currently employed at the Brighton, Ontario, wetland.

For HSSF wetlands, there is a treatment penalty with deeper beds (see, for example, Table 8.13). If shallower beds (0.3 m) are selected, there is the potential that some bed volume will be lost due to ice formation in the winter. For very cold situations, mulch insulation of the SSF wetland may be required, as discussed in Chapter 4.

## 22.4 CONTROL OF NUISANCE ANIMALS

Experience has shown that a large variety of creatures may interfere, in some way, with the desired operational conditions treatment wetlands. The list of animals that have caused some degree of concern includes deer, elk, cattle, wild hogs, gophers, monkeys, coyotes, feral cats, manatees, and turtles. However, most problematic are some birds, rodents, some fish, and mosquitoes.

### Birds

Blackbirds are attracted to treatment wetlands, both as a breeding location and as a place of refuge. Redwing blackbirds (*Agelaius phoeniceus*) love to nest in cattails and do so in great numbers in treatment wetlands of temperate North America. Yellowheaded blackbirds (*Xanthocephalus*

**FIGURE 22.11** Waterfowl at the Commerce Township, Michigan, municipal wastewater-polishing wetland.

*xanthocephalus*) also nest and find nighttime refuge in treatment wetlands (see Figure 19.5). Although their large numbers may contribute to pathogens in the wetland, no management techniques are typically used for blackbirds.

Waterfowl may be more problematic because of their large size and numbers during migration. Canada geese (*Branta canadensis*), ducks, and other waterfowl are known to cause significant depredation through grazing and uprooting of plant materials in FWS wetlands. There are a number of threatened and endangered birds that make use of wetlands in general and may be attracted to treatment wetlands. According to federal regulations in the United States, their presence requires that the area in question be managed on their behalf.

Wetlands in an urban setting are very attractive to geese, which congregate in large numbers at such isolated pockets of habitat. Even if their grazing does not seriously harm the wetland vegetation, they can deposit large quantities of fecal matter on walking paths and grassy margins of the wetlands (Figure 22.11). It is herbivory that can cause considerable grief for operators, especially during the vegetation establishment phase (see Figure 18.37). Young plants and tubers are preferred food for geese, swans, and some ducks. If the wetland planting happens to coincide with either the spring or autumn migration, the wetland can be essentially denuded in a day or two.

Under the Endangered Species Act, the U.S. Fish and Wildlife Service (USFWS) is mandated to identify and list plant and animal species that are threatened or endangered by extinction, or that are considered likely to be threatened in the future. Threatened and endangered species cannot be harmed, killed, or otherwise negatively affected by human activities. The USFWS reviews potential impacts to federally listed species and can veto a discharge permit by issuing a "jeopardy" opinion. The potential for occurrence of threatened or endangered species inhabiting a project site should be considered during project planning.

Experience indicates that the presence of federally protected species does not always necessitate substantial changes to wetland treatment project siting, design, or operation. In a number of cases, the discharge of treated wastewater effluents to constructed wetlands has enhanced the population of threatened or endangered wetland-dependent species by creating additional habitat and food resources. For example, populations of bald eagles (*Haliaeetus leucocephalus*), wood storks (*Mycteria americana*), and snail kites (*Rostrhamus sociabilis*), all federally protected bird species, have increased in and around the 485-ha Orlando Easterly constructed wetland treatment system in Florida. Conversely, the presence of protected species may require modifications of operations. For instance, the STAs of South Florida are attractive to burrowing owls and stilts, which nest in or on the levees. Therefore, flooding depths that endanger their nests are precluded. The treatment wetland operator should be aware that operations may have to be modified if threatened or endangered species begin using the wetland.

### Fish

Fish may be problematic in treatment wetlands, particularly those which feed or nest on the bottom. For instance, at the Des Plaines constructed wetlands in Illinois, carp (*Cyprinus carpio*) were unintentionally introduced into the wetland from the pumped source water (Des Plaines River), presumably as very small individuals. Over the course of two years, the fish grew in size to about 15 cm. These larger fish were observed to stir bottom sediments and impair suspended solids removal. TSS in the wetland outflow was at about 15–20 mg/L with fish present and was reduced to less than 10 mg/L after they were removed (Figure 22.12). The carp were removed from the wetland through a winter drawdown and freeze (Figure 22.13).

A similar phenomenon occurred at the Tarrant County constructed wetlands in Texas, where floodwaters from the source river brought carp (*Cyprinus carpio*), shad (*Dorosoma cepedianum*), and bullheads (*Ictalurus* spp.) into the system. The activity of the fish caused severe bioturbation of the sediments during feeding and spawning activities (APAI, 1994).

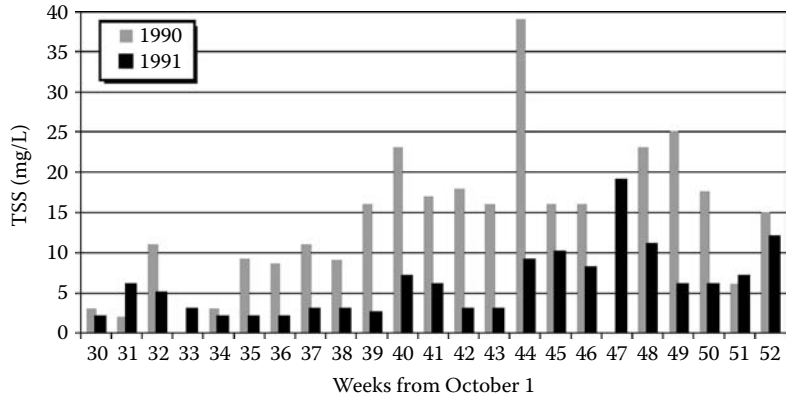

**FIGURE 22.12** Effect of carp on the TSS level in the Des Plaines, Illinois, treatment wetland. Carp were present in 1990 but had been removed in 1991.

The cells were dewatered, and egrets and herons effectively removed the stranded fish.

## Rodents

There are over 2,000 species in the order Rodentia, but it is primarily the water-loving types that are of concern in treatment wetlands. For HSSF wetlands, minor problems are often incurred by small burrowing rodents; in VF systems, such activities can cause a disruption of the filtering sand layer, leading to a loss of treatment efficiency (Weedon, 2002). There are design techniques that can help in controlling muskrats, nutria, and beavers in FWS treatment wetlands, but often these are not completely successful, and the operator should be prepared to exercise appropriate control measures.

**FIGURE 22.13** A drawdown followed by a freeze killed the carp in the Des Plaines, Illinois, treatment wetland.

### Muskrats (*Ondatra zibethicus*)

Muskrat grazing can change FWS treatment wetland areas from a densely vegetated environment to a patchwork of open and emergent areas. Cattails are particularly susceptible to damage due to herbivory and mound building. Additionally, muskrats create open water travel paths, connecting open water areas such as deep zones. These channels are hydraulic short-circuits, which impair the effectiveness of treatment (Figure 22.14).

Muskrat invasions of treatment wetlands are sometimes quite impressive in terms of numbers. Knowlton *et al.* (2002) note that muskrats have been problematic at the 37-ha Columbia, Missouri, project with removal of over 1,300 muskrats in 2.5 years.

Destruction of the wetland vegetative infrastructure may create an attendant loss of some water quality functions but may not harm others (Kadlec *et al.*, 2007). Some wetland functions may not be significantly impacted or even improved. Wetland operators at some sites, such as Brighton, Ontario, have reported that the water quality as it relates to permit limits has been relatively unaffected by herbivory. At the Olentangy, Ohio, site, reductions in oxidized nitrogen continued, with slight improvement, after the eatout. At Nanticoke, Ontario, the wetland continued to meet the effluent objectives with the exception of *E. coli*, after a muskrat eatout. Possibly, waterfowl and muskrat activity produced an abundance of fecal material around the entire perimeter of the wetland and within the wetland. Therefore, it is prudent to examine water quality performance before embarking upon an expensive set of control measures because of muskrat activity.

Muskrat control is given scant attention in existing treatment literature. Kadlec and Knight (1996) provide no information on potential muskrat problems or on the means to eliminate such difficulties. U.S. EPA (2000a) provides brief

**FIGURE 22.14** Muskrat travel channel, connecting two deep zones in the Hillsdale, Michigan, treatment wetland.

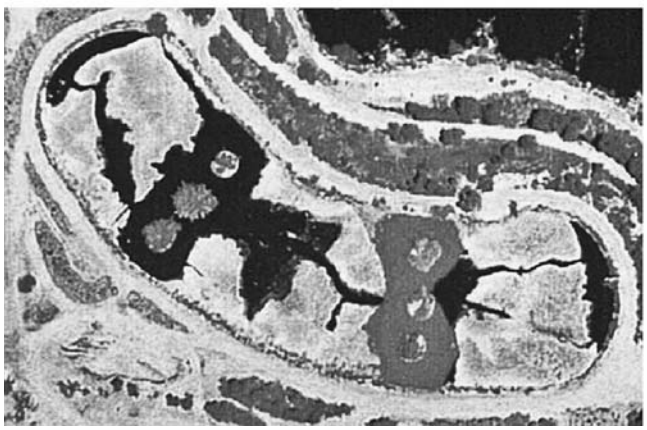
advice on the use of hazing and exclusion to protect wildlife from adverse conditions in the wetland and goes on to note that the excessive use of wetlands by wildlife may also cause problems. Controls include trapping, shooting, poisoning, hazing, and exclusion to protect the wetland from excessive vegetation destruction by these rodents (Kadlec *et al*., 2007).

Mink, the primary muskrat predator, is ubiquitous across the range of muskrats. These small animals can and will enter treatment wetlands in search of prey and are not deterred by chain-link fencing. Another option is the use of predator urines to scare off muskrats. When muskrats smell the urine of a predator they will typically avoid the area. Predator urine is commercially available from several sources, and for muskrat deterrent, bobcat urine is recommended. The efficacy of such scent deterrents is not known.

Trapping is an effective method of control and includes live, leg-hold, and colony traps. Live trapping involves the capture of live muskrats, which can be released outside of the treatment wetland environment. Lethal foothold traps capture muskrats around their feet and, typically, the animals are killed after capture to harvest their pelts. Such traps are nonspecific, and a drawback is that they also capture muskrat predators, especially mink. Colony traps can capture multiple muskrats at once and can be used as lethal or nonlethal devices. For muskrat captures, a colony trap is commonly placed underwater to quickly drown muskrats that enter it. Shooting muskrats is another control option. Concentrated efforts should be made at dusk or in the early morning hours for effective control. It is more selective than other methods as it ensures that only target animals are killed. Commercial, licensed hunting can be very expensive; one quotation was $100/h plus $25 per animal ($USD). Additionally, it may be difficult to control large muskrat populations with this method alone. Before this approach is used, local firearms regulations and permitting must be reviewed and abided by.

### Beavers (*Castor canadensis*)

There are two species of beavers: *Castor canadensis* in North America, with recent introduction in southern South America, and *Castor fiber* in Europe and Asia (Müller-Schwarze and Sun, 2003). In North America, beaver is a very destructive wildlife species, causing millions of dollars in damage to roads, dikes, and dams. Beaver damage management is, therefore, of great concern throughout the United States, with many agencies cooperating to minimize damage (U.S. Department of Agriculture, 2000). Many experts believe that the cost of beaver damage is greater than that caused by any other wildlife species in the United States. (U.S. Department of Agriculture, 2004). Their range is from the Gulf of Mexico to the Canadian subarctic, and northern Europe, Scandinavia, and the former Soviet Union. In the absence of habitat constraints or excessive mortality, populations grow rapidly with a typical pair producing three or four kits per year (Long, 2000).



#### *Structure Clogging*

Beavers have several activities that can cause difficulties for treatment wetland operations. The first, and far more serious, is their proclivity for damming sources of running water. This leads to the plugging of treatment wetland structures (see Figure 19.7). At a small wetland site, it is common for the animals to completely clog a structure in one night. Beavers are resourceful in finding and using local materials for damming and clogging structures. Mud, sticks, and small logs are commonly used, but they will also use stones up to several kilograms in weight. Vegetation research quadrat stakes and research sediment traps are also considered as useable dam materials, based on observations from the Des Plaines River wetland site in northern Illinois.

Because of a long history of interactions between beavers and man-made water structures, principally culverts, there has been a great deal of consideration given to methods of

(a)

(b)

**FIGURE 22.15** Beaver travel channel at the Tres Rios Hayfield treatment wetland near Phoenix, Arizona. This short-circuit became evident during this water drawdown event (a). The bottom panel shows that such channels connect the two interior deep zones (each with three islands), and the inlet and outlet deep zones (b).

prevention. There is a long list of patented devices designed to prevent beavers from damming culverts (Goedderz, 1987; Lambert, 1987; Carroll, 1991; Thurber, 1991; Fleury, 2002). These are typically grills, grates, and small mesh devices often installed to protect the upstream openings of culverts; however, they usually require frequent cleaning because they are easily dammed by beavers. Two of the lower maintenance alternatives are the "beaver deceiver" and the "beaver baffler" (U.S. Army Corps of Engineers, 2001).

A beaver deceiver is a fence that discourages damming due to its unnatural shape and large perimeter. Deceivers are usually trapezoidal but may be pentagonal or form long rectangles at narrow flowages. Fences are constructed of braced cedar posts and 6-gauge, wide mesh fencing. A beaver baffler is a cylindrical flow device constructed from multiple layers of wide mesh wire. This system excludes beavers from a culvert opening or dam breach while allowing free flow of water. The likelihood of beaver clogging is reduced by spreading the water intake over a large area. A baffler consists of two 5-m long, concentric cylinders of concrete reinforcing wire, including an inner cylinder that fits inside the culvert and an outer cylinder that is 30 cm larger in diameter.

### *Channelization*

Because beavers are primarily aquatic animals that are adept swimmers and capable of long periods of underwater activity, they prefer to travel in water. This affords protection from predators. Travel canals are often constructed so that the animals can proceed under water. This can pose a problem in treatment wetlands, particularly those with deep zones. Beavers may construct travel channels to move from one deep zone to another, thus constructing short-circuits (Figure 22.15).

### *Herbivory*

Beavers are herbivorous but can utilize an extremely varied diet. Various parts of trees are the preferred food at times of the year, including the inner bark (cambium) and roots, shoots, leaves, and buds. Favorites are poplars and aspen, willows, birches, and alder. However, they will also make use of water plants including reeds, rushes, and sedges (Long, 2000). Many treatment wetlands are built with a view toward integrating the system into the surrounding landscape by surrounding the system with appropriately sized clumps or bands of terrestrial vegetation. Trees are often an important component of these auxiliary plantings, which strive for habitat diversity. The combination of a wetland, particularly one with deep zones, and an adjacent tree plantation succeeds in providing ideal habitat for beavers. Once established, the animals go about their lifestyle, which includes felling trees, usually within a few tens of meters of the water. North American beavers prefer the genus *Populus* and will cut numerous trees in a hybrid poplar plantation (Figure 22.16).

### *Burrowing*

Beavers utilize both constructed lodges and bank dens as refugia and a wintering domicile in which to raise a family. The banks along lakes and streams are places for dens, which relieves the animals of the effort necessary to build elaborate in-water lodges (Müller-Schwarze and Sun, 2003). Less than half of Eurasian beavers build lodges, but slightly more than half of North American animals do so. The berms and levees of treatment wetlands apparently qualify as acceptable burrowing sites. The animals are not small (their weight ranges upward to 25 kg), and bank burrows are, therefore, not small either. Considerable amounts of wetland water leakage or transfer may occur as a result of such burrows. More seriously, the integrity of a containment levee may be compromised, ultimately resulting in failure (Figure 22.17).

### *Control*

A treatment wetland operator should be prepared to deal with beaver problems, despite proper preventative efforts of design and construction. There are various ways to manage beavers, so population goals can be met. In some circumstances, treatment wetland owners who have minor damage problems, such as a beaver chewing trees, may elect to do

**FIGURE 22.16** A hybrid poplar plantation adjacent to the Roblin, Manitoba, treatment wetland proved to be a favorite food source for beavers. Note that trees in the foreground have been clipped, but most enjoy some regrowth.

nothing. It is typically legal to shoot or trap beaver causing damage or a nuisance on a property, and trapping is effective. For example, in the state of Wisconsin, the annual harvest is on the order of 40,000. An average pelt price is about $20 USD, and therefore commercial trapping may be an option (Wisconsin Department of Natural Resources, 2005). In most cases, live-trapping and relocating beaver is not a good idea. Relocation may be less humane than killing beaver if they do not have time to store food or build a dam before winter or if the new location's habitat cannot support them.

Heavy wire mesh, heavy gauge hardware cloth, or tar paper will discourage beaver from cutting and gnawing trees along berms and in adjacent terrestrial plantings. About 1 m of height is wrapped. Mesh size should be less than 2 cm to be effective. Area fencing may also be used. Getting rid of attractive food items may discourage them from settling. As noted earlier, beaver prefer trees like poplar, willow, birch, and alders. Planting spruce and balsam trees are good alternatives to discourage beaver settling. Removal of the beaver dam, the lodge, and the beaver is generally the last option because of the difficulty and expense involved and because new beaver may recolonize.

### Nutria (*Myocastor coypus*)

Nutria is a nonnative species in North America. They are South American rodents that were introduced in North America in 1899 by California fur ranchers, but there are now feral populations in 22 states across the United States. Introduction of a few animals in Louisiana in 1938 led to a population of 20 million animals by the 1950s (Bounds, 2000). They were also introduced into Britain, where they caused serious damage to crops, drainage systems (through

**FIGURE 22.17** Beaver excavation on the containment berm of the Tres Rios Hayfield treatment wetland near Phoenix, Arizona.

burrowing), and native plant communities in East Anglian wetlands (Gosling *et al*., 1988).

Nutria are water-loving rodents, intermediate in size between muskrats and beavers, with a typical maximum body weight of 8 kg. They eat about 25% of their body weight each day. They consume the basal portions of plants, including roots, rhizomes, and tubers, and typically excavate the entire plant leaving little chance for regrowth. A vegetated marsh is converted into an open water. In Maryland, their diet (unfortunately for treatment wetlands) includes bulrushes (*Scirpus* spp.), spikerushes (*Eleocharis* spp.), cattails (*Typha* spp.), pickerel weed (*Pontederia* spp.), and arrowhead (*Sagittaria* spp.) (Bounds, 2000). Also, burrowing activities can damage dikes, levees, and other water control structures. Nutria can also outcompete and displace native muskrat populations (May, 2004).

As noted in Chapter 19, the Victoria, Texas, wetlands suffered significantly because of herbivory by the nutria, necessitating hunting and trapping. A contract trapper was employed at the Mt. Angel treatment wetland in Oregon. The treatment wetlands at Halsey, Oregon, also encountered nutria eatouts. Treatment wetlands in the southern tier of states, plus the east and west coastal states, could potentially encounter nutria problems, and operators should be prepared to implement control measures as necessary.

### Insects

The wetland environment offers a wide variety of niches for various insects. Aquatic insects comprise a diverse assemblage of 11 orders in freshwater systems and fill a wide spectrum of ecological niches, especially in FWS wetlands. Common are the nymphal and/or adult stages of the *Odonata* (dragonflies and damselflies), *Hemiptera* (true bugs such as back swimmers, creeping water bugs, and water scorpions), *Coleoptera* (aquatic beetles), and *Diptera* (mosquitoes, horse flies, deer flies, and midges).

Some stages of certain insects can cause extensive herbivory in treatment wetlands (Snoddy *et al*., 1989; Wallace *et al*., 2001). However, it is often observed that performance is not materially affected by such insect destruction, and a robust wetland ecosystem can recover quickly from these temporary events. Therefore, insect herbivory can generally be tolerated with no maintenance activity, despite the outward appearance of a vegetative disaster. It should be recalled that many of the treatment functions do not rely upon the green parts of plants. Further, insects typically attack one species of vegetation, and the diversity in the wetland plant community will lessen the impact of any one species being temporarily impaired. If the attack does not destroy the belowground plant parts, regrowth is probable. The general advice to the operator is do not panic, but watch the treatment performance.

Aquatic diptera are the most important macroinvertebrates in FWS wetlands in terms of number of species and population size. Mosquitoes (Family Culicidae) and midges (Families Chironomidae and Heleidae) are common wetland inhabitants. Only the larvae and pupae of these groups actually occur in the wetland water column because the adults emerge from their pupal skins and lead a terrestrial life feeding on nectar or blood. The nuisance potential of mosquitoes in wetlands and normal control methods are discussed here.

### Mosquitoes

Mosquitoes present a biting nuisance for both humans and animals. However, the bigger difficulty for treatment wetlands can be the potential for transmission of human diseases. Wetlands and other shallowly flooded habitats provide breeding habitat for mosquitoes. These mosquitoes are a nuisance and may transmit debilitating diseases to humans and livestock. Nonetheless, mosquitoes are an essential part of wetland biodiversity (Schäfer, 2004).

Females of most mosquito species require a blood meal from a vertebrate host to stimulate the development of each clutch of eggs, and this behavior potentially places the surrounding human population at risk of mosquito contact. Species associated with wetlands exhibit ambushing or hunting behavior to acquire blood. Although they engage in hunting behavior during crepuscular and nocturnal periods, *Aedes* and *Psorophora* also ambush hosts during the day and generally will attempt to feed whenever large mammals such as humans or domestic animals enter their immediate surroundings. These species are avid and persistent feeders, produce a painful bite, and will pursue potential hosts after they are encountered. Species that ambush during the day create the greatest demand for control due to public awareness but generally do not fly far during the day and infrequently are involved in pathogen transmission.

Eastern equine encephalomyelitis (EEE) currently occurs east of the Mississippi River in the United States. It operates in a transmission cycle among *Culiseta melanura* mosquitoes and wild birds. In the southwestern United States, only Western equine encephalomyelitis (WEE) and St. Louis encephalitis (SLE) viruses have caused widespread illness in humans and are likely to be transmitted by mosquitoes associated with wetlands. WEE is a zoonosis maintained in a cycle involving *Culex tarsalis* mosquitoes and birds such as sparrows, doves, and quail. Transmission to humans and domestic animals is incidental to the basic cycle. SLE is distributed widely throughout the Western Hemisphere, but most outbreaks typically have occurred at warm latitudes in North America. It may involve any or all of five *Culex* species and also operates through avian intermediate hosts. Human malaria is caused by infection with a blood parasite and was introduced into North America where it is transmitted effectively by several local *Anopheles* mosquito species. Malaria in the United States is typically associated with tourists or immigrants who acquire their infection abroad or relapse a previous infection. In North America, the West Nile (WN) virus has spread from east to west with startling rapidity, beginning in 1999. It follows a cycle that includes many types of birds as reservoirs and is transmitted to humans by biting. Severe cases of the disease are infrequent (about 1 in 150), but some severe cases result in death.

**TABLE 22.4**
**Mosquito Density by Site and System in the NADB v.2.0 (1998)**

| Site Name | System | System Name | Average Density (#/m$^3$) |
|---|---|---|---|

| Reedy Creek, Florida | 1 | Reedy Creek WTS1 | 791 |
| Reedy Creek, Florida | 3 | Reedy Creek WTS2 | 4,830 |
| Poinciana, Florida | 1 | Boot | 288 |

Mosquitoes are viewed quite differently in different climatic regions. In the far north and in moist temperate zones plus the humid subtropics, mosquitoes are pervasive and accepted as a part of the environment. However, in arid climates, mosquitoes are much less abundant and viewed as a controllable nuisance. States such as California and Arizona have mosquito control agencies, which operate under strict guidelines. Treatment wetlands in those states have been heavily regulated for mosquito control. In states where mosquitoes are naturally abundant, there is little or no regulation. Therefore, the sections that follow are directed to treatment wetland projects that will be subject to heavy regulation. Disease transmission by mosquito vectors is virtually nonexistent in cold climates.

### *Mosquitoes and Wetlands*

Mosquito species found in treatment wetlands can be classified into two groups based on their egg laying and hatching behavior. Females of some species lay their eggs directly on the water surface or on the leaves of aquatic plants. The eggs hatch usually within a few days and do not need an external hatching stimulus. These behavioral traits are characteristic of mosquitoes of the following genera (or subgenera): *Anopheles, Coquillettidia, Culiseta*, *Culex*, *Mansonia,* and *Uranotaenia*. By contrast, the eggs of floodwater mosquitoes in the genera *Aedes* and *Psorophora* normally are deposited on moist soil or debris on the shore around aquatic systems and do not hatch until submerged by rising water levels.

Reduced dissolved oxygen levels limit the effectiveness of natural aquatic predators such as mosquitofish (*Gambusia affinis*) and aquatic insects (dragonfly and damselfly larvae and beetles). Thick stands of surface vegetation may also limit the access of predaceous fish to mosquito larvae. The abundance of *Culex tarsalis* larvae in a wildlife habitat marsh wetland near Los Angeles, California, was found to correlate with the presence of floating mats of dead cattails and was less related to stem density of cattails (*Typha* spp.) or bulrush (*Scirpus californicus*) (Walton *et al*., 1990).

Generally speaking, adequately designed and properly operated FWS treatment systems will produce the same amount of mosquitoes as equivalent natural wetlands. Immature mosquito populations in treatment wetlands typically indicate low average densities (Table 22.4).

Mosquitoes can travel 1–5 km from their hatching location (Service, 1993). Mosquito population densities decrease exponentially with distance from their hatching site. The distance covered by hunting females tends to be species-specific but also depends upon host availability, mosquito population size, landscape features, and wind speed. Therefore, although flight is variable and influenced by landscape topography, mosquitoes developing in treatment wetlands have the potential to disperse long distances and infiltrate surrounding residential areas during host-seeking flights.

It is not possible to exclude egg-laying adult mosquitoes from FWS wetlands. Mosquito production is greatest in thick, heavy, monotypic stands of vegetation. Dense stands of monotypic vegetation physically obstruct predator access to mosquitoes and hinder control efforts. Unfortunately, plant species commonly used in FWS treatment systems, such as cattail, bulrush, and common reed, are favorable for mosquito production (Knight *et al*., 2004).

Heavy accumulation of plant detritus results in areas where mosquito larvae are sheltered from predators. Open-water areas with water depths greater than 30–40 cm rarely support mosquitoes (Sinclair Knight Merz, 2000). Deep zones provide refuge for mosquito fish and other predators, but unfortunately they are also preferred habitat for nuisance rodents.

## Control Strategies

The goal of system operators should be to minimize the number of larvae that can successfully survive to become adult, biting mosquitoes. This is generally achieved by either creating conditions favorable for mosquito larvae predators or through chemical/biological control of the mosquito larvae. Predators of mosquito larvae include a variety of aquatic insects (Greenway and Chapman, 2002). However, the most commonly used predator is the mosquito fish (*Gambusia holbrooki*). Mosquito fish do not survive in cold climatic zones, and their northern analogs (the top-minnows) are not nearly as effective for control of immature mosquito stages.

Two bacteria species, *Bacillus thuringiensis* variety *israelensis* (Bti) and *Bacillus sphaericus*, are commonly used for mosquito control in treatment wetlands (Williams *et al*., 1996). Pellet and granular forms are available for vegetated environments but are effective only if they can be distributed into areas where the mosquito larvae are present. As a result, effective use of *Bacillus* toxins requires functional access points into the wetland, including:

- Drivable access around all wetland cells
- Boat ramps, boardwalks, or other structures to allow access into deep-water zones
- Embankments and wetland areas that are free of power lines and other obstructions that might limit aerial spraying
- Piping and valving that allows application of chemical and biological control agents directly into the flow

Because water is continually flowing through the treatment wetland, control agents may have to be reapplied periodically.

Conventional chemical pesticides, such as the organophosphate compound temephos, are used for vector control operations in the United States because the chemicals are effective against a wide range of insects and remain economical for larviciding in large-scale abatement efforts (FCCMC, 1998). Such chemicals are not particularly toxic to mammals. Larviciding using either mosquito-specific or rapidly degrading control agents is preferred to adulticiding programs that use residual insecticides such as organophosphates (e.g., malathion, chlorpyrifos) or natural and synthetic pyrethroids (e.g., pyrethrin, resmethrin). After adult mosquitoes emerge from developmental sites and disperse into the region surrounding a wetland, control is more difficult than efforts focused on the developmental sites of the immature stages. However, adulticiding may be necessary if control efforts focusing on the aquatic, immature stages are ineffective.

Emergent vegetation in constructed treatment wetlands is an integral component of the water treatment process; however, dense emergent vegetation promotes mosquito production and impedes mosquito abatement efforts. Therefore, vegetation management activities may be a consequence of mosquito control. Forms of vegetation management by physical control include herbiciding, harvesting, and controlled burning.

## 22.5 VEGETATION MANAGEMENT

There are two perceptions that the treatment wetland operator should be aware of, and deal with appropriately: (1) the wetland only works if it is a large green expanse, and (2) the plants that were originally planted are the only ones that should be in the wetland. The first may be termed the "cosmetic concept." Although it is certainly true that full vegetation promotes the biogeochemical cycles that underlie many treatment processes, it is also true that the brown component (detritus and litter) is of equal or greater importance than the green leaves. This is especially true when considering cold climate wetlands, which, despite being brown (or even white) during many months, continue to provide treatment during those months. Thus, although human values place a premium on visible green plants, the correlation to treatment is not necessarily strong.

The second idea may be termed the "cornfield concept." As a carryover from agriculture, if the intent is to raise a particular crop, then anything else is a weed and should be removed so as to prevent interference with the crop. However, treatment wetlands are not generally intended to provide a specific crop but rather to promote utilization of nutrients, uptake of chemicals, and formation of microbial substrate. Therefore, it is often less important what species are present than their contributions to treatment.

### General System Care

Treatment wetlands require access facilities including walkable or drivable levees. These need to be kept in good condition. Berms may need mowing, particularly if local regulations prescribe this, as is often the case for treatment lagoons. A perceived problem is the growth of trees in wetland berms, such as cottonwood (*Populus deltoides*), willow (*Salix* spp.), and salt cedar (*Tamarix chinensis*). These are most easily controlled by mowing. This requires that berms be designed with flat enough side slopes for mowing equipment. Systems that are designed for public use will require that walking trails and other facilities be kept in a safe and useable condition.

### Harvesting

The harvest of wetland plants for the purpose of removal of stored chemicals is often suggested but seldom practiced. As set forth in Chapters 9 and 10, it is not effective in heavily loaded systems, because only a small fraction of the removal operates through the vegetation. Any consideration of harvest is therefore confined to agronomic (lightly loaded) systems. As noted in Chapter 3, there are drawbacks to harvesting. Techniques for harvesting large-scale systems are generally not available. Disposal of harvested plant material has associated costs, with few opportunities for product recovery. Harvest removes vegetation that would otherwise form litter and serve valuable treatment functions in the system, such as insulation via snow trapping and carbon supply for denitrification. Techniques for harvesting would presumably involve system dry-down or on-ice methods.

### Weeds

Treatment wetland vegetation is intended to enhance water quality functions in the system and not necessarily to provide habitat. Plants that are weeds from a habitat perspective may be desirable from a treatment perspective, but the two

**TABLE 22.5**
**Wetland Species That Are Sometimes Considered to Be Weeds from a North American Habitat Perspective**

| Scientific Name | Common Name |
|---|---|
| *Eichhornia crassipes* | Water hyacinth |
| *Hydrilla verticillata* | Hydrilla |
| *Lythrum salicaria* | Purple loosestrife |
| *Phalaris arundinacea* | Reed canary grass |
| *Phragmites australis* | Common reed |
| *Salix* spp. | Willow |
| *Typha latifolia* | Cattail |
| *Typha domingensis* | Cattail |
| *Typha angustifolia* | Cattail |
| *Elaeagnus angustifolia* | Russian olive |
| *Sapium* spp. | Chinese tallow |
| *Schinus terebinthifolius* | Brazilian pepper tree |
| *Casurina* spp. | Australian pine |
| *Tamarisk* spp. | Salt cedar |
| *Alternanthera philoxeroides* | Alligator weed |
| *Spiraea douglasii* | Douglas spiraea |
| *Ranunaulus repens* | Creeping buttercup |
| *Juncus effusus* | Soft rush |
| *Cytisus scoporius* | Scot's broom |
| *Lysinachia terrestris* | Yellow loosestrife |
| *Iris pseudacorus* | Yellow iris |

*Source:* From Hayes *et al*. (2000) *Wetlands Engineering Handbook*. ERDC/EL TP-WRP-RE21, U.S. Army Corps of Engineers: Washington, D.C.

categories are not mutually exclusive. It is useful to understand which categories of plant species are considered undesirable from a habitat perspective and what measures are recommended for their control (U.S. Army Corps of Engineers, 2000). Table 22.5 lists categories that include exotic species and some native species from the North American habitat perspective. If a treatment wetland is intended to serve multiple purposes including the ancillary benefit of providing optimal habitat, then these species may be excluded from the planting list and viewed as weeds if they subsequently volunteer into the wetland.

In general, control measures for undesirable species include burning, mowing, hand pulling, mechanical removal, and herbicide application.

However, there may also be reasons to favor the exclusion or eradication of some species from the point of view of enhancing treatment. Although there are not general rules, some plant species have disadvantages for the treatment of some pollutants. As an illustration, the Everglades protection wetlands (STAs) of South Florida target removal of phosphorus to ultra-low levels (≈10–50 μg/L). These are also uniquely large systems with attendant peculiarities of wind fetch. Huge amounts of research have shown that submerged aquatic vegetation is more effective than emergent plants. However, the wetlands are easily and often invaded by species that are moderately effective in phosphorus reduction, such as water hyacinths (*Eichhornia crassipes*), hydrilla (*Hydrilla verticillata*), and torpedo grass (*Panicum repens*). Hyacinths are moved by the wind and form dense windrows piled above water, which clog structures and create anoxic conditions. Torpedo grass and hydrilla form floating leaf canopies that block sunlight and oxygenation. Accordingly, these plants were regarded as undesirable and removed by herbiciding. Several different chemicals have been used, including 2,4-D, glyphosate, imazipyr, and diquat dibromide (Goforth, 2005).

## Burning

The value of prescribed fire in managing vegetation varies according to region and vegetation type. Fire may be used in treatment wetlands for the purpose of reducing and removing excessive thatch buildups that develop in arid climate systems. However, those climatic regions may also be prone to air pollution problems, which may preclude fire as a management tool. Fire is being used on a limited basis in some constructed FWS treatment wetland systems (e.g., West Jackson County, Mississippi) to periodically reduce the density of macrophyte growth. In arid regions, fire is often regarded as a necessary management tool to reduce the thatch in SSF wetlands (Wallace and Knight, 2006).

Fires are typically set in the late fall or winter after plant senescence, and wetland burns can be accomplished with or without shallow standing water in the wetland cells.

Fire mobilizes the stored nutrients and pollutants into water-soluble forms and permits the flushing of the materials the wetland was designed to store (Smith *et al*., 2001). The litter and sediment layers may be destroyed, thus necessitating a new microbial start-up period. If fire is used as a management tool, it is essential that the treatment wetland be designed with multiple parallel flow paths to allow bypassing flows around the cells receiving controlled burns. Following a planned fire in a wetland cell, water should be held for a period of several weeks to a few months before start-up and discharge to avoid the release of newly dissolved constituents.

White *et al*. (2002) studied the effects of fire in a FWS treatment wetland, the Orlando Easterly System in Florida. The vegetation communities included cattail, bulrush, and mixed species. A paired cell design was implemented with a burn in one cell, whereas the adjacent cell received no burn. Water quality parameters including soluble reactive phosphorus, total phosphorus, ammonium, total Kjeldahl nitrogen (TKN), and dissolved organic carbon were measured before and up to four months after the burn. A pre-and post-burn quantification of aboveground biomass was conducted to determine the net reduction in biomass as a result of the burn. The results showed that there was phosphorus released from the burned cell immediately after the fire, but over time, the concentrations dropped below that of the no-burn treatment, showing greater performance of the burned cell for treatment of water column phosphorus.

**FIGURE 22.18** This berm at the Hayward, California, treatment wetland is need of maintenance because of erosion.

## 22.6 MAINTENANCE OF STRUCTURES

It is obvious that wetland operation involves keeping the physical features in good condition, including inflow and outflow structures, pumps, piping, berms, and levees. Two features of FWS treatment wetlands may be singled out as distinctively different from many other civil works: berm maintenance and structure clogging.

Berm damage can occur as a result of animal activity, as discussed in the preceding text (see Figure 22.17). Animal control may be required in addition to repairs. Vegetative damage is much less likely, but nuisance species may need removal or mowing. Erosion damage from wave or rain action will occur if the original design and construction did not provide adequate stabilization (Figure 22.18, also see Figure 18.20). Repair and restabilization with riprap or appropriate berm plantings is required.

FWS treatment wetlands export plant debris, primarily as floating detritus (see Figure 18.29). Blockage of maintenance manholes, weirs, outflow piping, and rodent guards by dead floating leaf litter from emergent vegetation, floating aquatic plants (duckweed and algae), and large turtles can play havoc when trying to maintain flow rates and water levels. At the Brighton, Ontario, treatment wetland, stems and leaves break off from the dense growth of cattail and river bulrush around the perimeter of their wastewater lagoon and, along with mats of floating algae and duckweed discharges from the lagoon, are passed through a maintenance manhole prior to entering the wetland. However, much of this material remained in the maintenance manhole as a floating mat and built up to the point where it became thick enough to completely block the flow to the wetland (Figure 22.19). The wetland outflow was plagued by similar problems. Regular buildup of dead floating vegetation and other debris on the effluent rodent guard resulted in a blockage that would impede the outflow. In both cases, a simple fix was the installation of a snow fence barrier at the lagoon and wetland outflows. This allows the debris to become caught up against the barrier but allows the water flow to continue below it. Debris is routinely cleaned off the snow fencing to maintain the flow and water level in the wetland. For large FWS treatment wetlands, the situation is more complex, because of the size of the structures. Automatic self-cleaning trash racks can be used to span inlets that are several meters in width (Figure 22.20). Removal of the debris may require truck transport.

**FIGURE 22.19** Plant debris buildup in a control structure manhole at the Brighton, Ontario, project. (Photo courtesy J. Pries.)

## 22.7 LONG-TERM PROSPECTS

Part of the natural function of treatment wetlands is the buildup of sediments and soils in the system. This mechanism provides accretion of both incoming solids (settling) and of internally generated solids (see Chapter 7).

### FWS Wetlands

Sedimentation eventually compromises the operation of the system in two ways. Firstly, the sediment-trapping forebay

**FIGURE 22.20** The automated trash rack at the effluent pump station for the Everglades Nutrient Removal Project. Rakes pull the clogging floating vegetation up the inclined bar screen and deposit it on a conveyor, which removes it to a stockpile. The drained material is removed by truck.

or inlet zone can become filled and no longer provide the needed vertical-settling depth (see Figure 7.13 of Chapter 7). Secondly, solids accrete internally to the vegetated zones, regardless of how effective a sediment forebay or pond may be, because of internal wetland generation of solids. As noted in Chapter 7, the rate of accretion may be on the order of 1 or 2 cm/yr. Mass balance calculations may then be applied to determine the "life" of the wetland, in terms of the time required to fill the basin to a certain depth.

There is a major problem with such average accretion computations: the deposition is not uniform. If significant treatment is occurring, there may be more deposition in the wetland inlet region; in other words, there is likely to be a longitudinal gradient in the buildup of sediments and soils. The water in the inlet region can become shallower and consequently move with higher velocity. Transverse nonuniformity also creates difficulties, because channels can form in the new sediment layers, especially under shallow high-velocity conditions. In combination, the wetland may lose some of its original hydraulic efficiency. These processes are exacerbated by the fact that new sediments are slow to consolidate and usually create a "floc" layer that is relatively mobile. Thus, accretion can compromise the operation of a treatment wetland long before the containment (freeboard) is jeopardized.

The maintenance needed to correct for accretion is daunting. The wetland (or flow path) must be shut down, and the excess material excavated and disposed. Afterward, vegetation must be reestablished. This procedure has been applied to a portion of the Orlando Easterly Wetland system, with good results (Sees, 2005; Wang *et al*., 2006). That system had been in operation for about 18 years at the time of rejuvenation. In early 2007, after approximately 15 years of operation, some cells of the ENRP were selected for removal of accreted sediments. There is presently insufficient information to generally evaluate the trade-off between reduced efficiency and the cost of renovation.

### SSF Wetlands

Deposition of particulate matter, plant detritus, and microbial biofilms also function as clogging mechanisms in subsurface flow wetlands. For HSSF wetlands, this is observed as a marked reduction of the hydraulic conductivity of the inlet zone (Figure 2.22), which eventually leads to clogging and overland flow (Figures 2.26, 2.28, and 7.25). Design approaches such as reducing the organic loading over the inlet cross section (Figure 21.5) may reduce or delay clogging, but there is no evidence that inlet zone clogging can be avoided, as sedimentation is a cumulative process and the majority of the particulate matter is deposited in the inlet region (Figure 7.25) (Puigagut *et al*., 2006). In a recent survey of 255 SSF wetlands in the United Kingdom, with a median age of about ten years, 52% were reported to exhibit some degree of overland flow (Cooper *et al*., 2006a). Based on the performance of existing HSSF wetlands, it appears that inlet zone maintenance will be needed approximately every ten years to avoid a large degree of overland flow.

From an operational standpoint, bed clogging can be diagnosed as overland flow in the inlet region, and adjustments to the effluent water level control structure will not correct the problem (Figure 22.21).

At the present time, means of dealing with bed clogging are in the experimental stage. The basic options appear to be:

- Remove the clogged-bed media and replace with new material. It is an expensive option (Table 22.6) because not only must the replacement media be purchased, but there will likely be disposal costs associated with the clogged media.
- Removing the clogged-bed media, washing it, and returning it to the wetland bed (Cooper *et al*., 2006a). This method may be preferable to purchasing new bed media, but the washing equipment is only recently available and there will likely

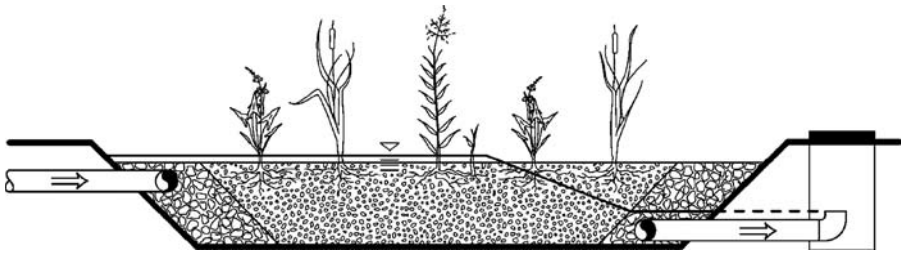

**FIGURE 22.21** Clogged-bed water level response in HSSF wetlands. (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

be disposal costs associated with the extracted biosolids.

- Using hydrogen peroxide ($H_2O_2$) to chemically oxidize the biosolids *in situ* (Hanson, 2002b; Behrends *et al*., 2006). In a study on a pilot-scale reciprocating bed wetland, Behrends (2006) attempted to rehabilitate the beds through the application of concentrated (30%) hydrogen peroxide at a dosage rate of approximately 9 L/m$^3$ of bed. Noticeable bubbling occurred, and sludge was redistributed, with some moving to the bed surface. No indications were given of improvement of either hydraulic conductivity or treatment efficiency. The success of this method has recently been demonstrated in Lake Elmo, Minnesota.

VF wetlands treating primary or secondary municipal wastewater will accumulate solids on the surface of the bed (Figure 7.30). However, VF systems that are treating waste streams inherently low in TSS, such as settled leachates, pretreated food wastes, or tertiary applications for municipal wastewater, will likely not form the same solids layer.

Accumulated solids must eventually be removed. Accumulation appears to be a function of the organic-loading rate and operational load-and-resting regime, and methods to quantify and predict solids accumulation have yet to be developed. Based on current information, a cleanout frequency of eight to ten years seems reasonable (Molle *et al*., 2004a) for the French raw sewage VF wetlands.

For biosolids dewatering wetlands, this accumulation is deliberate and part of the normal functioning of the system. The amount of dewatered sludge that can be accumulated in this way is a function of the available freeboard of the wetland cell, with accumulations of approximately 1.5 m over ten years of operation (Nielsen, 2002). The resulting material has a solids content of approximately 40% and is removed from the basin with an excavator or skid-steer loader. Some basins are constructed with concrete sidewalls to facilitate sludge removal (Figure 1.15).

**TABLE 22.6**
**History of Inlet Clogging for Selected HSSF Wetlands in Minnesota**

| System | Media $d_{10}$ (mm) | Cross-Sectional Organic Loading (g BOD/m$^2$·d) | Approximate Time for Inlet Zone Surfacing to Develop (years) | Cost of Inlet Zone Maintenance |
|---|---|---|---|---|
| St. George[a] | 2.1 | 448 | 2 | 19% |
| Spring Hill[b] | 5.0 | 353 | 4 | — |
| Prairie Hamlet[c] | 5.1 | 345 | 6 | — |
| Fields of St. Croix[b] | 4.0 | 304 | 6 | — |
| Jackson Meadow[a] | 5.8 | 287 | 6 | 10% |
| Lutsen[c] | 5.2 | 189 | 9 | — |

[a] Inlet zone maintenance is expressed as a percentage of the initial construction cost. Maintenance for these systems consisted of excavating clogged material, replacing with clean rock, lime stabilization to eliminate pathogens from the clogged rock, and reconfiguration of the inlet zone distribution to reduce the cross-sectional organic loading.

[b] Inlet zone maintenance was done on these systems, but cost data is not available.

[c] Some inlet clogging observed, inlet zone maintenance has not been required to date.

## 22.8 ASSISTANCE TO THE OPERATOR

It is not only the wetland itself that goes through start-up. Very often the system operator also goes through a kind of start-up, during which there is a steep learning curve. Familiarity with treatment wetlands in general is a prerequisite qualification for the wetland operator, but in many circumstances that may be "book knowledge." In virtually all cases, the operator will not have been involved in the wetland design, and therefore will not be familiar with the intended function of the system. Two steps can alleviate potential difficulties: (1) a start-up walk-through of the treatment system, from pretreatment to final discharge, and (2) preparation of a comprehensive operations and maintenance manual. The walk-through includes a discussion between the designer and operator, of the intended function of structures and controls, and of the wetland vegetation, detritus, and soils. It serves the purpose of defining what activities may be required on a seasonal basis.

The project operation and maintenance (O&M) manual is the reference document that the operator may consult as needed during future operation of the facility (Tables 22.7 and 22.8). It describes the design intent of the project. Start-up and normal operations are explained. Monitoring requirements, protocols, and reporting are listed. Routine O&M steps are outlined. Some of the foreseeable emergency situations, notably high-rainfall events, are discussed, and emergency measures defined. For later reference, it includes the as-built drawings for the wetland and the current regulatory permits.

For large projects, there may be a requirement for a project operation plan. For example, the stormwater treatment areas (STAs) of South Florida all have such documents. A typical outline for STA6 (SFWMD, 2004) is

The operations section of the overall plan discusses various modes of operation. The design intent for normal operation is specified, as to which structures are operating and what water depths are to prevail. However, the design included operations during the "standard project storm" of 55 cm of rain over a 24-hour period. The operating plan, therefore, includes information on extreme flow operations. The design calculations also indicated frequent dry periods, and the operations plan includes provisions for dealing with this lack of water. Should it become necessary to take treatment cells out of service (this has not happened in the first ten years of project operation for STA6), the document contains the design intent for earthwork to accommodate the temporary reconfiguration. The design of the project also contemplated expansion of the treatment wetland, by adding a third flowpath, and that intent is spelled out in the operation plan.

## SUMMARY

Treatment wetlands are sufficiently different from other treatment technologies to make learning their operation a nontrivial effort. Although they involve few sophisticated controls, they offer hydraulic and ecological challenges. Thus, although they are "low tech," they are "high bio." Given a conservatively designed wetland treatment system, successful operation is not a challenging task. There are few operational controls in most treatment wetlands, and these controls must be used wisely and with common sense to maintain top performance. Typically, the only system controls available are variation of inflow-loading rates through storage or diversion of flows, system rotation between alternate discharge locations or wetlands, and control over water levels within the wetland.

A certain level of routine maintenance measures is necessary, including mowing, structure cleaning, and berm inspection. Vegetation management might include depth management, selective herbiciding, and the controlled use of fire. Animal control is increasingly understood to be an important facet of FWS wetland operation. In particular, rodents can be quite destructive and require control in some circumstances. Mosquito control is an important issue in some wetland treatment projects, notably those in warm, arid climates. The owner and operator of these wetland systems should be prepared to deal with this possible issue.

It is becoming apparent that HSSF wetlands will require declogging one or more times during a 20-year life span. Methods for removing solids are currently under development.

Monitoring is one of the most important aspects of treatment wetlands operation. Monitoring of inflow and outflow water quality provides a system-level barometer of wetland health and performance. Monitoring of the internal wetland structure provides a reference for correlating changes in water quality performance with system structure. Routine monitoring and data analysis are essential for making informed decisions concerning control of operational variables such as water depth and mass loadings. Additional monitoring beyond regulatory requirements may be performed to accomplish specific operational goals. Because of its importance in optimizing system performance and averting unacceptable biological changes, some monitoring should be conducted in all treatment wetlands.

Although the totality of potential management issues is large, all of the issues identified in this chapter do not occur at any one wetland. In general, treatment wetland systems are operator-friendly, but they cannot be left unattended for prolonged periods.

# 23 Economics

The economics of treatment wetlands consists of two major factors: capital costs and operating costs. The capital cost components of free water surface (FWS) and subsurface flow (SSF) wetlands are essentially the same, except for the cost of the gravel required for SSF wetlands (Campbell and Ogden, 1999; U.S. EPA, 2000a). However, SSF systems have generally been implemented for smaller flows than FWS systems. For instance, the system database compiled by the Water Environment Research Foundation (WERF) has 214 FWS wetlands with a median design flow of 1,050 $m^3/d$, 707 HSSF wetlands with a median design flow of 9.5 $m^3/d$, and 566 VF wetlands with a median design flow of only 2.1 $m^3/d$ (Wallace and Knight, 2006). System areas from the WERF database show 330 FWS wetlands with a median area of 1.6 ha (16,000 $m^2$), 710 horizontal subsurface flow (HSSF) wetlands with a median area of 140 $m^2$, and 544 vertical flow (VF) wetlands with a median area of 44 $m^2$. Therefore, SSF wetlands do not enjoy the economy of scale experienced by FWS wetlands. There is now enough information to determine approximate capital cost functions that represent these scale effects.

Because wetland systems are constructed using local labor and local materials, it is not possible to offer precise universal cost estimates that will apply to all treatment systems. Generally, the basic components of a wetland treatment system—earthwork, gravel (in the case of SSF wetlands), liners, and plants—are produced in regional markets that are distance sensitive. For instance, the installed cost per cubic meter of gravel is highly dependent on the distance between the source of supply (a local gravel pit) and the site of wetland construction. Labor costs are also highly variable. To assess the feasibility of a wetland treatment system, local cost figures should be used to compare the capital and operating costs of a wetland system against that of other treatment technologies.

Within the United States, Construction Cost Indices (CCI) are published by the Engineering News Record (ENR). These cost indices track inflationary changes within the construction industry over time. The ENR CCI started at 100 in the year 1913 and has increased to 7,856 in March 2007. Cost indices are available as a national average, but are also published for 20 major metropolitan areas in the United States. For the purposes of this chapter, costs are based on the 2006 United States national average ENR CCI of 7,751. As a side note, construction in high-cost metropolitan areas is almost double that of low-cost metropolitan areas.

In general, capital costs of treatment wetlands are comparable to alternative technologies for accomplishing the same task. However, the costs of operating a treatment wetland are typically much lower than for competing technologies. Mechanical devices are always more energy intensive, and will always be more expensive to operate, than a passive wetland system (Type *A*) (Brix, 1999). The basic exchange is land for energy (Campbell and Ogden, 1999). As a consequence, the lifecycle cost of a wetland project, as represented by the present worth of capital and operating expenses, is very often quite favorable compared to alternative treatment technologies.

Operating costs can be quite low, especially for Type *A* passive systems. Energy costs are typically close to zero for gravity-driven FWS wetlands, and are generally low for all types of treatment wetlands (see Table 1.1). Water quality monitoring is often a principal part of O&M costs. However, operation and maintenance (O&M) costs can become appreciable if it is attempted to maintain specific vegetation types, thus encountering "weeding" costs.

## 23.1 CAPITAL COSTS

Although it is not possible to offer universal cost guidelines, every system shares a similar set of construction components. Therefore, it is possible to estimate the cost of each component within a regional market. The basic direct cost components of a wetland treatment system include:

- Land
- Site investigation and system design
- Earthwork
- Liners
- Media
- Plants
- Water control structures and piping
- Site work (site preparation, fencing, access roads, etc.)
- Human use facilities

These costs include material, labor, overhead, and profit, and represent the contractors installed cost. Additionally, there are indirect costs associated with permitting, engineering, financing, mobilization, and construction management. In general, these costs are all incurred prior to system start-up. Detailed estimates are usually made after final sizing and siting. More precise economic estimating is possible after final design drawings have been prepared.

### Regional Variation

Economics vary geographically because of differing unit costs, and because of differences in the selection of materials

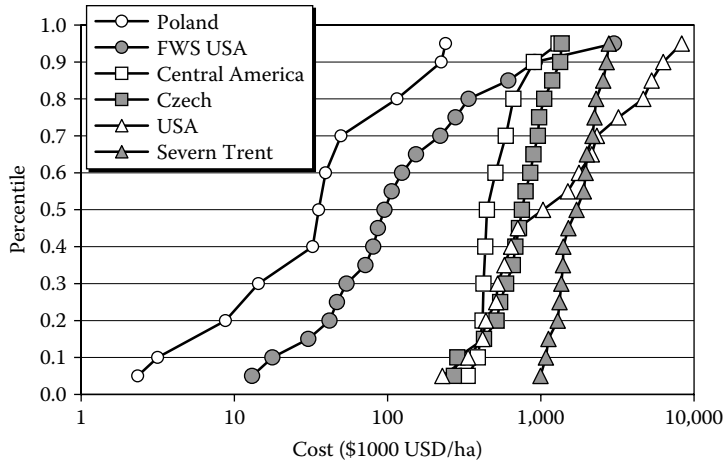

**FIGURE 23.1** Capital costs distribution for treatment wetlands. All are HSSF systems except FWS (United States). Costs adjusted to 2006 using CCI = 7,751 and the 2006 exchange rate. Data for Poland from Kowalik and Obarska-Pempkowiak (1998) In *Constructed Wetlands for Wastewater Treatment in Europe*. Vymazal *et al*. (Eds.), Backhuys Publishers, Leiden, The Netherlands, pp. 217–225. Data for the Czech Republic from Vymazal (1996) *Ecological Engineering* 7: 1–14. Data for Severn Trent from Green and Upton (1994) *Water Environment Research* 66(3): 188–192. Data for Central America from Platzer *et al*. (2002) *Investigations and Experiences with Subsurface Flow Constructed Wetlands in Nicaragua*, *Central America*. Mbwette (Ed.). Proceedings of the 8th International Conference on Wetland Systems for Water Pollution Control, 16–19 September 2002, Comprint International Limited: University of Dar Es Salaam, Tanzania, pp. 350–365. Data for the United States: Various.

and other design features. The cost of labor and materials within a particular regional market plays a large role in the cost of a wetland treatment system. Cost differentials are even greater when comparing across worldwide geographic locations and their accompanying economies. The effect of regional market cost factors is illustrated in Figure 23.1, which demonstrates treatment wetland capital cost distributions for various locations. HSSF wetland systems in Poland (Kowalik and Obarska-Pempkowiak, 1998) exhibit lower capital costs than those in Nicaragua (Platzer *et al*., 2002) or the Czech Republic (Vymazal, 1996). Severn Trent tertiary systems in the United Kingdom (Green and Upton, 1994) are more expensive than those in the Czech Republic; HSSF systems in the United States have a distribution of capital costs that spans the range from the inexpensive Czech systems to those that are more expensive than the U.K. systems.

Some of the regional differences have to do with design sizing criteria. Different criteria are used in different countries, and also at different times in the same country. Others have to do with structural specifications. For instance, a number of U.K. systems are sited in basins lined with brick or concrete, and some have stainless steel level and flow control elements. Clearly, such systems will have greater capital costs than those sited in earthen basins with plastic piping and simplified flow control elements.

There are also economies of scale, which will be addressed in a subsequent section. However, it is useful to first examine the various components of capital costs in more detail.

## Direct Costs

### Land

Land costs are highly site specific. Information on land availability and land costs is generally obtained with the assistance of real estate professionals who are familiar with local market conditions. Wetlands are more land intensive than many other wastewater treatment processes. If land needs to be purchased for the project, this can be a significant cost component. In the United States, treatment wetland land purchase prices have ranged from $3,000/ha in remote locations with low population density and low agricultural utility to over $100,000/ha in urbanizing agricultural landscapes. Land acquisition in or near urban areas is sometimes viewed as preservation of green space, and valued for ancillary benefits.

Land costs can be a significant fraction of the total capital cost. For example, Wossink and Hunt (2003) identify three categories of land cost for urban stormwater wetlands in North Carolina: zero cost because the project is required for community green space, $125,000/ha for vacant land that may be used for residential development, and $550,000/ha for land that may be used for commercial development.

As will be discussed, land costs occupy a special role in the present worth analysis of a wetland system.

### Site Evaluation

The design and construction of a wetland requires that site characteristics be well understood—including soils,

groundwater elevations, and site topography. These activities usually precede or accompany engineering design, but are additional to that design.

### *Topographic Survey*

The ground elevation of the site is a critical factor in design, because it controls the cut-and-fill calculations that normally dictate the elevations of berms and bottoms. Associated with balancing of earth import and export is the issue of the potential for gravity flow. Sometimes proper cell elevations can eliminate the need for one or more pumps, and thus may interact with cut-and-fill considerations. The topographic survey will influence the direction of flow and the sequencing of cells, and the need for long or short distribution and collection canals, which for large systems can influence the project cost. The potential need to level cell bottoms for purposes of evening the hydraulic flow distribution can only be evaluated with detailed site topography. The shallow water depths in wetlands, especially large FWS systems, creates a need for accurate as-built topography as an aid to understanding water depth and movement. The costs for such surveys are typically \$50/ha–\$500/ha, depending on scale and grid size requirements. For instance, the topographic survey for the Incline Village, Nevada, treatment wetland cost \$370/ha for the 175-ha wetland, adjusted to 2006. However, the survey work for cell 4 of STA2 of the Everglades phosphorus control project required only \$45/ha.

### *Geotechnical Investigations*

Many small-scale wetland projects are designed in conjunction with soil infiltration systems. In these situations, it is common to use shallow soil borings or backhoe pits to determine local soil characteristics. Costs for these initial site investigations vary with the size of the project. In the U.S., the cost for a site investigation can range from a few hundred dollars (for a single-home system) up to several thousand dollars (for a system serving a small community).

Larger-scale projects, including those that discharge to surface waters, also require soil investigations. Even though such large projects rarely require liners, there is a need to assess the potential for seepage from the project, and hence the need for seepage collection canals. It is critical to determine if site soils are adequate for the berms and levees, and if so how much compaction may be required, and how much allowance for subsidence.

Soils that may be used for rooting media in FWS systems, as well as the gravel substrate for SSF systems, may need to be assessed for contaminants of concern, including nutrients. A modest amount of chemical testing may be required to identify any potential problems, or to form the basis for forecasting the sorption life expectancy for contaminants.

### *Hydrogeological Investigations*

The location of the groundwater table and direction of groundwater movement can be a critical factor in wetland design. For small community and on-site systems involving soil infiltration, the depth to groundwater is an important consideration. For "normal" infiltration beds (septic fields), there is a required minimum unsaturated depth that is likely to carry over to the wetland/infiltration situation.

For a wetland with a liner, it is also necessary to know the depth to groundwater, because rising, shallow water tables can lift a synthetic wetland liner, displacing air from the soil environment. This has the potential to create large underliner bubbles that push the liner up out of the water; these are commonly called "whale backs." The solution to such potential difficulties is the construction of an under-drain system beneath the wetland liner that vents air and controls the level of the water table. The need for this feature, and its associated cost, will be determined through site-specific hydrogeological investigations.

In some cases, there may be a concern for regional use of the groundwater as a potable water supply. The treatment wetland might be viewed as a possible source of contamination if partially treated water entered into the unprotected drinking water aquifer, and moved to the wells that withdraw potable water. This would usually occasion the need for a hydrogeological study to ascertain the depths and directions of regional groundwater flow, and the consequences of even small leaks from the treatment wetland to the water quality of the aquifer. This was the case at the Columbia, Missouri, project. The hydrogeological study included calibration and modeling to address this issue, at a cost of \$750/ha for the 36-ha wetland, adjusted to 2006 (Brunner *et al.*, 1992).

## Earthwork

The construction of a wetland treatment system requires excavation and grading of the site to produce level basins that are enclosed by earthen berms. For small systems (generally less than 0.05 ha) backhoes or similar types of excavation equipment are commonly used. Larger basins are generally constructed using bulldozers or construction scrapers. Area-specific earthwork costs are the product of two components. The first component is the cost to move earth, which is a volumetric (per cubic meter) cost. This cost component is a function of equipment costs, labor costs, and the source of earth supply (on-site or imported). The second component is the amount of earth that must be moved to grade the site. This areal requirement ($m^3$ of earth per $m^2$ of wetland area) is a function of the project site conditions. Earthwork costs are lowest on flat sites that require minimal grading and have suitable soils on-site (low areal grading requirement and volumetric cost). Sloping a site requires terracing, which increases earthwork costs (due to the large areal grading requirement). If the fill needs to be imported, earthwork costs will increase (due to the high volumetric cost). Earthwork construction techniques are essentially the same for FWS and HSSF wetlands, and hence volumetric earthwork costs for the two types should be comparable for similar-sized wetlands.

**TABLE 23.1**
**Earthmoving Costs for HSSF Wetlands in Minnesota**

| System Name | Design Flow ($m^3/d$) | Wetland Area ($m^2$) | Earthwork Volume ($m^3$) | Cost Volumetric ($/$m^3$) | Grading Req. ($m^3$ earth per $m^2$ wetland) | Cost (Areal) ($/$m^2$) |
|---|---|---|---|---|---|---|
| St. George, Minnesota | 25 | 595 | 631 | 8.54 | 1.06 | 9.06 |
| Darfur, Minnesota | 38 | 1,301 | 383 | 5.70 | 0.29 | 1.68 |
| Northern Tier High Adventure Base, Minnesota | 34 | 297 | 306 | 13.56 | 1.03 | 13.97 |
| Lakes of Fairhaven, Minnesota | 59 | 1,828 | 383 | 7.56 | 0.21 | 1.58 |
| Delft, Minnesota | 22 | 664 | 306 | 18.15 | 0.46 | 8.36 |
| St. Croix Chippewa, Wisconsin | 251 | 6,141 | 6,885 | 4.51 | 1.12 | 5.06 |
| Prinsburg, Minnesota | 206 | 4,094 | 7,069 | 2.17 | 1.73 | 3.75 |
| **Median Values** | | | | **7.56** | **1.03** | **5.06** |

### *Clearing and Grubbing*

If the undeveloped site has undesirable vegetation, buildings, or other existing features that are incompatible with the wetland, these will need to be removed as part of the earthwork process. Brush and trees were removed from the sites at Ouray, Colorado; Sorrento, Louisiana; and West Jackson County, Mississippi, at an average cost of $9,800/ha. On larger projects, roads and ditches may require degrading, and buildings may require removal.

### *FWS Wetlands*

In a study of two municipal FWS wetland systems (West Jackson County, Mississippi and Gustine, California) the U.S. Environmental Protection Agency (EPA) estimated a volumetric cost of $10.80/$m^3$ when adjusted to 2006 USD (U.S. EPA, 2000a). The 20.2-ha wetland system in West Jackson County, Mississippi, had an areal grading requirement of only 0.26 $m^3/m^2$, and the 9.7-ha system in Gustine, California, had an areal grading requirement of 0.35 $m^3/m^2$.

Larger treatment wetlands require far less earthmoving on a per-hectare basis than do small systems. For instance, Cell 4 of STA2 of the Everglades phosphorus control project required only 0.056 $m^3/m^2$ of earthmoving based on the 816-ha wetland footprint. However, the construction of such a large system does not involve scraping a thin layer from the entire footprint. Rather, the inlet spreader canal, outlet collection canal, and seepage return canal are the source of the fill material for the containment levees.

Even large wetlands may require significant earthmoving if built on sloping terrain. For example, the Inman Road treatment wetland in Clayton County, Georgia, has 22 wetted hectares in a terraced arrangement of 22 cells. The site presented slopes of 2–25%, and about 30 m of vertical variation (Inman *et al.*, 2001, 2003). Construction required moving 420,000 $m^3$ of earth, or 1.9 $m^3/m^2$.

Regional factors and site conditions can alter the cost of earthmoving. Cell 4 of STA2 of the Everglades phosphorus control project moved 460,000 $m^3$ of material, in a nearly balanced cut and fill. The breakdown of per cubic meter costs was: $2.61 to blast rock, $2.13 to excavate, and $2.09 to build levees, for a total of $7.96/$m^3$ (adjusted to 2006 USD).

### *HSSF Wetlands*

Earthwork costs for some HSSF wetland systems in the Minnesota–Wisconsin regional market are summarized in Table 23.1. Data from these seven HSSF wetland systems clearly show the impact of local site conditions on earthwork costs. Areal grading requirements varied from 0.21 $m^3/m^2$ to 1.73 $m^3/m^2$, with a median value of 1.03 $m^3/m^2$.

Volumetric earthwork costs for the systems in Table 23.1 varied between $2.17/$m^3$ and $18.15/$m^3$, with a median value of $7.56/$m^3$ (cost adjusted to 2006 USD, ENR CCI = 7751). Combining areal grading requirements with volumetric earthwork costs resulted in areal earthwork costs ranging between $1.68/$m^2$ and $13.97/$m^2$, with a median value of $5.06/$m^2$ (adjusted to 2006 USD).

## Liners

The decision to install a liner in a wetland system, and which type of liner to use, depends on the project goals, regulatory requirements, and feasibility. Some wetlands are unlined, either because the *in situ* native soils are deemed to have sufficient sealing properties, or because groundwater recharge is a function of the system. Very large FWS wetlands cannot be plastic lined because it is not feasible for systems of more than a few hectares, but clay lining has been implemented on systems up to 40 ha, such as Columbia, Missouri. If the wetland must be lined, there are a variety of liner materials available. The two most common liner materials used are 0.76-mm polyvinyl chloride (PVC) and 1.0-mm high-density polyethylene (HDPE). PVC liners are generally factory seamed, one-piece liners used on small projects less than 0.1 ha in size. HDPE liners generally come in rolls and are field seamed for larger projects.

The total *installed* cost of the liner includes not only the material cost but also the labor cost associated with field seaming, seam testing, material inspection, and leak testing. If local soil conditions include sharp or angular rocks,

**TABLE 23.2**
**Approximate Cost of Installed Liners (2006 USD)**

| Material | Thickness | Installed Cost ($/m²) |
|---|---|---|
| Bentonite | 10 kg/m² | 7.96 |
| Native clay[a] | 30 cm | 7.50 |
| Clay geotextile sandwich | NS | 4.84 |
| Polyvinyl chloride | 0.76 mm | 4.09 |
| High-density polyethylene | 1.02 mm | 4.73 |
| Polypropylene | 1.02 mm | 5.92 |
| Reinforced polypropylene | 1.14 mm | 6.89 |
| Hypalon | 0.76 mm | 6.89 |
| Hypalon | 1.52 mm | 8.07 |
| XR-5 | NS | 11.19 |

[a] Assumes $25/m³ delivered, placed, and compacted.

*Source:* Data from U.S. EPA (2000a) *Constructed wetlands treatment of municipal wastewaters*. EPA 625/R-99/010, U.S. EPA Office of Research and Development: Washington D.C.; and Interstate Technology and Regulatory Council (2003) Technical and Regulatory Guidance Document for Constructed Treatment Wetlands. *http://www.itrcweb.org/WTLND-1.pdf.*

a layer of sand or other granular material may have to be placed before the liner can be installed. If the gravel used to line the bed has sharp or angular edges, it may be necessary to cover the interior of the liner with a protective layer of geotextile fabric, since sharp rock can puncture a liner. Table 23.2 shows approximate installed costs of a variety of liner materials.

Liner costs for the FWS wetland system at Ouray, Colorado, were $6.97/m², and $13.23/m² for the HSSF wetland system at Ten Stones, Vermont (both adjusted to 2006 USD) (U.S. EPA, 2000a). Liner and geotextile fabric costs for 12 HSSF wetlands in the Minnesota–Wisconsin regional market are summarized in Table 23.3. Data from these wetland systems indicate that installed liner costs (adjusted to 2006 USD; ENR CCI = 7751) ranged from $3.74/m² to $19.71/m², with a median cost of $8.66/m². The use of a geotextile fabric will increase the installed liner cost. The data in Table 23.3 indicate that the installed cost will increase by approximately $3.00/m² when a geotextile fabric is used.

If soil at the site contains rocks or other debris that could damage the liner during installation, a layer of sand or similar granular material is often placed prior to installing the liner. For example, 8 cm of sand was placed prior to installing the liner in three Minnesota HSSF wetlands. The installed cost for sand bedding ranged from $1.38/m² to $3.08/m², with a median cost of $2.24/m² (2006 USD; ENR CCI = 7751).

## Media and Mulch

The major cost variation between FWS and SSF wetlands results from differences in the rooting media. FWS systems typically use 30–40 cm of soil, which may be entirely available on the site, whereas SSF wetlands use 50–80 cm of gravel or other similar media, which must usually be purchased and transported to the site.

### *Soils for FWS Systems*

If *in situ* native soils are suitable, they are typically used as the rooting substrate for emergent wetland plants in FWS systems. If *in situ* native soils are unsuitable for use as rooting media, soil may be imported and mixed with existing soil to create conditions adequate for rooting wetland plants. For these reasons, the cost of the rooting medium is usually reflected in the volumetric earthwork costs. However, it is sometimes advantageous to add organic material to the rooting soil for a FWS system, to provide sorption capacity immediately upon start-up (Figure 23.2). Such a blending

**TABLE 23.3**

| **Median Value** | | | **8.66** | **3.08** |

*Note:* Geotextile is a nonwoven, needle-punched polypropylene material (230 g/m² fabric weight) used as a protective layer on top of the liner.

**FIGURE 23.2** Organic materials may be added to the rooting soils to promote early sorption potential. At the Hillsdale, Michigan, site, soils were borrowed from an adjacent floodplain, creating a pond and island complex in the borrow site.

operation may involve approximately 10 cm of amendment material, thus adding 0.1 $m^3/m^2$ of earthmoving to the project, plus the cost of the composting material. Municipal yard waste compost has been successfully used at Isanti-Chisago, Minnesota, and at Saginaw, Michigan, treatment wetlands. The use of purchased topsoil, either entirely or as an amendment, is a very expensive option, because high-quality (horticultural) topsoil typically sells for up to $\$25/m^3$.

### *Media for SSF Wetlands*

A number of innovative types of media have been used in SSF treatment wetlands. Examples include recycled glass fragments, such at Millersylvania State Park, Washington, blast furnace slag (Mann and Bavor, 1993; Drizo *et al.*, 1999), and lightweight expanded clay aggregates (LECA) (Zhu *et al.*, 1997; Jenssen and Krogstad, 2003). The cost of LECA is quite high; for instance, Scholz *et al.* (2001) report $\$204/m^3$ (2006 costs), but it is available in large units (Figure 23.3).

**FIGURE 23.3** Light expanded clay aggregate (LECA) can be purchased in large units in Europe.

The wide variety of SSF wetland media leads to wide variations in costs, but gravel is perhaps the most common material used in Europe and North America (Figure 23.4).

In a HSSF wetland, the rooting medium comprises the material used in the main wetland bed (typically gravel) and the coarser material used in the inlet and outlet zones (typically coarse rock). Costs for these materials are a function of regional market conditions as well as the distance between the source of supply and the project site. For instance, the 4.0-ha VF wetland at Connell, Washington, utilized 36,000 $m^3$ of 2.6-mm coarse sand that was available immediately adjacent to the bed, thus incurring only a cut-and-fill cost (Burgoon *et al.*, 1999). That situation is extremely rare, and most often media will be mined, screened, washed, and transported to the wetland site at considerable cost.

Media costs for 12 selected HSSF wetlands in the Minnesota–Wisconsin regional market are summarized in Table 23.4. This region was glaciated and typically has ample sources of gravel within a reasonable distance of a project. Data indicate that installed gravel media costs (used in the main portion of the bed) range between $\$15.95/m^3$ and $\$70.26/m^3$, with a median cost of $\$41.87/m^3$ (adjusted to 2006 USD). The gravel used in these systems was 9–25 mm in size. Within the Minnesota–Wisconsin regional market, distances between the source of supply (local gravel pit) and the project site were the primary factor in determining unit costs. As the depth of the bed media is established during the design process, calculation of areal costs is relatively straightforward. All of the HSSF systems in Table 23.4 were designed with a bed depth of 0.45 m, resulting in a median areal cost of $\$18.84/m^2$.

Media costs presented in Table 23.4 are higher than those presented in the literature for other HSSF systems. For three HSSF wetlands (Mesquite, Nevada; Carville, Louisiana; and Ten Stones, Vermont), U.S. EPA (2000a) reported bed media costs of \$14.33, \$23.58, and $\$14.74/m^2$, respectively (2006 USD). These were deeper beds (0.8, 0.75, and 0.75 m, respectively), and the volumetric cost of the media was less.

**FIGURE 23.4** Gravel media being placed at the Grand Lake, Minnesota, HSSF wetland.

### *Mulch*

In cold-climate regions, it may be necessary to insulate a HSSF system. This may be done with straw, or cover blankets for small systems. Mulch may be used as an insulating layer for cold-climate wetlands, and is a common design feature of HSSF wetlands in Canada and the northern regions of the United States (Figure 23.5). All of the wetlands in Table 23.4 were insulated with 0.09 m of reed-sedge peat. Installed costs for this peat material (2006 USD) ranged between \$23.94/$m^3$ and \$82.98/$m^3$, with a median cost of \$49.89/$m^3$. This converts to an areal cost of \$4.49/$m^2$.

### *Coarse Stone*

The berm slopes of FWS wetlands may be armored against burrowing animals and wave erosion by the use of rip rap. Coarse rock is a common choice (see Figure 18.19), but concrete matting has also been used (see Figure 18.23).

HSSF wetlands commonly use a coarser material (drain rock) in the inlet and outlet portions of the bed (Figure 23.6). In the United Kingdom, the stone inlet and outlet zones are typically 0.5 m wide, at full bed depth, and packed with 50–200 mm stone (Cooper *et al.*, 1996). Drain rock used in the 12 HSSF wetlands summarized in Table 23.4 was 20–75 mm in size. Installed drain rock costs ranged from \$25.53/$m^3$ to \$74.41/$m^3$, with a median cost of \$47.59/$m^3$ (adjusted to 2005 USD). U.S. EPA (2000a) reports that costs for outlet materials were \$10.39/$m^3$ (50-mm stone) and \$24.24/$m^3$ (100-mm stone) for the HSSF wetland at Ten Stones, Vermont (2006 USD).

## Plants

The plant component of capital cost varies according to the method chosen for vegetation establishment. It is presupposed that the media is in place, either the soil layer in a FWS system or the gravel in an SSF system. The FWS

**FIGURE 23.5** Peat mulch in place at the Grand Lake, Minnesota, wetland.

wetland offers the largest number of options, including natural recruitment, seeding, and planting.

### *Natural Recruitment*

This option is the least costly but the least controllable, and usually of the longest duration. It is not free from cost, because moist soil conditions must be maintained, which in turn requires water management on the wetland. Virtually all of the Florida stormwater treatment wetlands (STAs) were established in this way. A newer strategy for these STAs is the use of a seeded sacrificial rice cover crop (*Oryza sativa*), which assists in soil stabilization and initial nutrient immobilization. This cover crop lasts only one growing season, does not renew itself, and gives way to other wetland vegetation.

**FIGURE 23.6** Inlet coarse rock zone at the Fish and Royer, Indiana, HSSF wetland.

### *Seeding*

Seeding is the next least expensive method of vegetation establishment. The techniques range from scattering in the wind (Figure 23.7), to back-pack broadcasting, to the use of seed drills. The seed is then pressed into the soils using a roller or cultipacker, or by light raking. The use of foot travel has also been used effectively, at the Isanti-Chisago site in Minnesota (Loer *et al.*, 1999). Volunteer labor has been used successfully at Brighton, Ontario, and Roblin, Manitoba, where grades 9 and 10 science students participated in seeding (PFRA, 2002). Hydroseeding has been used successfully (U.S. EPA, 2000a) but requires the addition of detergent to loosen the seed covering. In the Great Lakes region of the United States, the optimum seeding time is autumn through late spring.

Seeds for wetland plants may be harvested from local sources as part of the project work, particularly for *Typha*, which produces large seed heads with extremely numerous seeds, and which are easily picked in autumn. Seeds are also available from wetland nurseries in the United States, for over a hundred wetland species. The cost is considerable, ranging from $125 to $1,500 per kilogram of live seeds for common wetland plants in the northern United States (Table 23.5). The seeding rate is typically on the order of 2–4 kg of live seed per hectare. The purchased price of the seed is consequently in the range of $400–$3,000 per hectare, with a median of about $1,200 per hectare. The cost of installation includes the seeding itself (minor) and the fostering of germination and growth, via soil moisture/water management (major). Dry seeding has been estimated at ten man-hours per hectare, and hydroseeding at $145/ha (U.S. Army Corps of Engineers, 2000). Such required activities are usually inexpensive, and are less than the cost of the seed itself.

(a) (b)

**FIGURE 23.7** Seeding of the Brighton, Ontario, wetland (a) and the resulting growth (b). (Photos courtesy J. Pries.)

### *Planting*

The choice to plant originates with the desire to propagate a selected suite of plant species in a short period of time. Planting costs are a function of several different factors. These include the form of plant material (plugs or rootstock), the source of material (locally harvested, on-site nursery, or commercial nursery), the method of planting (manual or mechanical, volunteer or, contractor labor), and the overall planting density (number of plants per square meter). Because

*Source:* Data based on averages from J.F. New, Walkerton, Indiana (http://www.jfnew.com/) and Southern Tier Consulting, West Clarksville, New York (http://www.southerntierconsulting.com/).

(a) (b)

**FIGURE 23.8** Homemade planter used for the Hillsdale, Michigan, treatment wetland (a). The 1.4 ha of basins were quickly planted (b). See Figure 19.6 for a view of the wetland one year later.

of these variables, planting costs vary widely among wetland projects. In projects that employ hand planting, plant material costs may be a small fraction of the installed cost.

Commercial nurseries sell a wide range of wetland plants as potted "plugs" or bare root stock (Table 23.5). The median (2007) cost of bare root propagules was \$0.65 (n = 14), and for plugs, \$0.93 (n = 13). Transportation costs must be added to these, leading to a delivered cost of about \$1.20 per plant. It is sometimes possible to obtain plants from existing stands, such as cattails from roadside ditches. Extraction requires mechanical digging, typically with a backhoe, to a depth of about 30 cm, so as to gather the majority of the root mass. The plants are then separated from the mass by hand, with each propagule containing at least one healthy shoot and at least 20 cm of associated rhizome. The shoot is topped to a height of 30–40 cm, to reduce the amount of foliage that the transplant must maintain after the trauma of transplanting. On-site nurseries may also be established prior to wetland construction, for the purpose of supplying plant materials. However, the planting contractor may prefer to avoid the effort needed to extract and prepare the plants, and opt for the use of purchased plants, as was the case at Columbia, Missouri (Brunner and Kadlec, 1993). Established treatment wetlands may serve as sources of plant materials for new systems. For example, the plants for the Connell, Washington, system (Kadlec *et al.*, 1997) were extracted from the Arcata, California, project, and successfully established in the new wetland. Marsh establishment on the Texas coast required 11.3–29.3 man-hours per 1,000 plants to hand-dig, separate, and transplant various propagule types of 11 marsh species (Dodd and Webb [1975], as referenced by U.S. Army Corps of Engineers [2000]).

The total cost of plants depends on planting density, which ranges over about 0.25–4.0 plants per square meter (spacing of 0.5–2.0 m). If the plants are on 1-m centers, there are 10,000 per hectare. This value is used in Table 23.5 to establish the per-hectare cost of nursery-purchased plant plugs, which ranges from \$8,000 to \$31,000, with a median of \$9,250/ha.

The cost of putting the plants into the ground can be extremely variable. In some instances, innovation has been employed to quickly and efficiently plant a wetland with mechanical equipment (Figure 23.8). However, most small wetlands are planted by hand, with rates of up to 150 plants per person per hour for experienced planting crews. Allowing for lesser efficiency of 50 plants per person per hour, thus requiring 200 man-hours per hectare at 10,000 plants per hectare. This matches estimates provided by the U.S. ACE publication (U.S. Army Corps of Engineers, 2000). For labor at \$20/h, insertion costs would be about \$2,000/ha at 10,000 plants per hectare, or \$0.40 per plant. When combined with the per-plant purchase price, the cost would be \$1.60 per plant installed.

U.S. EPA (2000a) suggests a planting cost for FWS wetlands of \$0.83 per plant installed (adjusted to 2006 USD). This may be a reasonable estimate for locally harvested plants, but is probably too low for nursery-purchased plants.

Table 23.6 summarizes planting costs for HSSF wetland systems in the Minnesota–Wisconsin, U.S. regional market. All of these systems were hand-planted with rootstock (primarily *Scirpus atrovirens*, *Scirpus fluviatilis*, and *Scirpus cyperinus*) purchased from commercial wetland plant nurseries in Wisconsin. All 12 systems were planted at a density of 2.7 plants/per square meter. This represents an aggressive planting approach that uses well-established rootstock and is designed to achieve complete plant coverage in about two growing seasons (which is approximately 18 weeks per year in this climatic region). The median of \$4.58 per plant installed, in Table 23.6, is much higher than the estimate mentioned previously. The difference may be attributable not only to labor costs and other regional market factors but also to the unfamiliarity of the contractors with planting as a construction activity. On an areal basis, Table 23.6 shows a median of \$12.32/m$^2$. In another adjacent climatic region, for the Minoa, New York, HSSF wetland, planting costs were \$9.45/m$^2$.

For small to medium size wetlands (less than 10 ha), planting costs are less than 10% of the total capital cost. This

**TABLE 23.6**

[a] Costs in 2006 USD.

fraction applies to all regions, such as Spain (Nogueira *et al.*, 2006). For very large FWS wetlands, planting is too expensive, and natural recruitment is relied on.

## Structures

Hydraulic control of wetlands is generally provided through distribution piping and water level control structures. Inlet distribution, outlet collection, and water level control are required in all systems.

Many FWS systems operated with parallel paths, thus a splitter structure is needed to apportion the flows among flow paths. Depending on the size of the system and the complexity of the structure, costs will vary, but may be about $5,000–$10,000 for a 1-ha wetland (Wallace and Knight, 2006). In FWS wetlands, inlet distribution is normally accomplished using an inlet deep zone across the width of the wetland, also called an inlet spreader canal. The cost for this is part of the cut and fill for the overall project. These deep zones may be filled with coarse rock to discourage rodents, thus incurring the cost of the rock.

Sometimes a perforated pipe is placed at the bottom of the deep zone, to aid in uniform introduction of the water. The cost of 10-cm diameter perforated PVC is roughly $20/m. In warm climates, distribution piping may be above ground and above water (see Figure 18.23). Gated aluminum irrigation piping costs on the order of $30/m for 30 cm diameter, with lesser costs for smaller diameters. The 30-cm size can convey up to 15,000 $m^3/d$ without excessive headloss, and smaller diameters may be used for smaller flow rates.

Small HSSF wetlands may receive nearly raw wastewater, which will necessitate some form of inlet trash screening. In the United Kingdom, this may be a Copasac™ chamber with a filter bag; in other countries, a cleanable bar screen is used. If the water is delivered from a septic tank, or other settlement chamber, then this screening device may be unnecessary.

In small- to mid-sized HSSF wetlands, flow is generally distributed across the width of the bed in the inlet zone using perforated pipes or infiltration chambers. Perforated PVC pipe (100-mm diameter) is commonly used as a low-cost distribution method for small systems. The drawback of using perforated pipe is that the influent organic loading is concentrated at the perforations. Infiltration chambers (Figure 23.9) have a louvered sidewall which provides a greater number

**FIGURE 23.9** Placement of inlet distribution chamber at Lake Elmo, Minnesota. (From Wallace and Knight (2006) *Small-scale constructed wetland treatment systems: Feasibility, design criteria, and O&M requirements*. Final Report, Project 01-CTS-5, Water Environment Research Foundation (WERF): Alexandria, Virginia. Reprinted with permission.)

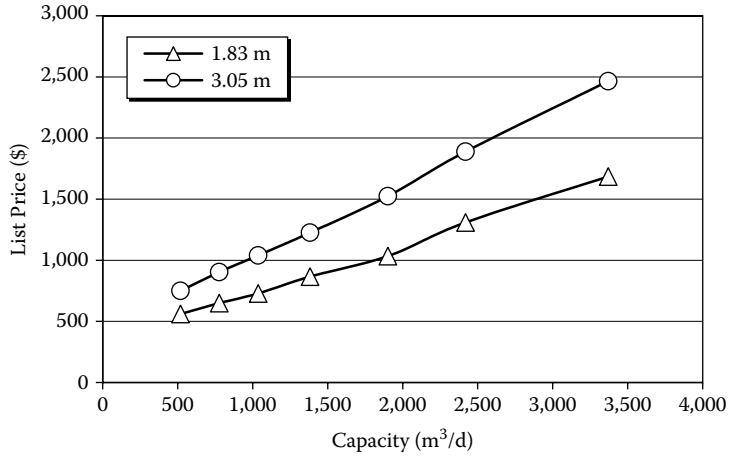

**FIGURE 23.10** Example pricing of simple in-line stoplog structures. The height of these contained units is variable; data are shown for 1.83 and 3.05 total structure height. The capacity is for a height over the weir of 25 cm. See Figure 18.26. (Data from Agri Drain Corporation, Adair, Iowa. Date: March 30, 2007, CCI = 7,856. http://www.agridrain.com/watercontrolproductsinline.asp.)

of openings and a larger cross-sectional area, both of which are desirable for evenly distributing the influent organic load. Generally, the same device (perforated pipe or infiltration chamber) is used at the outlet end of the bed for effluent collection. Installed costs for perforated pipe and infiltration chamber approaches in the northern United States are about $20/m and $40/m, respectively (Wallace and Knight, 2006).

The water level within a wetland cell is regulated by a downstream water level control structure. A typical outlet structure for small FWS wetlands is shown in Figure 18.27, and an outlet for a moderately large system in Figure 18.28. The costs for typical low-flow level control structures are given in Figure 23.10. A simple flexible pipe outlet level control structure for a HSSF wetland is shown in Figure 23.11. Some small systems use premanufactured "pond valves" that utilize stacking plates (with a 100 mm inlet and outlet pipe) to set the water level. Costs for this approach are below $1,000 for flows under 500 $m^3$/d (Wallace and Knight, 2006). Larger projects may use precast or cast-in-place concrete structures with a weir device (stop log, fixed plate, or adjustable weir gate). The ability to adjust the water level is an important control element, and providing operational control over the water depth in the wetland is well worth the incremental cost over fixed-level structures.

**FIGURE 23.11** Outlet level control structure at Pribraz, Czech Republic. Flexible pipes may be raised or lowered to adjust water level. There are two cells controlled by this device.

Large inlet and outlet structures for FWS systems can be fairly complicated, with many cost components (see Figure 18.22). These may involve remote sensing of water levels, sent to an operations center by telemetry, and remote control of opening and closing. Therefore, there is a need for electrical power, and the associated control equipment. The structure requires appropriate bedding, which usually means imported gravel. The cost breakdown for an example is given in Table 23.7. Despite the apparent complexity and cost, such structures are more economical when measured in terms of cost per unit flow rate. The structure of Table 23.7 cost approximately $0.42 per $m^3$/d, whereas the AgriDrain™ units cost about $0.71 per $m^3$/d.

**TABLE 23.7**
**Capital Cost of One Inlet Structure for STA2 Cell 4**

| Item | Description | Cost ($) |
|---|---|---|
| Piping | 40 m of 1.68-m diameter @ $983/m | 39,323 |
| Structure | Slide gate | 29,595 |
| Excavate, bed, install | 917 $m^3$ gravel | 9,095 |
| Sensors | — | 21,244 |
| Telemetry | — | 9,560 |
| Stilling wells | — | 26,644 |
| Electrical control | — | 36,115 |
| **Total** | | **171,577** |

*Note:* Adjusted to 2006 USD, CCI = 7,751. There are six such structures for the 816-ha wetland.

*Source:* Data from Brown and Caldwell (2005) *Basis of design report, Stormwater Treatment Area 2 Cell 4 Expansion Project*. Report to South Florida Water Management District. http://www.sfwmd.gov, West Palm Beach, Florida.

### Site Work

These site work costs generally include construction elements such as construction of access roads to the project site, fencing (if required), installation of electrical power to the project site, erosion control, seeding (outside wetland areas), and surface restoration. As the nature and extent of these site work requirements change from project to project, these costs will also vary. Fencing is a common requirement, and three-meter cyclone fencing costs approximately $50/m installed (Marsh *et al.*, 1998). Rodent exclusion fencing cost an additional $75/m installed at the 2-ha Hillsdale Michigan site (Kadlec *et al.*, 2007). Site work costs for 12 HSSF wetlands in the northern United States, ranging from 400 to 6,000 $m^2$, had a median of $46.08/$m^2$ (2006 USD), which was 8.1% of the total project cost (Wallace and Knight, 2006).

### Ancillary Benefits

As discussed in Chapter 19, ancillary benefits are sometimes part of the design philosophy of a treatment wetland, particularly a FWS system. Boardwalks, viewing platforms, hiking trails, information kiosks, visitor centers, and parking lots are typical added features for those treatment wetlands, and can add considerable expense. However, challenges to those expenditures are rare or nonexistent, because of the great public interest and acceptance of visitor features.

## Indirect Costs

### Engineering and Permitting

Engineering activities include conceptual design, final sizing, preparation of plans and specifications, preparation of the O&M manual, and permitting. These costs depend upon the size, complexity, and novelty of the project. In the United States, single-home HSSF wetland designs for domestic wastewater treatment wetlands can be produced for a few hundred dollars—in those locations where prescriptive design criteria have already been approved by local regulators. The time required to produce approved plans is a matter of weeks.

However, FWS wetlands, targeting other wastewater sources and differing cleanup goals, present a much different situation. Designs become performance based, and require significant expertise in conceptual design and sizing. There are likely to be no well-established regulatory procedures, which means that obtaining the necessary permits can become a challenging and time-consuming process. Because of scale, the number and complexity of drawings increases. A larger project is likely to go through several design phases and produce a conceptual design, a basis of the design report, and 10%, 30%, 90%, and final design reports—each subject to scrutiny and possible revision. The project may be subjected to value engineering, a process by which outside experts examine the project plans to ascertain if further economies might be realized.

Design costs for larger projects are usually expressed as a percentage of the overall construction costs. The cost of the routine engineering design has often been estimated at approximately 10–15% of the overall construction cost (U.S. EPA, 2000a). This amount is probably insufficient to deal with a long, drawn-out permitting process.

### Nonconstruction Contractor Costs

In addition to the construction elements of site work for a wetland system, the project will incur other project costs. Contractor expense costs are incurred by the contractor, but are not directly connected to the wetland construction. These typically include mobilization, bonding, insurance, traffic control (if required), and construction surveying and staking. These costs are dependent on factors such as the distance to the project site the contractor has to mobilize, the contractor's previous history with insurance carriers and bonding companies, bonding requirements in the construction contract, whether the construction work will impact existing traffic patterns, and the extent of surveying required to set reference stakes for site grading and pipe installation. Contractor overhead, or burden, is the cost of doing business that is not attached to any particular project, and it is commonly associated with the direct labor charges as a percentage. Because these items change from project to project, some variation in nonconstruction costs can be expected. Nonconstruction contractor costs for 11 HSSF wetlands in the northern United States ranged from 0.8% to 6.8% of the overall construction cost, with a median value of 4.0% (Wallace and Knight, 2006).

### Construction Observation and Start-Up Services

Services provided during construction and start-up typically include construction observation, inspections, testing, start-up assistance, and operator training. These components constitute approximately 10% of the overall construction cost (U.S. EPA, 2000a). Construction supervision needs to involve the services of a knowledgeable treatment wetland specialist, as a complement to the usual supervision of the implementation of civil works. Start-up also requires such services for the period of vegetation establishment. Operator training should include a good foundation of the general principles of treatment wetlands, as well as the specific characteristics of the project.

### Contingency and Escalation

Escalation is an allowance for inflation. Contingency is a percentage of the base cost to cover errors in human judgment, and it is intended to be spent. The amount of money set aside or planned for unforeseen events is a function of the level of the economic estimate being formulated. A project's risk elements may include accidents, vandalism, theft, work quantity and productivity variances, unfavorable weather, and bankruptcies. Contingency allotments of 10–30% are typically used.

### Illustrations

It is instructive to combine the various elements of capital cost into a summary by category. There are too many variables to do this in a general way, and consequently a few illustrations are presented here.

Table 23.8 shows a capital cost list for a hypothetical small-scale FWS treatment wetland. The 1-ha system might receive a hydraulic loading of 300 $m^3$/d (3 cm/d). The direct cost is $320,000/ha. It is seen that over 50% of the direct cost is for earthwork and liner, and another 28% is associated with planting soil and plants. The cost of land has been included, but is a small fraction of the total for this small wetland. The indirect costs are 50% of the direct costs.

Table 23.9 is the listing of estimated direct capital costs for STA2 Cell 4 of the Florida Everglades protection project, an 816-ha system construction-completed in 2006, and Table 23.10 lists the indirect costs (Brown and Caldwell, 2005). The direct cost is $8,513,000, or $10,433/ha. Most of the cost is associated with earthwork (31%), site preparation (28%), and structures (28%). There are no liner costs, and no planting soil or plant costs. Land costs have not been included, because the property was acquired through a convoluted set of purchases, sales, and exchanges. An approximate estimate is $12,500/ha, which would increase the capital unit cost to $23,000/ha. Regardless of the cost distribution, this very large system is much less expensive on a per-hectare basis than the 1-ha system, emphasizing that economy of scale is highly important. In fact, there is so much change with scale that any "universal" value for dollars per hectare, mean, or median is meaningless. The indirect costs for this project, or markups, total $6,144,000, i.e., 74% of direct costs excluding land, or 33% based on land plus construction.

**TABLE 23.8**

*Note:* Land costs are not included. There is no liner and no planting. Flow is by gravity.

[a] Costs in 2006 USD.

Capital costs for HSSF wetland systems are generally estimated using the same "line item" cost approach discussed for FWS wetlands. Construction quantities are calculated from the design, and the cost for each of these items is estimated using local or regional cost information. An example of this approach, using excerpts from an actual bid tabulation, is shown in Table 23.11. This example does not include land costs, but the contractors indirect charges are included, and are dispersed throughout the unit costs. Not surprisingly, most of the construction cost is for the media (36%) and liner (24%).

*Note:* Engineering costs are not included.

## Economy of Scale

A strong determinant in the overall cost of a wetland treatment system is the size of the system. Larger projects generally benefit from economies of scale, resulting in lower unit costs. The size of the project may be measured as the wetland area, or as the flow rate treated, or as the population served if the water is domestic wastewater. Cost functions relate capital expenditure to these measures, and commonly take the form of a power law, with an exponent of 0.6–0.7 often being appropriate. Cost data in the wetland literature is often ambiguous about what has been included or excluded. Land costs are often not included, and the same is true of indirect costs. For small HSSF domestic systems, costs of the collection system and pretreatment devices (septic tanks) may be included. Therefore, the reader is advised that the following compilations of reported costs are subject to considerable variability, and will generally be lower than the summation of the various categories enumerated previously.

Figures 23.12 through 23.15 present the trends of costs with size or flow capacity for FWS and HSSF systems in the United States. These are reasonably well represented by the following relationships:

Areal:

$$\text{FWS:}\quad C = 194A^{0.690}\quad R^2 = 0.79\quad 0.03 < A < 10{,}000 \tag{23.1}$$

$$\text{HSSF}\quad C = 652A^{0.704}\quad R^2 = 0.75\quad 0.005 < A < 20 \tag{23.2}$$

Flow:

$$\text{FWS:}\quad C = 518Q^{0.729}\quad R^2 = 0.79\quad 1 < Q < 5{,}000{,}000 \tag{23.3}$$

$$\text{HSSF:}\quad C = 561Q^{0.498}\quad R^2 = 0.76\quad 0.5 < Q < 10{,}000 \tag{23.4}$$

where

$A$ = wetland area, ha
$C$ = cost, 2006 dollars in thousands
$Q$ = flow rate, $m^3/d$ in thousands

**TABLE 23.11**
**Selected Bid Results for a 300-$m^2$ HSSF Wetland on the U.S.–Canadian Border[a]**

| **Constructed Wetland Subtotal** | | | | **37,489.84** | | **34,367.86** |

[a] Costs in 2006 USD.

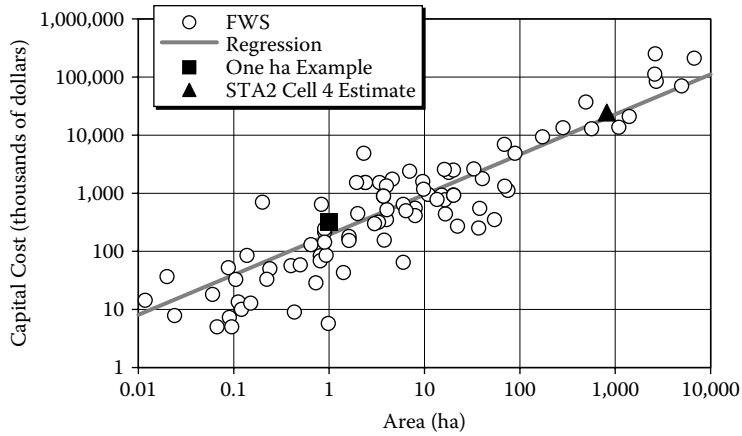

**FIGURE 23.12** The capital cost for FWS wetlands as a function of size (N = 84 wetlands). Points for $A < 300$ m$^2$ were excluded from the regression. $C = 194\,A^{0.690}$; $R^2 = 0.79$; $C$ in 1,000s of dollars.

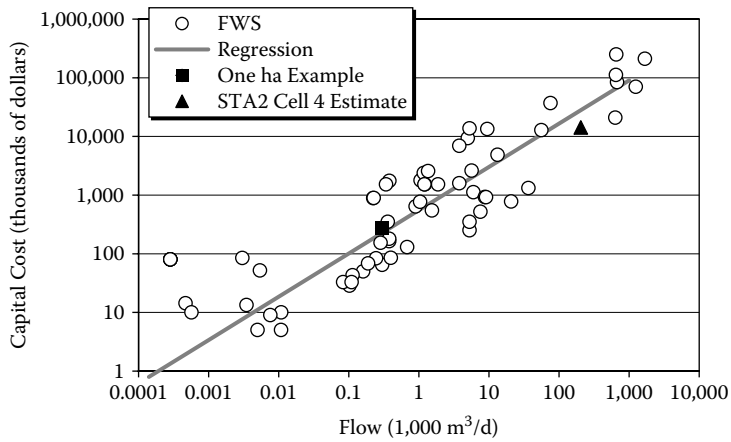

**FIGURE 23.13** The capital cost for FWS wetlands as a function of flow rate (N = 61 wetlands). Points for $Q < 1$ m$^3$/d are not considered in the regression. $C = 518Q^{0.729}$; $R^2 = 0.79$; $Q$ and $C$ in 1,000s of dollars.

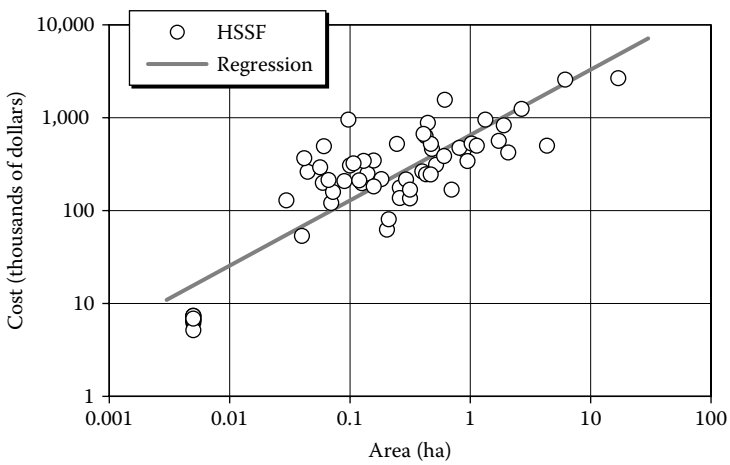

**FIGURE 23.14** The capital cost for HSSF wetlands as a function of size (N = 63 wetlands). $C = 652\,A^{0.704}$; $R^2 = 0.75$; $C$ in 1,000s of dollars.

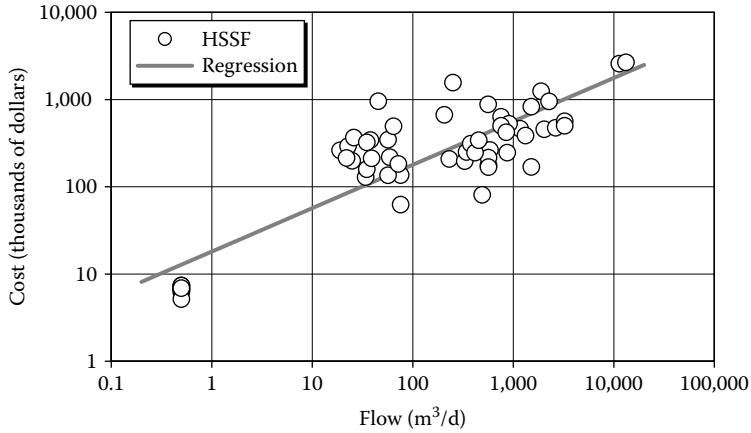

**FIGURE 23.15** The capital cost for HSSF wetlands as a function of flow rate (N = 58 wetlands). $C = 18Q^{0.498}$; $R^2 = 0.76$; $C$ in 1,000s of dollars.

The result of the nearly identical exponents for area is a nearly fixed ratio of costs for FWS and HSSF systems over the range of areas where both are used (about 0.1–10 ha). That ratio is 3.32 ± 0.14, with HSSF being the more expensive. The literature contains several estimates of the median cost per hectare for FWS and HSSF wetlands. For the data reviewed here, these medians are $98,000/ha for FWS and $1,230,000/ha for HSSF systems. These unit costs are not usable in a comparison, because they cover entirely different size ranges. As detailed in Chapter 16, treatment per unit area is about the same for FWS and HSSF systems, and as seen here HSSF costs are about triple those for the equivalent FWS system.

A direct comparison of costs on a flow basis is inappropriate, because FWS and HSSF systems are generally designed for different pollutants and different removals.

These cost functions may be used to obtain an approximate cost for a prospective project, but should not be used in lieu of detailed cost estimation.

In many cases, for domestic wastewater treatment, the measure of HSSF wetland size is the population served, partly because only design flows are known and partly because the cost to the individuals served is the desired result. Some results reported in the literature are:

$$\text{HSSF (Central America):} \quad C = 360\ PE^{0.755} \quad R^2 = 0.97 \qquad \text{Platzer } et\ al. \text{ (2002)} \qquad (23.5)$$

$$\text{HSSF (Spain):} \quad C = 490\ PE^{0.707} \quad R^2 = 0.71 \qquad \text{Nogueira } et\ al. \text{ (2006)} \qquad (23.6)$$

$$\text{HSSF (Portugal):} \quad C = 2{,}200\ PE^{0.679} \quad \text{estimated} \qquad \text{Junca de Morais } et\ al. \text{ (2003)} \qquad (23.7)$$

where
PE = Population equivalent
$C$ = Cost, 2006 USD

The high regional variability is apparent in these relations.

No matter which measure of scale is used, it is clear that an exponent of something like 0.7 is appropriate for scaling of these continuous flow systems.

Stormwater systems present a different situation, because the wetland size is often determined from the watershed size, and not any specific performance specification. Scaling to the size of the watershed may then be more appropriate (Wossink and Hunt, 2003). For the state of North Carolina, the following cost function has been derived by Wossink and Hunt (2003):

$$\text{Stormwater wetlands} \quad C = 6{,}910\ WS^{0.484} \quad 1 < WS < 100 \qquad (23.8)$$

where
WS = Watershed area, ha
$C$ = Cost, 2006 USD

This amounts to a set of formulas when converted to wetland area, because the guidelines for sizing in North Carolina specify wetland to watershed area ratios (WWARs) of between 1.0 and 6.5%.

## 23.2 OPERATION AND MAINTENANCE COSTS

Wetland systems have very low intrinsic O&M costs, including pumping energy, compliance monitoring, maintenance of access roads and berms, and mechanical component repair. These basic costs are much lower than those for competing concrete and steel technologies, by a factor of 2–10. Attempts at harvesting, or at maintenance of a particular vegetation species composition, can prove costly. Ancillary research costs—which can occur at the directive of the regulatory agencies—have sometimes cancelled out this large potential advantage, especially for natural treatment wetlands. Most maintenance tasks associated with operating a wetland facility deal with servicing pump headworks, and other conventional components of the treatment plant (U.S. EPA, 2000a).

### Free Water Surface Wetlands

The O&M costs for a FWS facility include pumping energy, compliance monitoring, dike maintenance, and equipment replacement and repairs. Dike maintenance consists of mowing and preservation of structural integrity. Equipment replacement and repairs pertain to piping and pipe supports, structures, and pumps. Pumping energy may be accurately quantified, as can the initial level of compliance monitoring, once a permit is issued. Mowing is primarily a matter of aesthetics, with secondary emphasis on visual detection of snakes and alligators. If public use is encouraged, there may be a need to maintain signage, trails, and boardwalks. Nuisance control or removal may be required, most often targeting mosquitoes, burrowing rodents, and bottom-stirring fish. Nuisance control, such as mosquito and rodent eradication, has sometimes proved to be troublesome.

The sum total of these activities is usually relatively inexpensive. No chemical purchases are involved, and there is not a need for highly trained personnel, nor significant time requirements for the necessary semiskilled employees. Annual costs range from $5,000 to $50,000 per year for small systems. However, ancillary research can greatly increase these expenditures. The estimate for the Incline Village system, made at the time of final conceptual design, was $163,000 per year (Table 23.12).

Permit-related sampling and reporting, combined with maintenance of upstream and downstream treatment processes, constitute most of the routine O&M associated with FWS wetlands. At Arcata, California, it has been estimated that O&M tasks directly associated with the wetlands require about $1600/ha·yr when adjusted to 2006 USD (U.S. EPA, 2000a). These types of routine checks do not include muskrat or nutria removal, or mosquito control, which will increase operating costs. Costs for these types of animal or vector control activities are highly site specific in nature, and are generally best estimated by assessing the amount of operator labor involved plus the cost of any control agents or equipment.

**TABLE 23.12**
**Estimated O&M Costs for the 135-ha Incline Village FWS Wetland System**

| Item | Annual Cost ($) |
|---|---|
| Personnel | 95,315 |
| Energy | 4,766 |
| Monitoring | 40,032 |
| Maintenance materials | 22,876 |
| **Total** | **162,988** |

*Note:* This information was developed after the conceptual design was finalized. It does not include research costs, nor profits derived from hunter use charges. Costs are in 2006 USD. O&M = operation and maintenance.

*Source:* Data from CWC (1983) *Draft Design Memorandum, Incline Village General Improvement District Wetlands*. Culp, Wesner, and Culp (CWC): 3461 Robin Lake, Cameron Park, California.

The limited amount of FWS O&M data from the literature is presented in Figure 23.16, and shows a median cost of about $2,000/ha.

### Subsurface Flow Wetlands

One primary operating cost of a single-home HSSF system is the cost associated with pumping the septic tank. Other costs are mainly determined by local permit requirements, which vary widely across the United States. In western Ohio, the annual maintenance and monitoring costs are approximately $250/yr when adjusted to 2006 costs (Steer *et al.*, 2003). Many systems are permitted at the state or provincial level, and are required to have licensed operators submit monthly discharge monitoring reports. An example of the cost breakdown for an HSSF system is shown in Table 23.13. Most of the O&M is associated with permit-related sampling and correspondence, followed by management of pumps, septic tanks, control

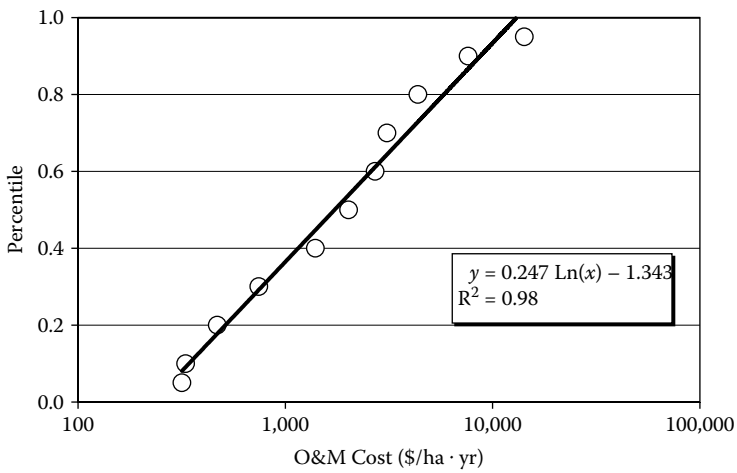

**FIGURE 23.16** Operation and maintenance (O&M) costs for FWS wetlands (N = 21).

| *Subtotal* | *8,101* |
| **Overhead** | |
| Billing | 1,437 |
| **Total** | **25,085** |

*Note:* Costs are in 2006 USD. Note that the inlet zone of the wetland bed line item accounts for nearly 50% of the maintenance cost.

panels, and other conventional treatment components. For small-scale systems, it is not meaningful to project per-hectare O&M costs because small HSSF systems have essentially the same monitoring and reporting requirements as large systems. For larger systems, it is possible to separate wetland O&M from total O&M required, including the rest of the facility. The annual O&M expenses for the HSSF wetland at Carville, Louisiana (568 $m^3$/d, 0.26 ha), were estimated at $780/yr or $3,000/ha.yr (U.S. EPA, 2000a) (2006 USD). This is approximately 6% of the O&M budget for the entire treatment system.

Inlet zone maintenance has the potential to be a large component of HSSF maintenance costs. Inlet zone maintenance will depend on the remedy method selected (replacement, washing, or chemical cleaning; none of these procedures have been used widely to fix clogged HSSF wetlands). Also, the time interval between bed maintenance is a factor. To date, no rational methods to predict bed clogging have been developed, although it is apparent that it is a widespread problem in full-scale HSSF wetlands (Cooper *et al.*, 2006a).

Here, we will consider the potential economic consequences of inlet zone maintenance. In the example of Table 23.13, it was assumed that inlet zone maintenance would be 15% of the construction cost, and inlet zone maintenance would occur every five years. These assumptions are based on the very limited data presented in Table 22.6. Based on these assumptions, and Equation 23.2, the cost for inlet zone maintenance every five years is predicted at $20,438 (2006 USD); at a 5% interest rate, the annual cost is $3,698. The assumption parameters (time to clog, percentage of construction costs) can, however, vary. It is apparent at this stage of technology development that inlet zone clogging is likely to be the largest maintenance cost component associated with HSSF wetlands. When evaluating the cost-effectiveness of any future projects, inlet zone maintenance costs must be considered. The continued viability of HSSF wetlands as an economically efficient technology is dependent on finding a cost-effective solution to the clogging problem.

## 23.3 PRESENT WORTH ANALYSES

The capital costs for a wetland project are "up front" needs, typically expended in the first year of the project. In contrast, the O&M costs are recurring, with a need for expenditure in every year of operation. Thus, when evaluating alternatives or planning for financing, it is necessary to combine these two types of costs to obtain a true picture of the overall project cost. Two basic choices are available. The first is to convert the future time stream of O&M costs to an amount of money that one would need to put in the bank to pay for the future O&M, and add it to the initial capital investment. This procedure produces the present worth of the project (Humphreys, 1991). The second choice is to convert the initial capital investment into a time series of payments that may be added to the time series of O&M costs, to create an annualized project cost. In essence, the capital cost is borrowed, and repaid over time. It is this latter approach that is often used for financing wastewater treatment projects. In fact, in the United States, a homeowner may well be paying the two bills separately each month: one payment to pay off the debt on building the system, and a second to pay for operating costs. Unfortunately, only a very few literature sources deal with the combination of both types of project costs for treatment wetlands.

Treatment wetlands are distinctively different from mechanical plants in a few very important ways. It is therefore necessary to examine the basic elements of the accumulation of costs, and for simplicity we here consider only the present worth analysis. However, it is a relatively simple matter to weave these concepts into an annualized cost analysis. Over the life of the project, in a simplified sense, it is expected that the following costs will be incurred:

- Capital costs, both direct and indirect, usually in the first year of the project life.
- Annual O&M costs. These include monitoring and other routine activities.
- Periodic, nonannual costs. These might include sediment cleanout, for instance.
- End of project costs and values, sometimes termed "salvage values." These may include not only demolition and disposal costs, but also the resale value of project assets.

The preceding sections have detailed the costs in the first two categories (capital and O&M).

## Present Worth Concepts

The total cost of a project at the time of inception is the total of capital costs, engineering services, and the present worth of O&M costs over the project life. This approach to economic estimating is required when the alternatives under consideration vary greatly in their life expectancy, and in their O&M costs. This is the case for wetlands. The overall project evaluation requires consideration of both capital and O&M costs, and the present worth technique is the appropriate vehicle for combining the two. The present worth of O&M costs, including equipment repairs and replacements, is the money that needs to be set aside now, at the prevailing interest rate, to pay for these future costs.

It is not possible to anticipate all the project-specific details of the economics of treatment wetlands. However, there are certain common features of many projects that are considered here.

### Discount Rate

The time value of money reflects the interest on borrowed sums and the inflation rate. The discount rate used in present worth calculations is the excess of the interest rate over inflation. In treatment wetland evaluations, discount rates of 4–8% are commonly used.

### Life Expectancy

Traditionally, the life expectancy of a "conventional" treatment alternative is 20 years. A treatment wetland has a longer life expectancy than concrete and steel equipment. Although there are no examples of engineered systems with long periods of operation, there are long-lived FWS wetland systems that have retained their effectiveness for up to 80 years, based on ex post facto monitoring. Both the Brillion Marsh, Wisconsin (Spangler *et al.*, 1976b), and Great Meadows Marsh, Massachusetts (Yonika *et al.*, 1979), operated for over 70 years, and in later years were shown to have retained treatment efficiency. As fully functional ecosystems, treatment wetlands may be expected to sustain their character for as long as appropriate hydrology is maintained. It is early in the history of constructed wetland facilities, so there is not a long track record on life expectancies for wetland components. However, in general terms, pumps and piping may last on the order of 40 years, and repair frequencies are known. Berms, dikes, and levees have lives in excess of 50 years. Therefore, it is plausible that treatment wetlands should be ascribed a basic life of 40–50 years, with mechanical components being replaced at greater frequency.

### Present Worth of Future One-Time Costs

The amount of money needed for a future expenditure reflects the discount rate in a simple, compound interest sense:

$$P = S\frac{1}{(1+i)^m} \tag{23.9}$$

where

$i$ = discount rate, fraction per year
$m$ = years before need
$P$ = present value, $
$S$ = future amount, $

Thus a $1,000 pump replacement ten years from now will require $614 today if the discount rate is 5%.

### Present Worth of Future O&M

Many O&M costs occur as a continuing stream. In analysis, it is usual to aggregate these into a yearly amount, and then to compute the sum of all such future payments. This may be done sequentially using Equation 23.9, or the sum can be directly evaluated from

$$P = Y\frac{(1+i)^N - 1}{i(1+i)^N} = Y \cdot F_{\text{pw}} \tag{23.10}$$

where

$i$ = discount rate, fraction per year
$F_{\text{pw}}$ = present value factor, dimensionless
$N$ = life expectancy, yr
$P$ = present value, $
$Y$ = yearly amount of O&M, $

Thus, the median FWS O&M of $2,000/ha·yr (Figure 23.16), over a 50-year lifetime, will require $36,512 today if the discount rate is 5%. Note that payment number 50 requires only $174 of today's money.

### Salvage Values and Decommissioning Costs

It is common practice to claim no salvage value at the end of project life in a feasibility study for mechanical plants; but this does not make sense in the context of a wetland project. Typically, the entire acquisition price is charged to the project up front, and there is no "salvage" value at the end of 20 years. In contrast to the crumbling concrete and rusted steel left after the mechanical process reaches the end of its useful life, the land associated with the wetland project will probably have greater (or equal) value than that at the time of acquisition. This principal component of the wetland project will probably have appreciated in value. It may be more accurate to delete land cost from the comparison for that reason. Investments in land are not subject to normal wear-out and replacement charges in a long-term view of the project economics. Therefore, the "salvage" value of the wetland property, which may have appreciated over the project life, is typically much higher than that of a mechanical plant, which may have depreciated. The present worth of the land after the nominal project life should be included as a credit in economic evaluation if comparisons are being made. These end-of-life costs and values are brought to present-day dollars by use of the present worth factor for the last year of the project.

## Total Present Worth

The various costs, consisting of capital plus the present worth of O&M, various replacement costs, and salvage values, are combined to yield the total present worth of the project. Thus, the example project in Table 23.8 (1 ha), with no replacements or equipment salvage, would yield at 5% discount rate and a 50-year life:

| | |
|---|---|
| Capital cost | $480,000 |
| Present worth of O&M | $36,512 |
| Present worth of final land value | $10,000 |
| Total present worth | $506,512 |

## An Illustration

An alternative comparison is illustrated in Table 23.14, evaluating wetland treatment and chemical treatment to remove phosphorus from agricultural runoff water in southern Florida. The dollar values in this example are large, because it is based on a system for the treatment of a very large flow (≈760,000 $m^3$/d). The estimates in this table were developed from information available at the time of final conceptual design, and are subject to change during final design and the accompanying modifications. The example is included here to illustrate the unique features of evaluating wetland alternatives.

The chemical treatment alternative is 17% cheaper than the treatment wetland on the basis of the capital expenditures needed to build the project. On the surface, this makes chemical treatment the more attractive alternative. This up-front comparison presumes a life span short enough that equipment does not need to be replaced, nominally 20 years. However, if the life span of the project is taken to be 50 years—which is characteristic of constructed wetlands, and has been demonstrated in the region—the analysis changes. It becomes necessary to consider the salvage value of worn out components, and their replacement costs. In Table 23.14, it is assumed that worn out equipment has zero value: it is unsalable, and there is no charge for disposal. On the other hand, land acquired for the project is assumed to maintain its value; no replacement purchases are necessary. It is therefore logical to exclude land costs from the analysis, because it can be sold at the conclusion of the project with no loss in value.

When these factors are taken into consideration, the treatment wetlands are 13% cheaper than chemical treatment. The conclusion of the capital cost analysis is reversed.

Next, the O&M costs are totaled and converted to their present worth. Chemical treatment, as the name implies, requires more energy, materials, labor, and supplies than wetland treatment. Monitoring costs would be the same. In this example, and in virtually all similar cases, O&M costs are higher for the equipment-oriented technology. The annual O&M for chemical treatment is twice as expensive. The present worth of O&M is a significant fraction of the project cost. Consequently, the total present worth of the wetlands project is only 70% of the total present worth of the chemical treatment alternative.

*Source:* Base information from Brown and Caldwell (1993) *Phase II Evaluation of Alternative Treatment Technologies*. Report to the South Florida Water Management District, 18 February 1993.

The assumed factors in this example will not prevail in all circumstances, but it does serve to indicate that extra care should be taken in economic analysis of a wetland alternative.

### Annualized Cost

This procedure has all the same elements as present worth, but the total project costs are allocated to a uniform series of annual payments over the life of the project. In simplest terms, a loan for the initial capital investment is repaid over the life of the wetland, and added to the annual O&M charges. This total annualized cost becomes the basis for comparison. For example, the capital costs for the project in Table 23.13 were $513,515 (2006 USD). At a 5% discount rate and 20-year life, the annual repayment would be $41,206. The O&M is $21,386 per year, and thus the total annualized cost is $62,592.

Another situation in which an annualized cost approach may be warranted is in the calculation of sewer bills. In the United States, homes are typically billed for sewer service on a quarterly or monthly basis. Funds are accumulated and used to pay off debt associated with capital costs, routine maintenance, emergency repairs, and component replacement. An example of this type of rate calculation for a 53-home treatment system is shown in Table 23.15; the associated cash flow is shown in Figure 23.17.

Annualization has also been applied to urban stormwater wetlands in North Carolina (Wossink and Hunt, 2003). For watersheds of 6–20 ha, annual costs were found to be $22,000–$85,000/ha, depending upon the (irrecoverable) value ascribed to land. Those land values were taken to be $125,000/ha for undeveloped residential land, and $540,000/ha for land in commercial development zones. Wetland watershed area ratios of 1.0–6.5% were applied, on a regionally variable basis.

## Cost per Pollutant Load Removed

It is sometimes appropriate to measure the cost of a project, not in terms of the population served or the hectares required, but per-unit mass of pollutant removed. This may be done by dividing the cost by the removal. For instance, phosphorus removal in the Florida Everglades wetland projects has been assessed in terms of the present worth of dollars required divided by the lifetime total mass of phosphorus removed in kilograms. For a discount rate of 8% and a lifetime of 20 years, the present worth for removing an estimated 157,000 kg of phosphorus per year for 20 years was $81,000,000, or about $26/kg.

The concept of nutrient credit trading, coupled with the land needed for treatment wetlands, has spurred consideration of the use of off-site wetlands to remove nitrogen and phosphorus rather than on-plant-site mechanical equipment (Hey *et al.*, 2005). The loads that need to be removed at large wastewater treatment plants are easily identified, as can the costs of such nutrient removal at the plant. Therefore, the wetland alternative needs to be evaluated on the basis of cost per kilogram of nitrogen and phosphorus. FWS treatment wetlands are more economical than traditional removal (Hey *et al.*, 2005).

### Economics of Storage

Cold climate conditions may engender the need for winter storage of wastewater. Overland flow systems require storage whenever the mean daily temperature is below freezing (Crites *et al.*, 2006), but FWS constructed wetlands have a wider operating window. For example, storages for northern wetlands are 180 days at Minot, North Dakota; Houghton Lake, Michigan; and Estevan, Saskatchewan. However, storage may be as much as 320 days in the arctic (Dillon Consulting, Ltd., 2006).

The use of winter storage avoids the "bottleneck" winter period, when some wetland processes are operating at their slowest pace. As discussed in Chapter 17, this period may be avoided if a storage pond is available, or is constructed. There are several competing factors that must be considered in the evaluation of alternatives. First, if the wetland is to operate in winter, the area needed will be larger than that needed in warm conditions. The area factor is on the order of three, meaning that the winter size will be about triple the summer size to accomplish the same degree of treatment for the same flow. This corresponds to a temperature coefficient of about $\theta = 1.07$, and a temperature difference of 16°C (mean summer 18°C, mean winter 2°C). Second, the flow is not the same if storage is added; the entire year's flow must be disposed of during the warm season. For instance, if six months' storage is employed, then the warm season flow will be double the annual average. Therefore, the wetland size is reduced according to the warmer temperatures, but increased to account for the increased flow. Nevertheless, the size of the wetland will decrease if storage is added. Third, the storage pond, however, adds to the overall project footprint, thus increasing land and liner costs. In general, there is only a small difference in total area for storage periods of 90 days, but a significant increase (≈70%) in total project area for 180 days of storage, compared to year-round operation with a large wetland to deal with the winter bottleneck. Fourth, the amount of earthmoving increases, nearly in direct proportion to the volume of water being treated (for level sites).

### An Illustration

As an illustration, consider a system to be constructed on a level site, with a (square) storage pond and a square wetland outline, which may have internal compartments and parallel flow paths (Figure 23.18). The further assumptions are:

- The design hydraulic loading during the warm season is 5 cm/d. If storage is used, this loading rate prevails on average throughout the discharge (warm) season, and determines the required area.
- The design hydraulic loading during the cold season is 1.25 cm/d. If the wetland is to be used year-round, this determines the required area.

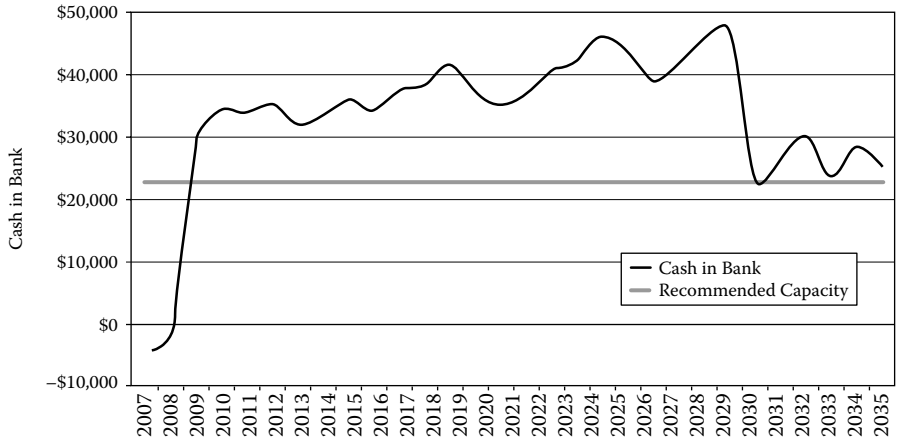

**FIGURE 23.17** Example of cash-flow projection for a 53-home treatment wetland system based on the user rate structure of Table 23.15, using AccuRate financial planning software.

- The soils on the site are acceptable for berms, and thus cut and fill may be balanced. This is presumed for pond and wetland individually.
- Setbacks around the project are 20% of the bermed areas.
- The berms have 3:1 side slopes, and a 3-m top width.
- The storage pond requires a 0.5-m freeboard and a 0.5-m minimum depth. The operating depth change is to be 2 m. Thus, the total depth of the basin is 3 m.
- The wetland requires a 1-m freeboard (to allow for solids accumulation and depth increases) and a 0.3-m average depth. Thus, the total depth of the basin is 1.3 m.
- Wetland internals, meaning inlet and outlet deep zones and cell divider berms, are not considered.

The results of cut-and-fill calculations are given in Table 23.16, for three flow rates (10, 100, and 1,000 $m^3/d$), and for 0, 90, and 180 days of storage. Even though this is a highly simplified illustration, several important issues can be identified. First, the increased summer flows partially balance the higher area requirements for winter operation. This results in a wetland size of one third to half the winter size, not a reduction to one fourth as the loading implies. The earth moved is in the range of 0.4–1.2 $m^3/m^2$ of the total bermed area. The total project area increases with the addition of storage, but only minimally for 90 days. In general, 90 days of storage means less earthmoving than for zero storage, and 180 days does not require much more. The nature of the cut and fill is such that the wetland water surface is near the original ground elevation (−0.29 to +0.09 cm). However, the maximum pond water elevation is above the original grade (0.43–2.09 m).

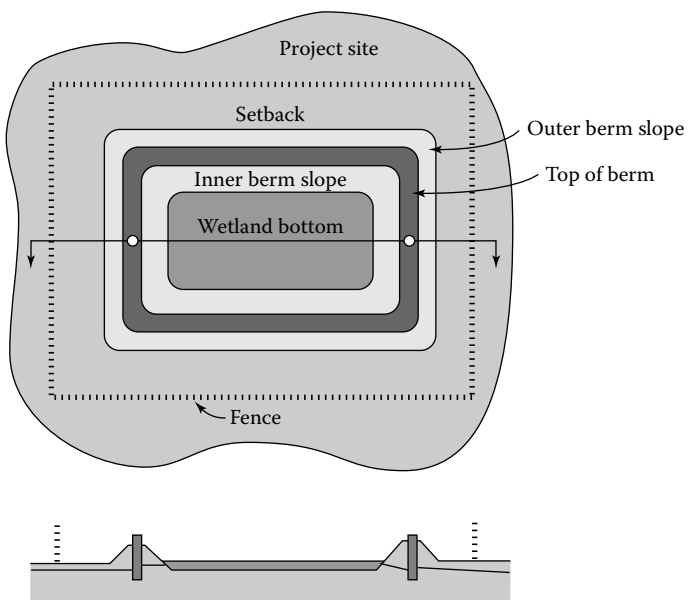

**FIGURE 23.18** General layout of a treatment wetland. For a small system, the overall project footprint is much larger than the wetted area.

**TABLE 23.16**
**Effects of Storage on Project Areas and Earthmoving for Hypothetical Site Conditions[a]**

| | Wetland Wetted Area ($m^2$) | Wetland Earth Moved ($m^3$) | Storage Volume ($m^3$) | Storage Top Area ($m^2$) | Storage Earth Moved ($m^3$) | Project Total Area ($m^2$) | Total Earth Moved ($m^3$) |
|---|---|---|---|---|---|---|---|
| **10 $m^3$/d** | | | | | | | |
| No storage | 800 | 1,207 | 0 | 0 | 0 | 2,332 | 1,207 |
| 90 days | 265 | 446 | 900 | 896 | 708 | 3,204 | 1,154 |
| 180 days | 395 | 634 | 1,800 | 1,505 | 1,280 | 4,681 | 1,914 |
| **100 $m^3$/d** | | | | | | | |
| No storage | 8,000 | 10,901 | 0 | 0 | 0 | 13,852 | 10,901 |
| 90 days | 4,705 | 3,745 | 9,000 | 5,775 | 4,666 | 14,459 | 8,411 |

| 180 days | 39,459 | 52,394 | 180,000 | 95,469 | 34,852 | 187,883 | 87,246 |

[a] See text for conditions and assumptions.

This illustration is not intended to be used in design, because of the highly restrictive assumptions. However, modern computer-aided design tools are capable of easily dealing with irregular sites, more general basin geometries, and wetland internals.

Economics vary from location to location. The relative costs of land and earthmoving combine with the size and volume calculations to provide a basis for alternative selection. In the event that costs of storage or no storage are competitively close, the choice to avoid winter operation is likely to be more attractive. Additionally, controlled discharge strategies can modify the storage and wetland requirements as detailed in Chapter 17. The treatment potential of the combination is evaluated for the wetland (using the procedures in this book) and lagoon (from other sources) performance calculations.

## SUMMARY

Despite the inherent variability in costing a wetland treatment system, basic cost components of a wetland can be estimated using a line-item approach. Wetland treatment systems generally share a basic list of common components, which usually includes items such as land, earthwork, liner, rooting medium, wetland plants, and hydraulic control structures. The cost of these basic components can be estimated using pricing and availability information for a given regional economy. However, the line-item approach makes estimating economies of scale difficult, and has limited application in areas in which local pricing information is unavailable. Other components of wetland system design, such as site investigation, engineering design fees, and operation and maintenance (O&M) costs, should also be included when developing an overall cost estimate.

# 24 Modified and Combined Systems

Treatment wetlands can be designed to be "au natural" or complex. Examples of designs along a full spectrum from almost zero fossil-fuel input to highly engineered and managed systems can be found around the world. In this book we term these design and operation strategies as Type *A* and Type *B* wetlands. Type *A* systems are at the most natural, low-energy end of the scale. Type *B* wetlands are higher-energy and more highly engineered systems. There are good reasons to slide on this scale of design and management complexity, depending upon project goals. In this chapter we describe some of the rationale in selecting the appropriate level of management intensity.

Type *A* treatment wetlands clearly cost less to operate than Type *B* systems. Type *A* systems may also cost less to construct, even though they typically occupy a larger footprint area than Type *B* systems. They are the preferred solution when a number of factors are not limiting:

- Relatively inexpensive land area is abundant.
- Land is relatively level.
- There is insufficient treatment potential with a Type *A* approach.
- There is insignificant potential for unauthorized human interaction with the wastewater in the wetland.

Habitat and aesthetic benefits outweigh the potential for nuisance conditions related to mosquitoes or other wildlife.

Type *A* wetlands are typically constructed free water surface (FWS) marshes and relatively low-tech constant-flow horizontal subsurface flow (HSSF) wetlands.

The Type *B* treatment wetland-management strategy is preferred when one or more of the factors in the preceding list are limiting the design. Specific examples of Type *B* treatment wetlands include:

- HSSF wetlands augmented with reactive media intended for phosphorus or metals removal
- Addition of aerators for treatment improvement
- Operation of vertical flow (VF) wetlands in a fill-and-drain mode for improvement of nitrification and denitrification
- Combinations of VF, HSSF, or FWS wetlands to achieve specific process goals
- Recycling of treated effluent to improve denitrification and/or address influent toxicity issues
- Step-feeding of influent to reduce the impact of localized loading zones
- Wetlands and aquatic plant treatment systems with plant harvesting
- High-solids treatment wetlands with frequently cleaned forebays
- Operating wetlands in a load-and-rest operating regime to address bed clogging or improve treatment efficiency

There are situations where these wetland modifications make sense from a process design and economic standpoint, as discussed in this chapter. However, the system will invariably require more operator attention, and there is often a reduction in system reliability. For instance, if a treatment wetland requires an air blower to achieve regulatory compliance, system reliability is essentially governed by the mechanical blower, not the wetland ecosystem. The same is true for different operating regimes; if a treatment wetland requires alternating periods of loading and resting to avoid bed clogging, failure to follow the prescribed operating sequence will lead to system failure.

Constructed wetlands have limits of performance, which have been discussed in previous chapters. It is human nature to attempt to relieve some of these constraints by modifying the basic wetland construct or its operation. It is the purpose of this chapter to explore some of the innovative ideas that have been implemented to enhance wetland performance. These fall roughly into four categories:

- Ecological or environmental modifications
- Chemical additions
- Operational strategies
- Integrated sequences of natural systems, including one or more wetlands

These will typically move the wetland system from a passive mode (Type *A*) to a mode of active management (Type *B*). They will also usually involve more capital and operating cost, so the potential advantages should be weighed against other options for improving performance, such as alternative technologies or increased size.

## 24.1 ECOLOGICAL OR ENVIRONMENTAL MODIFICATIONS

Natural wetlands have been regarded as "self-designing" systems. They have also been ascribed certain functions that provide many kinds of benefits: habitat, flood control, biodiversity, and water quality improvement. Treatment wetlands target the water quality improvement functions. It is therefore logical—to humans—to try to nudge the wetland to a condition that fosters water quality. For instance, it has been

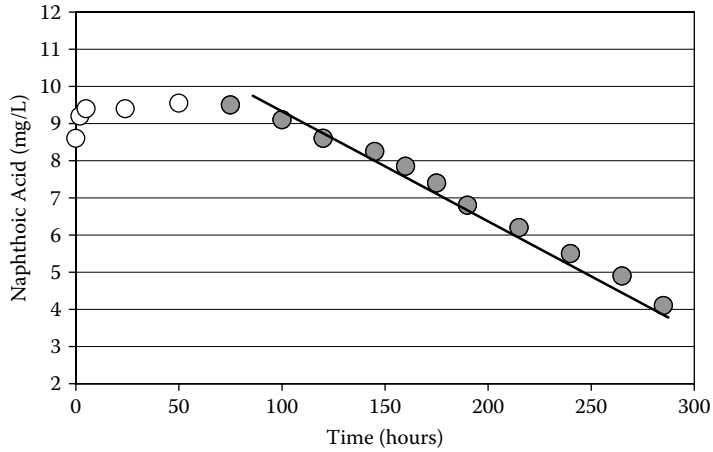

**FIGURE 24.1** Disappearance of naphthoic acid in cattail mesocosms. A zero-order fit is appropriate after an induction period. ($R^2$ = 0.99). (Data from Kadlec and Srinivasan (1995). *Wetland treatment of oil and gas well wastewaters*. Final Report DOE/MT/92010–10 (DE95000176), U.S. Department of Energy: Bartlesville, Oklahoma; graph from Kadlec and Knight (1996) *Treatment Wetlands*. First Edition, CRC Press, Boca Raton, Florida.)

suggested that magnetic fields can improve wetland performance (Rasit, 2006). Ecological and environmental modifications that have been implemented to enhance the treatment performance of wetlands are briefly discussed in the following text.

### Microbial Enhancement

Microbial processing plays a very important role in the reduction of many pollutants in treatment wetlands. In virtually every case, among the many thousands of treatment wetlands, the presence of microbial populations that will deal with the target pollutants is assumed in the design. For the major categories of contaminants, that presumption appears justified: if there is ammonia, nitrifiers are there; if there is nitrate, denitrifiers are there; if there is sulfate, sulfur bacteria are there. However, these populations cannot establish instantaneously, and a period of some weeks of grow-in may be necessary. In general, it does not seem necessary to inoculate a wetland with the desired microorganisms.

It has been found that specialty bacteria—those that focus on particular or unusual compounds—will also require a period of time to develop. This leads to the observation of an induction period, during which little or no pollutant reduction occurs. For instance, Kadlec and Srinivasan (1995) found no degradation of naphthoic acid for about 100 hours in batch cattail mesocosms, but thereafter a steady decline (Figure 24.1).

Runes *et al*. (2001) found that bioaugmentation of sediment with small quantities of an atrazine spill-site soil (1:100 w/w) resulted in the mineralization of 25–30% of atrazine under both unsaturated and water-saturated conditions. Atrazine and its daughter products were almost undetectable after 30 days. Unbioaugmented sediment supplemented with organic amendments (cellulose or cattail leaves) mineralized only 2–3% of atrazine. The population density of atrazine-degrading microorganisms in unbioaugmented sediment was increased from $10^2$ to $10^4$/g by bioaugmentation, and increased to $6 \times 10^5$/g) after incubation. A high population of atrazine degraders (approximately $10^6$ $g^{-1}$) and enhanced rates of atrazine mineralization also developed in bioaugmented sediment after incubation in flooded mesocosms planted with cattails (*Typha latifolia*) and with atrazine at 3.2 mg/L. Runes *et al*. (2001) concluded that bioaugmentation could be a way to enhance constructed wetlands. However, the persistence of degraders was not determined, and could be a constraint.

### Willow Wetlands with Zero Discharge

The growth habit of willows allows their use to provide zero-discharge, zero-percolation treatment for small households. There are approximately 1,400 willow systems in use in Denmark, and these have been described in Chapter 3. They rely upon an excess of evapotranspiration (*ET*) over precipitation, which would not provide acceptable water disposal for *regional* values of *ET*. However, willow wetlands can be configured to enhance *ET* losses by using linear layouts in a crosswind aspect (see Figure 3.27). Willow systems are small, serving 30 PE or less, and are essentially "wind rows" that multiply regional *ET* by a factor of 2.5 due to the clothesline effect described in Chapter 4. The gravel beds that support the willows serve as a reservoir to accumulate wastewater during the wet seasons and periods. During dry periods, the interstitial water is drawn down. Therefore, sizing is determined by the water balance, which in turn is specific to a particular climatic zone (Gregersen and Brix, 2001; Brix and Gregersen, 2002; Brix and Arias, 2005). Approximately 120–300 $m^2$ are required for a single household under Danish climatic conditions.

Raw sewage is pretreated in a sedimentation tank, and the supernatant is pumped onto or just under the surface of the plastic-lined bed. Treated effluent may be collected in a system of drainage pipes, and water may be recirculated back to the pumping well or the sedimentation tank. Zero-discharge

willow systems are constructed with a width of eight meters and a depth of 1.5 meters (Gregersen *et al*., 2003). A drainage pipe is placed at the bottom of the bed, which is used to purge salt water from the bed after salinity rises too much. One third or one half of the willows are harvested every year to keep them in a young and healthy state with high transpiration rates (Brix and Arias, 2005). Harvesting at such small scale can readily be accomplished by hand labor.

The willow systems will me*et al*l regulatory requirements because there is no outflow to any receiving water bodies. Willow systems may also be used in conjunction with soil infiltration. The willows will evaporate all wastewater during the growing season, but during winter there is partial discharge that is infiltrated into the soil.

## Engineered Plants

In previous chapters it has been shown that the particular species of plants used in treatment wetlands is not critical, provided they create and sustain the desired biogeochemical cycles. However, there are differences among plants for some pollutants, most notably for trace metals and trace chemicals. Thus, in addition to the possibility of selection of hyperaccumulators, there is the longer-term possibility of genetic engineering for the desired traits.

In recent years, much attention has been focused on the improvement of plants for the purpose of enhancing phytoremediation through genetic engineering. One approach is to influence the enzymatic pathways for assimilation and volatilization by overexpressing genes of rate-limiting enzymes in plants (Berken *et al*., 2002). Another approach is to introduce additional metabolic pathways for hyperaccumulators. In this way the capacity of plants to take up, accumulate, and volatilize compounds can be increased beyond that of any naturally occurring plant species.

An ideal plant for environmental cleanup can be envisioned as one with high biomass production, combined with superior capacity for pollutant tolerance, accumulation, and degradation. With genetic engineering, it may be feasible to manipulate a plant's capacity to tolerate, accumulate, and metabolize pollutants and thus create an improved plant for environmental cleanup. Pilon-Smits and Pilon (2002) found that mercury volatilization and tolerance was increased by genetic engineering approaches by two- to threefold more metal per plant. Nandakumar *et al*. (2005) found that *Typha latifolia* could be genetically transformed by *Agrobacterium tumefaciens* to enhance phytoremediation enzyme production.

Heaton *et al*. (1998) proposed the use of transgenic aquatic, salt marsh, and upland plants to remove available inorganic mercury and methylmercury from contaminated soils and sediments. They noted that plants engineered with a modified bacterial mercuric reductase gene were capable of converting Hg(II) taken up by roots to the much less toxic Hg(0), which is volatilized from the plant. Plants engineered to express the bacterial organomercurial lyase gene were capable of converting methylmercury taken up by plant roots into sulfhydryl-bound Hg(II).

Results from lab and greenhouse studies are beginning to show promise for transgenics, but field studies are needed to establish their treatment potential, competitiveness in the wetland environment, and risks associated with their use.

## Artificial Enclosures

One extreme example of environmental modification is to place the treatment wetland in an artificial environment. In fact, this is commonly done for bench- and pilot-scale treatment units because the convenience of working indoors (especially in cold climates) outweighs added operational costs such as artificial lighting (Figure 24.2).

In larger-scale applications, greenhouses have been used as artificial enclosures to maximize the use of available sunlight (Figure 24.3). Due to the high cost of the building envelope; greenhouse systems are designed as mechanical activated-sludge processes (U.S. EPA, 1997), although floating plant racks are used on top of the aeration tanks. Plants used in the system may contribute to more stable operation due to retention of biosolids, and lower waste-activated sludge production has been reported (Austin, 2001).

**FIGURE 24.2** Indoor bench-scale unit treating landfill leachate; White Bear Lake, Minnesota. Two 1,000-Watt lights are required to provide the necessary light intensity to support plant growth in these four mesocosms. Care must be taken to ensure that the lights do not cause the plants to dry out or burn. This setup was later modified by constructing a mini-greenhouse over the reactors using a PVC frame and a clear plastic sheet.

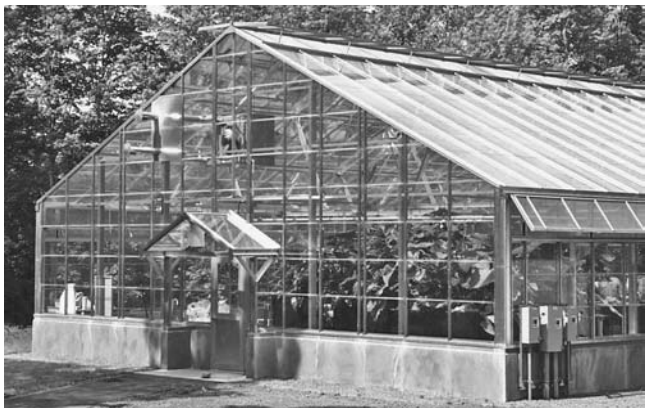

**FIGURE 24.3** Greenhouse-based treatment system near Land O' Lakes, Wisconsin. In the winter, considerable heating costs are incurred to minimize snow loads on the roof.

The energy input associated with the activated-sludge process is quite high compared to treatment wetlands (see Table 1.1), and if the system is located in a cold climate, heating demands can significantly increase energy costs (Brix, 1999).

Due to the high capital and operating costs associated with indoor systems, they have been used in applications where ancillary benefits such as aesthetics, visitor access, and education are at a premium.

## 24.2 CHEMICAL ADDITIONS

Wetlands do not necessarily supply sufficient reactants that may be desirable or required to foster a particular removal process. Those additional reactants may be supplied via the media for either FWS or SSF wetlands, or they may be supplied as additional chemical streams entering the wetland.

### Reactants via Media

The selection of media to support specific chemical reactions is a design issue. In the case of FWS units, it is common to ensure that adsorption capacity is present by the incorporation of organic material in the rooting medium. Peat, compost, or organic soils components also condition the soil and promote easier plant establishment and maintenance. In the case of HSSF systems, a much wider choice can be considered, but typically materials are in three categories:

- Sorbents for phosphorus
- Reactive media for metals, including alkalinity/sulfide generators to generate precipitation reactions
- Materials that are designed to decompose and generate a source of organic carbon for denitrification or sulfate reduction

Light expanded clay aggregates, zeolites, ferrous or calcitic substrates, or organic materials can all be considered. Their phosphorus binding potential has been discussed in Chapter 10. Metals typically will bind to organics, and therefore mine drainage applications incorporate some form of compost as a layer in their substrate. This zone of wetland bed also functions anaerobically to reduce sulfate to sulfide, which then precipitates metals (see Chapter 11). Mulch applied to the top of an SSF wetland bed can be used to supply organic carbon in excess of the plant biogeochemical cycle to fuel reactions such as denitrification if this is a process objective.

All of these techniques of bed solids used as a chemical addition have the implied need for periodic maintenance. Sorbents become saturated, and surface mulches become depleted in soluble materials unless the plant geochemical cycle can produce sufficient organic carbon after start-up. Therefore, these solid reactants must be replaced on some schedule, determined by the stoichiometry and loadings of the materials being treated. Because of the cost and difficulty of restructuring the bed, and reestablishing the wetland, the projected lifetime of a bed solid reactant typically needs to be at least five to ten years. Alternatively, reactant chemicals may be added as separate flows to the wetland.

### Reactants via Added Streams

Mechanical treatment plants often utilize chemical additions to sustain particular portions of their treatment processes. Aeration or oxygen addition fosters both biochemical oxygen demand (BOD) reduction and nitrification. In plants that include denitrification, some means of resupplying the carbon requirement is needed for conventional denitrification, such as utilization of an internal carbon-rich stream or the addition of an external carbon source (Metcalf and Eddy Inc., 1991). Removal of phosphorus in mechanical plants can involve the use of iron or aluminum salts to precipitate phosphorus. These process steps all have analogs in constructed wetland technology.

The processing of nitrogen in a wetland requires oxygen for nitrification and carbon for conventional denitrification (see Chapter 9). Supplies of these necessary reactants may not be sufficient to support the full requirements of required removals. Thus, HSSF wetlands are usually limited in their nitrification capabilities, and VF wetlands are usually limited in their denitrification capabilities. The capacity of a wetland to foster nitrogen reduction may be increased by inclusion of stream additions of carbon or oxygen, often at some considerable operational expense. The cost of such an enhancement should be weighed against other options, including the capital cost of increasing the size of the system if necessary to be closer to the Type *A* end of the spectrum.

### Aeration of FWS Wetlands

Although the entire water surface of a FWS wetland is exposed to air, reaeration is still subject to mass transfer resistances as discussed in Chapter 5. Oxygen supply may therefore be a constraint on BOD reduction and nitrification. It has been supposed that open-water areas may contribute to enhanced oxygen supply (U.S. EPA, 2000a), but

that presumption is in question based on operating data (Kadlec, 2003d; 2005e). Therefore, forced-air diffusers have been considered for augmenting FWS performance, although such attempts have been few. At West Jackson County, Mississippi, air injection was attempted in the deep-zone cross trenches. No conclusive data was obtained because nutria ate the plastic air diffusers.

### *Ouray, Colorado*

Situated at 2,365 meters above sea level, this municipal constructed wetland is surrounded by the San Juan Range, the youngest and steepest range of the Rocky Mountains (Campbell and Ogden, 1999; HDR/ERO, 2001). There is an average annual flow of about 1,500 $m^3$/d, higher in summer during the tourist season. The wetlands are arranged in two parallel paths of three cells each. Each path is 21 × 143 m, for a total system area of 6,100 $m^2$. Vegetation in all six cells is 80 to 90% cattail (*Typha* spp.), with the exception of Cell 3, which is 80% duckweed (*Lemna minor*) and 20% cattail (*Typha latifolia*). Other species present include common reed (*Phragmites australis*), curly dock (*Rumex crispus*), and lady's thumb (*Polygonum persicaria*). Because of concerns of sulfate reduction in the wetland inlet, the inlet deep zone of the wetlands is aerated with submerged perforated air distributors.

The water quality from the aerated lagoon pretreatment is approximately secondary. The wetlands reduced the concentrations of BOD to 4 mg/L, and total suspended solids (TSS) to 6 mg/L, over the period 1996–2000. These are clearly near background, and thus it is not possible to assign any advantage or disadvantage to aeration in these reductions. Ammonia in the wetland influent was not monitored, but the wetland effluent ammonia was 9 mg/L over the same four-year period. This is a high concentration, which exceeds that expected for an aerated lagoon alone, and therefore no large advantage could have been achieved in the wetland aeration for ammonia reduction.

## Carbon Additions to FWS Wetlands

Under many circumstances, denitrification in FWS wetlands is not carbon limited. The decomposing dead biomass is a moderately large carbon supply, although only a fraction of that material is useable (see Chapters 9 and 17). However, some waters contain large enough concentrations of nitrate that removal is constrained by the carbon supply. For instance, Stengel *et al*. (1987) worked with tap water at 30 mg/L nitrate nitrogen and augmented that to 110 mg/L to emulate groundwaters in northern Germany. It was concluded that, under some circumstances, insufficient carbon would be present to support full denitrification.

As noted in Chapter 9, a C:N ratio of 5 or 10 to 1 has been deemed to be required for denitrification. This ratio determines the potential need for an external carbon supply. For instance, for a HLR = 10 cm/d and a nitrate concentration of 50 mg/L, the $NO_x$-N load is 5 g/$m^2$·d. Decomposition of 1,000 g/$m^2$·yr (dry weight) of biomass would yield about 500 gC/$m^2$·yr, or 1.4 gC/$m^2$·d. Thus, the C:N ratio of 1.4:5 is far less than needed to support full denitrification.

### *Lamb–Weston, Connell, Washington*

The Lamb–Weston company built an integrated natural system for treating and reusing wastewater from a potato processing facility near Connell, Washington (Kadlec *et al*., 1997; Burgoon *et al*., 1999). Two 1-ha free water surface wetlands were constructed in series for denitrification of nitrified effluent from VF beds (intermittent sand filters) (see Figure 24.18). The wetlands were designed to remove $NO_3$-N from wastewater prior to land application. During a five-month period of intensive study, the flow was 4,950 $m^3$/d, producing a direct hydraulic loading of 25 cm/d. When coupled with an inlet nitrate nitrogen of 45 mg/L, the denitrification wetlands received a very high nitrate load of 110 kg/ha·d. The chemical oxygen demand (COD) in the nitrified water was insufficient to support denitrification, even with the carbon generated by the wetland plants. Therefore, a small flow of untreated potato wastewater (COD ≈ 3,000 mg/L) was directed to the wetlands as a supplemental carbon supply. This flow raised the hydraulic loading rate (HLR) to 28 cm/d. Addition of this primary effluent resulted in a COD:$NO_3$-N mass load ratio that ranged from 10 to 25. The $NO_3$-N mass removal rate ranged from 50 to 99% of the influent load. During the five months January to May 1998, average monthly effluent $NO_3$-N was 1.6 mg/L, and an average of 85% of the nitrate load was removed (Burgoon, 2001). Thus the feed-forward of untreated water provided the necessary carbon to allow nearly complete denitrification at high loading rates.

Sources of carbon are not always conveniently at hand. Some wetlands have utilized methanol or molasses, but these are expensive. Multiple wastewater sources can potentially provide synergism. For example, the remediation of a high-nitrate source water could be enhanced in a wetland that also received high BOD municipal or food processing wastewaters. At the time of this writing, such multisource systems have been proposed but not built.

## Aluminum and Iron Additions to FWS Wetlands

The phosphorus-binding capabilities of iron and aluminum, and their role in the wetland biogeochemistry of phosphorus, are very well known (Reddy and DeLaune, 2007). Very early in the history of FWS technology development, it was observed that naturally occurring, blending streams of water containing iron were very effective in phosphorus removal. At Waitangi, New Zealand, phosphorus deposition occurred predominantly by reaction between treatment wetland waters (high in phosphorus, alkaline pH) with natural wetland waters (high in Fe and Al, acid pH) immediately below the confluence of their flow streams (Cooper, 1992; 1994).

This study, coupled with the knowledge of mechanical plant phosphorus precipitation technology, led to investigation of the direct addition of these metal salts to FWS wetlands for the purpose of enhancing phosphorus removal (Bachand *et al*., 1999; Bachand and Richardson, 1999). Preliminary jar

test results suggested that treatment with ferric chloride and alum could effectively remove phosphorus to between 8 and 30 µg/L (Metcalf and Eddy Inc., 1997). It was hoped that chemical amendments directly within the treatment wetlands would create a synergistic effect in which phosphorus is more effectively and efficiently removed than by either of these two methods, chemical amendments and wetlands, alone. It was also hoped that addition of a polymeric coagulant might not be necessary because the wetland would effectively serve as a settling basin with very long HRT. However, small flocs formed, which did not quickly settle. Total phosphorus concentrations in the water column remained elevated. This approach was therefore abandoned as a means of enhancing wetland operational effectiveness.

### Aeration of SSF Wetlands

Here for the first time we encounter a significant influence of patents on SSF treatment wetland technology. Aeration of HSSF systems has developed both in the open literature and in the proprietary sector. Aerated subsurface flow wetlands are available as a patented technology in North America (Wallace, 1998; Dufay, 2000; Wallace, 2001b; Wallace, 2002a; Flowers, 2003; Wallace and Lambrecht, 2003). We cannot access all the proprietary data, and hence cannot independently evaluate it. For most patented systems, only anecdotal, qualitative information has been presented. However, we can summarize the results from the open literature and provide interpretation of it. Nothing here should be taken as supporting or refuting the claims in existing patents.

The growing realization in North America during the mid-1990s that HSSF wetlands were inherently oxygen-transfer-limited systems led to considerable interest in artificial aeration through the application of a mechanical blower and diffuser tubing as a means to boost treatment performance (especially for ammonia) in these systems. One of the most basic applications of the technology is shown schematically in Figure 24.4:

In the most simplistic sense, this can be thought of as "blowing bubbles" inside a saturated-flow HSSF wetland. However, implementation of the technology requires an understanding of the frictional loss of compressible fluids, hydrodynamics, and oxygen transfer theory. Nevertheless, a variety of successful application areas have been developed, including petroleum hydrocarbons (Wallace and Kadlec, 2005), ammonia (Wallace *et al*., 2006a), domestic wastewater (Wallace *et al*., 2006b), and airport de-icing runoff (Wallace *et al*., 2007a).

The decision to aerate a SSF wetland comes at a heavy operational cost, as operation and maintenance (O&M) of the facility is greatly increased. From an economic viewpoint, aeration is only justified when the lifecycle cost of aeration is sufficiently offset by the reduction in capital cost, as the net savings of reduced wetland size less the cost of aeration equipment.

Aerated wetlands typically occupy a much smaller footprint than a nonaerated wetland, which translates into lower construction cost. Or, sufficient land may not be available for a more passive Type *A* wetland, or not available at an economically feasible price.

At the time of this writing, performance information on aerated HSSF wetlands is a mixture of forensic analysis of full-scale systems, as well as analysis of performance data from pilot-scale systems or mesocosms.

In the first generation of aerated wetland design, assumptions from other treatment technologies, such as lagoons, were often "borrowed" to support blower sizing and diffuser-tube placement in HSSF wetland systems. As a result, these systems were not optimally designed. In recent years, there has been an increased focus on pilot-scale systems, especially for industrial effluents. A well-designed and implemented pilot study can produce data on rate coefficients (essential for first-order modeling), but questions about the hydrodynamic aspects of the pilot reactor versus the proposed full-scale system often remain (Noorvee *et al*., 2005b).

Apart from reaction rates, there is the issue of oxygen transfer rates. These depend upon bed depth, interstitial

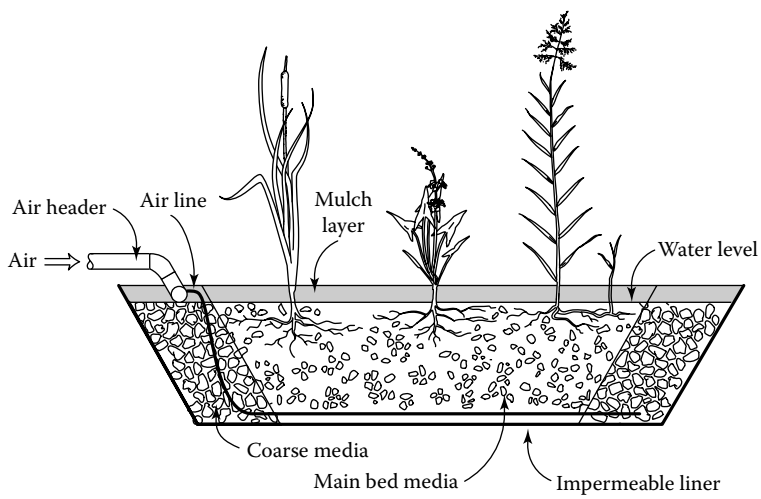

**FIGURE 24.4** Schematic of an aerated HSSF wetland.

oxygen concentrations, diffuser geometry, and other factors. However, relatively gentle aeration can deliver something on the order of 50 to 100 gO/m$^2$·d to the HSSF bed. This rate of oxygen delivery is significantly greater than rates that can be inferred from Type *A* nonaerated HSSF wetlands (Tables 9.26, 9.27, Chapter 9), which are usually in the range of 1 to 6 gO/m$^2$·d.

The energy requirement for such gentle aeration can nevertheless be an important factor in overall energy usage (see Table 1.1, Chapter 1), especially compared to passive Type *A* wetlands, but is generally much lower than conventional mechanical treatment processes.

### *Domestic Wastewater Treatment*

In a recent study, Wallace *et al*. (2006b) compared the treatment efficiency of 17 full-scale aerated HSSF wetlands and 22 full-scale nonaerated wetlands, using the loading chart and statistical methods presented in Wallace and Knight, 2006. The conclusion of this study was that aeration resulted in significant improvements in the reduction of both $BOD_5$ and TSS. With aeration, the equivalent wetland size needed for $BOD_5$ removal could be reduced by 67%; for TSS, the size reduction was approximately 36%.

### *Ammonia Oxidation*

Aeration of SSF wetlands for ammonia removal has been studied in recent pilot-scale systems. For an effluent containing a mixture of cyanide/iron/ammonia from a gold mine in South America, aeration was found to increase the ammonia oxidation rate over tenfold, from a volumetric rate (2 TIS) of 0.52 $d^{-1}$ to 5.7 $d^{-1}$ (Wallace *et al*., 2006a). A study of ammonia oxidation at different temperatures for domestic wastewater at a pilot-scale wetland in Canada (Wallace *et al*., 2006a) yielded a temperature correction factor (θ) of 1.02, indicating that temperature sensitivity is of some importance in aerated wetlands (compare with Table 9.17, Chapter 9). This would be consistent with a view that heavily loaded aerated HSSF wetlands are microbially dominated ecosystems.

### *De-icing Runoff*

Treatment of de-icing compounds (discussed in Chapter 13) has been studied under aerated and nonaerated conditions in HSSF mesocosms. For removals of $CBOD_5$ associated with de-icing runoff, the volumetric rate coefficient was measured at 0.6 $d^{-1}$ (2 TIS); aeration at 0.85 m$^3$ air per hour (per m$^3$ of wetland bed) improved the rate to 5.5 $d^{-1}$. Additional aeration at a rate of 2.0 m$^3$ air per hour (per m$^3$ of wetland bed) further increased the degradation rate coefficient to 15.9 $d^{-1}$. Based on the range of temperatures studied (22 to 4°C), the temperature correction factor was 1.03 (Wallace *et al*., 2007a).

### *Petroleum Hydrocarbons*

Aeration has been demonstrated to improve removals of petroleum hydrocarbons through aerobic degradation and volatilization. Early work was conducted at the Gulf Strachan Gas Plant in Alberta, where an aeration system initially designed for freeze resistance during winter operations resulted in improved removals of total petroleum hydrocarbons (TPH) and benzene, toluene, ethylbenzene, and xylene (BTEX) compounds (Moore *et al*., 2000a). A full-scale aerated wetland system was constructed by Williams Pipeline for a terminal facility in Watertown, South Dakota, and has been operating successfully (Wallace, 2002b).

Pilot-aerated SSF wetland studies were conducted by Ferro *et al*. (2002) for the purpose of reducing petroleum hydrocarbons in extracted groundwater. Both aerated and nonaerated degradation rates were measured, as summarized in Table 13.2, Chapter 13 (Wallace and Kadlec, 2005). These findings are consistent with the growing body of knowledge of biodegradation and volatilization rates for hydrocarbons under aerobic and anaerobic conditions (Suarez and Rifai, 1999).

### *Aquaculture Waste*

A study at the Botanical Garden of Montreal investigated the effects of aeration in mesocosms for the treatment of aquaculture waste (Ouellet-Plamondon *et al*., 2006). Aeration improved the removal of TSS, COD, and total Kjeldahl nitrogen (TKN). For instance, the first-order COD rate coefficient (plug flow) improved from 0.15 to 0.25 m/d for unplanted mesocosms, and from 0.19 to 0.24 m/d for *Typha*-planted mesocosms. Aeration was only used in the inlet region of the HSSF bed. The researchers concluded that aeration was a promising approach for improving the performance of HSSF wetlands.

## Oxygen Transfer

A recent study was conducted to measure the standard oxygen transfer efficiency of aerated SSF beds using off-gas measurements (Wallace *et al*., 2007b). Oxygen transfer is a function of the contact time between the bubble and the water column, which depends on the water depth. It also depends on constituents within the wastewater that affect oxygen mass transfer at the bubble/water interface (Metcalf and Eddy Inc., 1998). The average oxygen transfer efficiency in a HSSF wetland mesocosm using a standard sodium sulfite solution was 4.7% per meter of water depth. As a frame of reference, coarse bubble diffusers have a transfer efficiency of approximately 2.6% per meter, and fine bubble diffusers have efficiencies of approximately 6.6% per meter (U.S. EPA, 1989). Because most HSSF wetlands have a bed depth of 0.3 to 0.6 m, this would put the oxygen transfer efficiency in the range of 1.4 to 2.8%, depending on the bed depth.

The linear diffuser tubing used in this study was a fine bubble aeration device. In an open-water tank, the expected oxygen transfer would be approximately 6.6% per meter. The lower-than-expected oxygen transfer rate could speculatively be from the influence of the granular media, which may serve to coalesce bubbles and increase their size, reducing the oxygen transfer efficiency.

Air-induced mixing of the wetland was greatly reduced by the presence of the granular bed media; based on visual

**FIGURE 24.5** Testing of HSSF wetland aeration system for BTEX degradation; Casper, Wyoming. Rows of bubbles represent the location of linear air diffuser tubes, which were placed in radial arcs within this circular wetland. The wetland basin was artificially flooded to allow visual observation of the bubble pattern.

observations, the influence of aeration was generally restricted to a radius of approximately 15 cm from the point of bubble introduction (Wallace *et al*., 2007b). Aerated wetlands are hydraulically inefficient, as shown by tests yielding number of tanks in series (*N*TIS) of 1 to 3. It is apparent that a very uniform aeration grid is required to maintain oxygenated conditions in the wetland bed. Figure 24.5 shows the test of such an aeration system.

Aeration of SSF wetlands is not a maintenance-free activity. Without aeration, the system will fall back into the operating envelope of nonaerated wetlands. However, because regulatory compliance is dependent on the aeration system, scheduled, proactive maintenance of blowers and other aeration components need to be carried out by the system operator. Wetland designers should also consider the fouling of air diffusers within SSF wetlands, and provisions to replace or chemically clean diffuser assemblies should be addressed.

### Carbon Additions to HSSF Wetlands

Early work on denitrification in HSSF wetlands was conducted by Gersberg *et al*., 1984. HSSF wetlands were fed with secondary effluent low in BOD (3.3 mg/L) and high in nitrate (18.8 mg/L). In initial trials, the removal of total nitrogen was limited by the availability of organic carbon, and ranged between 9 and 19% at hydraulic loading rates of 8.4 to 20 cm/d. Utilization of methanol as a supplemental organic carbon supply dramatically increased denitrification efficiency, up to 97% at a hydraulic loading rate of 16.8 cm/d (Gersberg *et al*., 1984). As a lower-cost carbon supply, plant biomass was mulched and placed on top of the beds. At a hydraulic loading of 8.4–12.5 cm/d, the mean removal rate was 89% for total nitrogen, although the carbon loading (0.09 kg/m$^3$) was higher than that required for methanol (0.03 kg/m$^3$). This finding is consistent with more recent studies on the bioavailability of plant detritus to fuel denitrification (see, for instance, Ingersoll and Baker, 1998; Baker, 1998; Hume *et al*., 2002a).

Use of organic materials as a thermal insulator has the drawback of producing leachates with BOD that adds to the loading for that contaminant in domestic and municipal systems (Wallace *et al*., 2001). However, in systems treating low BOD sources, such as many runoff and groundwater remediation projects, such an additional source of organics is desirable and may be essential to the proper functioning of the wetland. Surface mulching of HSSF wetlands is also an option for supplying carbon for denitrification of nitrate-rich influents, as demonstrated by Gersberg *et al*., 1984. Mass-balance considerations to fuel denitrification processes are discussed in Chapter 9.

VF wetlands are effective in oxidizing ammonia to nitrate, but typically are not efficient in denitrification processes (Cooper, 2001). One of the limitations of denitrification is availability or organic carbon; and VF wetlands are often combined with HSSF wetland stages for this purpose (Seidel, 1973; Brix, 1994d; Cooper, 2001).

## 24.3 OPERATIONAL STRATEGIES

The flow of water need not be continuous, nor need it be unidirectional from inlet to outlet of a wetland or integrated natural system. There are other methods of operation, involving spatial or temporal sequencing, and the potential of recycle flows. Some of these concepts are explored in the following text.

### Step Feed

Step feeding refers to the introduction of water to a system at several points along the flow path. In activated-sludge mechanical plants, it refers to the introduction of settled wastewater at several points along the flow in a plug-flow aeration tank (Metcalf and Eddy Inc., 1991; Crites and Tchobanoglous, 1998). In water hyacinth systems, as many as eight points of introduction have been used (Water Environment Federation, 2001). The Gustine, California, FWS system was

**FIGURE 24.6** The step feed distribution pipe in the Gustine, California, system.

built with provisions for step feeding (U.S. EPA, 1988b). The reason for step feeding is, in all cases, stated to be the avoidance of "overloading" of the inlet zone of the system. Because the concept of loading to an interior zone of the wetland is fuzzy, a hypothetical situation is considered.

The Gustine example is selected as the framework, for which a step feed at the one-third point of the length is possible (Figure 24.6). The original design called for either one third or two thirds of the flow to be introduced at this interior point (U.S. EPA, 1988b). It is known that the decline of BOD through this system is exponential (see Figure 8.7, Chapter 8). Because of the high length-to-width ratio (337 m:11.6 m = 29:1), the plug-flow version of the $k$-$C^*$ model will be used. Calibration to the Gustine data of Walker and Walker (1990) yields $k = 48$ m/yr and $C^* = 4$ mg/L. The average BOD entering the system was about 200 mg/L, and the hydraulic loading was 3.3 cm/d. Figure 24.7 shows the effect of the step feed of one third of the influent to the one-third point. The front end of the wetland receives a lesser flow and does a more effective job of reduction of concentration. Upon blending with the step feed, the concentration goes up above that which would occur without step feed and stays above for the rest of the wetland travel distance. The outlet concentration is 29% higher for the step-feed option. It may be shown that for any step-feed operation and first-order kinetics, step feed gives lesser performance.

The overall BOD load to the wetland is not changed by step feeding because the area is fixed, and the inlet flow and concentration are fixed. The question then becomes: what has been accomplished? If all that is considered is BOD, the answer is, nothing. However, if it is presumed that part of BOD removal has to do with the sedimentation of solids, then TSS accumulation might factor into our thinking. The Gustine system reduced TSS from 75 mg/L to about 30 mg/L. Suppose that the entire accretion is to an inlet zone of 37 m length (1/9 of the length), at a bulk density of 0.5. Then the buildup would be about 1 cm per year. By step feeding, one-third of that accretion would be transferred to the step-feed zone, and the inlet buildup would be only two thirds of a centimeter per year. Therefore, the evaluation of step feeding as

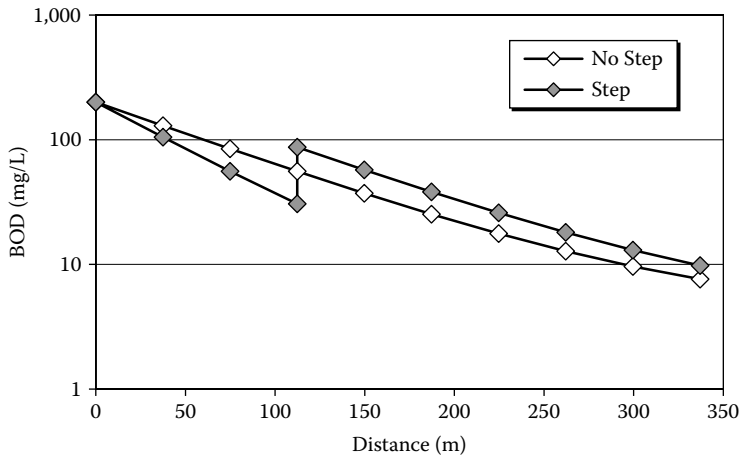

**FIGURE 24.7** Effect of step feed on BOD concentrations. These are model-based calculations, based on calibrations to the Gustine, California, system.

**FIGURE 24.8** A leachate seepage outbreak at the Saginaw, Michigan, closed landfill. This water contained ammonia at concentrations sometimes exceeding 1,000 mg/L, and was severely toxic to all vegetation.

an alternative depends upon the necessity for spreading out the solids and the corresponding penalty in performance.

## Recycle

Recycle can serve two important purposes in treatment wetlands: (1) it brings products of reactions in the wetlands from the exit back to the inlet, and (2) it dilutes reactants entering the system. Both of these functions can be used to advantage in some wetland situations.

### Dilution of Influents

Wetland vegetation can be sensitive to high concentrations of some pollutants in the water. Therefore, strong influents can damage or destroy vegetation, and the problem will be most severe in the inlet of the wetland before any treatment has occurred. For example, landfill leachates can be inimical to wetland vegetation (Figure 24.8). Recycling treated water from the wetland system outlet can serve to dilute the incoming water, but at some price in terms of cost and level of treatment.

To illustrate the concept, a hypothetical wetland is considered, with a recycle of water back to the inlet. A fresh-feed Damköhler number $k/q = 2.0$, $P = 4$ TIS, and $C^* = 0$ are chosen, to be representative of a moderate degree of removal of the contaminant (80%). Figure 24.9 shows the calculated concentration profiles through the system for differing amounts of recycle up to 200% of the incoming raw water. Note that as the recycle ratio goes to very high levels, the effect is to create a single well-mixed unit because of the intense recirculation. The limiting concentration reduction for this extreme is 67%. Typical recycle rates are 200% or less, for which the reduction is 72% for this example. Thus, a price in performance has been incurred by recycle. However, the concentration in the inlet region is cut in half (52%) by 200% recycle.

The economic consequences of a recycle pump and piping may not be large for very small systems, but for large FWS wetlands they may be a significant contribution to cost. Recycle is being used on the large Everglades-constructed wetlands to process seepage collected around their perimeters.

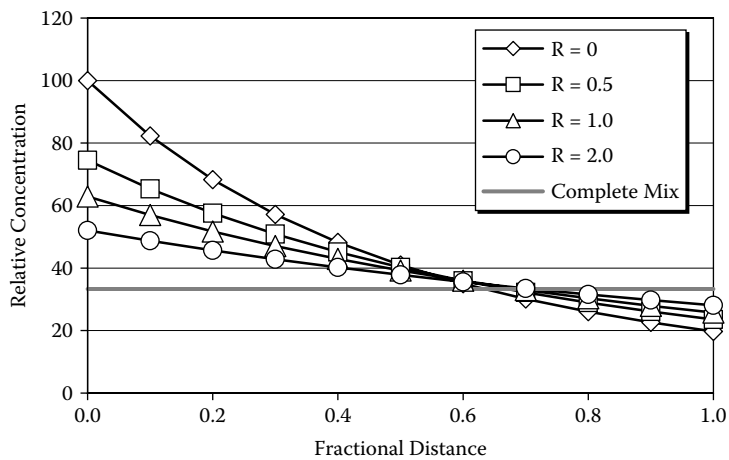

**FIGURE 24.9** The effect of recycle on a hypothetical wetland. The fresh-feed Damköhler number is $k/q = 2.0$, $P = 4$, and $C^* = 0$.

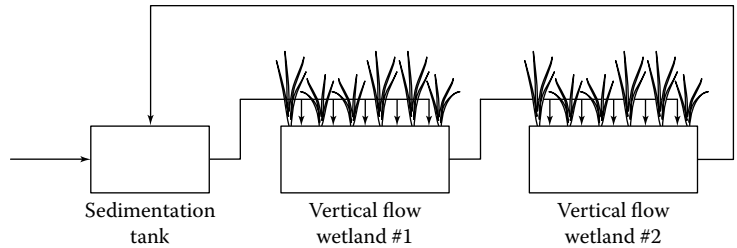

**FIGURE 24.10** Basic components of the experimental recycle VF system in Denmark. (Adapted from Brix *et al*. (2002a) *BOD and Nitrogen Removal from Municipal Wastewater in an Experimental Two-Stage Vertical Flow Constructed Wetland System with Recycling*. Mbwette (Ed.). Proceedings of the 8th International Conference on Wetland Systems for Water Pollution Control, 16–19 September 2002; Comprint International Limited: University of Dar Es Salaam, Tanzania.)

### Recycled Nitrate

One of the dilemmas of once-through treatment wetlands is that carbon (BOD or COD) is utilized in the front end of the wetland, prior to the nitrification of a significant fraction of any ammonia that may be present. This is due to the more rapid rate of elimination of BOD, compared to ammonia. Thus, although both processes occur more or less simultaneously in wetlands, the carbon is gone before a large share of the nitrate is formed. Therefore, denitrification is hampered by a lack of carbon in the exit section of the wetland. This phenomenon is present in all types of treatment wetlands but is especially problematic in VF systems. One "cure" is to add another wetland component with the capability of providing the carbon needed, which would usually be a FWS system with its litter decomposition as the carbon supply. Another possibility is to recycle the nitrate back to the inlet of the wetland, where there is a supply of carbon associated with the incoming fresh feed to the system.

For example, Brix *et al*. (2002a) performed comparison studies on a two-stage VF system treating municipal wastewater, with and without recycle (Figure 24.10; see also Figure 16.11, Chapter 16). Table 24.1 shows data from one pair of two-month campaigns, out of four that were conducted. Several conclusions can be drawn from these results. First, the wetlands are very effective in reducing $BOD_5$ and TSS, whether or not there is recycle. The sedimentation tank effectively reduces organic nitrogen, and the wetlands reduce it further to levels less than 1 mg/L, whether or not there is recycle. The wetlands are very effective in reducing ammonia, whether or not there is recycle. The major effect of recycle is in the reduction of oxidized nitrogen and consequently total nitrogen leaving the system. The effluent oxidized nitrogen was 38 mg/L without recycle, and 18 mg/L with recycle.

Because of the success of this strategy, the Danish guidelines for small on-site treatment wetlands require recycle at a recycle ratio of 50% (Brix and Arias, 2005).

## FWS Timed Operational Sequences

The flows to FWS wetlands need not be steady and continuous. Event-driven systems constitute one group of systems that receive nonsteady flows, and these have been discussed

**TABLE 24.1**
**Comparison of Recycled and Once-Through Operation of a Two-Stage Experimental System in Trige, Denmark**

| | Raw Input | | Combined | Sedimentation Tank Out | | Wetlands Out | |
|---|---|---|---|---|---|---|---|
| | No Recycle | Recycle | Input | No Recycle | Recycle | No Recycle | Recycle |

Proceedings of the 8th International Conference on Wetland Systems for Water Pollution Control, September 16–19, 2002; Comprint International Limited: University of Dar Es Salaam, Tanzania.

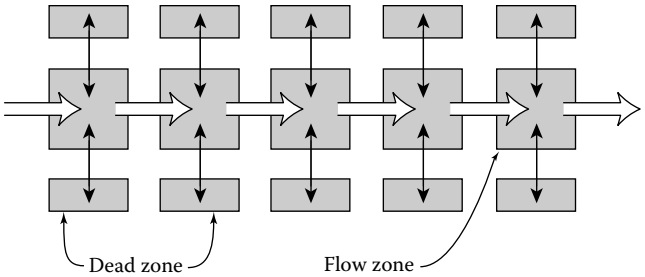

**FIGURE 24.11** Conceptual model of wetlands with dead zones under a fill-and-draw operation. This is the finite stage model with five stages (see Appendix B). (Adapted from Helsel (1992) *Fill and Draw Wetlands*. M.S. Thesis, University of Michigan, Ann Arbor.)

in Chapter 14. Another set of systems operate in the batch mode, and these also have been covered in Chapter 14. There remains another strategy that targets hydraulic inefficiency in what are otherwise continuous flow systems: a fill-and-drain operation.

Helsel (1992) explored the potential advantages of a fill-and-draw operation for a hypothetical FWS system describable by a finite stage model with five units (Figure 24.11; see Appendix B). Under steady operation, it was envisioned that some fraction of the wetland existed out of the main flow path, with essentially no flushing by the wastewater flow, termed a dead-zone fraction. In the long term, under steady operation, this reduces the effective wetland area. Under fill and draw, these dead zones are emptied and refilled to an extent determined by the fraction of the wetland water that is drained. Therefore, more of the wetland area becomes involved in treatment. The effectiveness then depends upon how the wetland performance depends upon depth. Helsel (1992) assumed a constant volumetric first-order rate coefficient, thus taking a penalty for decreased detention time at smaller water depths. A sample of results is given in Figure 24.12. In steady operation, percent removal drops off rapidly as the dead zone fraction increases. A fill-and-draw operation lessens the penalty but does not forecast improvement over full utilization of the wetland area. Therefore, proper design should eliminate the need to access the dead zones by raising and lowering water levels.

The Oxelösund FWS system in Sweden is operated in a partial fill-and-draw mode, in that the flow is alternated between two parallel inlet cells (Wittgren and Tobiason, 1994; Kallner and Wittgren, 2001). This system has highly irregular shape, with possibilities of dead zones (see Figure 1.19, Chapter 1). However, operational data reports do not include any comparative evaluation of performance.

## SSF Timed Operational Sequences

Most SSF wetlands operate with pulsed flow because of the use of pump-induced dosing in HSSF systems and the loading and resting operating regime deliberately used in many VF systems as a means of reducing bed clogging.

Although these can be considered Type *B* approaches to wetland design and operation, they are fairly standard in the wetland field, and numerous examples of these systems have been presented previously in this book.

### Fill-and-Drain SSF Wetlands

It has been demonstrated that the treatment performance of HSSF wetlands can be improved by fluctuating the water level. The basic operational sequence is best explained in terms of nitrogen and BOD removal (Austin *et al*., 2003; Maciolek and Austin, 2006):

1. The wetland basin is filled with water; ammonia is absorbed onto the bed media (McBride and Tanner, 2000); organic matter is degraded by microbial biofilms.
2. The wetland basin is drained; bulk water is routed to the next wetland basin. As water is drained, air enters the bed. Microbial biofilms are rapidly oxidized due to atmospheric diffusion, ammonia is converted to nitrate, and degradation of sorbed and particulate organic matter continues.

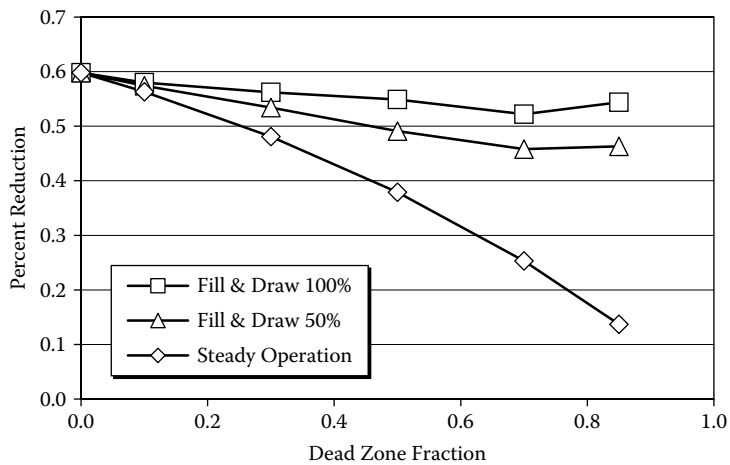

**FIGURE 24.12** Behavior of wetlands with dead zones under a fill-and-draw operation. (Data from Helsel (1992) *Fill and Draw Wetlands*. M.S. Thesis, University of Michigan, Ann Arbor.)

3. The wetland basin is filled a second time; due to the charge reversal, nitrate and nitrite are released from the bed media; influent organic matter provides a carbon supply for denitrification processes to drive total nitrogen reduction.

The filling and draining sequence can be done in two ways. The simplest approach is to use the influent flow to fill the wetland basin to the target water level. The wetland basin can then be immediately drained or allowed to operate as a continuous-flow, constant-water-level system for some percentage of the operational sequence. The treatment performance of a full-scale HSSF wetland in Minoa, New York, significantly improved after the facility was converted from a constant-flow to a fill-and-drain mode of operation (Liebowitz *et al*., 2000). The presence of sulfide precipitates in the wetland effluent was used as an indicator that the bed should be drained. The rate of cycling was about four days for the second-stage wetland basin, and about every two weeks for the first-stage wetland basin. A two-stage HSSF wetland system at Dolni Mesto in the Czech Republic also demonstrated improved treatment for BOD, COD, and ammonia when it was operated in a fill-and-drain mode instead of having a constant water level (Vymazal and Masa, 2003). The wetland basin was drained whenever it had filled to a target water level; fluctuations of 8 cm and 15 cm were evaluated, with a 15-cm fluctuation providing greater improvement. Influent flow rates were not measured, so the cycle frequency could not be determined.

The second operational strategy is to accelerate the fill-and-drain cycle frequency by pumping or recirculating the flow between several wetland beds. These types of wetlands are essentially vertical flow systems. A fill-and-drain pilot-scale wetland operating on these principles has been developed in Israel (Green *et al*., 1998). This system utilizes surface flooding of the bed to ensure uniformity in influent distribution, unsaturated flow through a deep bed (2.4 m) (Green *et al*., 2004), and a siphon or timer-controlled outlet. The rapid release of the effluent is desirable as air is drawn into the wetland bed through passive ventilation pipes, increasing the oxygen transfer (Green *et al*., 1997a). Such a system has shown successful treatment of dairy wastewater, although the each bed must be rested approximately 70% of the time to avoid clogging (Green *et al*., 2002). This implies that 3 or 4 beds in parallel would be needed to treat such a type of wastewater.

Fill-and-drain wetlands operating under an accelerated cycle frequency are commonly called "reciprocating" or "tidal flow" wetlands. The fill-and-drain operational sequence helps BOD removal and nitrogen removal to occur simultaneously, and some nitrate-bound oxygen may be recovered. To achieve the necessary degree of oxygen transfer to drive the treatment process, cells must be filled and drained multiple times per day; greater than 6 cycles per day is often needed to meet treatment goals (McBride and Tanner, 2000). The rate of fill-and-drain cycles is dependent on the overall oxygen transfer requirements, and will generally require an internal pumping system to fill and drain wetland cells independent of the influent flow rate (Cooper, 1999; Sun *et al*., 1999).

Fill-and-drain wetlands that rely on pumps to accelerate the cycle frequency are available as a patented technology in North America (Zoeller and Byers, 1999; Behrends, 1999a; Austin *et al*., 2002; Austin *et al*., 2004). In one variation of this technology, flow is pumped back and forth (reciprocated) between two wetland beds; this is known as the ReCip® process in the United States (Behrends *et al*., 1996b; Behrends, 1999a; Behrends *et al*., 2000).

Here, for the second time, we encounter a significant influence of patents on SSF treatment wetland technology. We cannot access the proprietary data, and hence cannot independently evaluate it. For most patented systems, only anecdotal, qualitative information has been presented. However, we can summarize the results from the open literature and provide interpretation of it. Nothing here should be taken as supporting or refuting the claims in existing patents.

There is a growing understanding that the cation exchange capacity (CEC) plays a fundamental role in the effective performance of fill-and-drain SSF wetlands. A recent laboratory study by Austin (2006) indicated that fill-and-drain columns filled with an expanded shale aggregate (CEC of approximately 4 meq/100 g) significantly outperformed columns filled with high-density polyethylene (HDPE) media (zero surface charge) despite the fact that the HDPE media provided more surface area for microbial biofilms. Expanded-shale columns outperformed HDPE in terms of TSS, COD, TKN, and total nitrogen (TN). Improved performance for ammonia (TKN) can be explained in terms of the CEC (Johns *et al*., 1998; Gisvold *et al*., 2000). The reasons for improvement for other parameters are less clear.

Fill-and-drain wetland reactors are also susceptible to bed plugging despite the reactors being flushed several times per day, and there is the apparent potential to "purge" fine mineral sediments. Behrends *et al*. (2006) found reciprocating beds were "severely" clogged after seven years.

One approach to predicting bed clogging has been advanced by Austin *et al*. (2006a), which utilizes a dimensionless ratio between the rate of reaction and the rate of mass transport to assess the potential for bed clogging based on Monod kinetics. The analysis is dependent on empirical methods to estimate the effective surface area available for microbial biofilms but has been successfully calibrated to mesocosm tidal-flow reactors, based on observed increases and decreases in microbial biomass as a function of organic loading. It is interesting that the short-term clogging results of Figure 21.5, Chapter 21, can be predicted using this method, indicating that Monod-based predictions of microbial biomass will likely be a part of the more advanced design methods that will inevitably be presented as treatment wetland technology continues to evolve.

## 24.4 INTEGRATED NATURAL SYSTEMS

Increasing demands for improved treatment, together with the limitations of each individual wetland type, makes the selection of multiple-unit systems inevitable in many situations. The alternative wetland categories, FWS, HSSF, and

VF, are all being used as "stand-alone" wastewater treatment technologies. They each have the potential to provide effective treatment of a variety of pollutants as long as loading rates are appropriate and the desired plant community is maintained. Although these technologies work alone, it is often beneficial to combine one or more of these options into integrated natural-treatment systems.

In many sectors of industry, including wastewater treatment, there exists a set of processing units that may be combined to develop the integrated plant that performs the required tasks. These may include filters, reactors, clarifiers, and biological treatment units of several kinds (Metcalf and Eddy Inc., 1991). There are also several kinds of land-based units that comprise the suite of "natural" treatment systems (Water Environment Federation, 2001). These include wetlands and ponds of various types, which are here termed unit ecosystems.

Table 24.2 summarizes the major advantages of several unit ecosystem technologies described in this book or elsewhere. Each of the various wetland alternatives described previously provides numerous treatment benefits. However, they each have certain water quality treatment properties that outshine the companion technologies. For example, constructed FWS treatment wetlands provide excellent reduction of TSS and denitrification of nitrate and nitrite nitrogen, but they are not extremely effective at nitrifying ammonium nitrogen. HSSF treatment wetlands are also effective at TSS and nitrate reduction but at a much higher unit cost. However, these systems clearly excel at avoiding potential impacts of poorly treated wastes on wildlife and humans by keeping the wastewater belowground. VF treatment wetlands have excellent nitrification potential, in addition to their benefits for reduction of BOD and TSS. However, they are not very effective for denitrification.

Unit ecosystems can be combined in series or in parallel to provide flexibility and to take advantage of higher pollutant transformation rates characteristic of each ecosystem type. This section provides suggestions for integrating these diverse ecosystem units into optimal treatment systems. Several examples are presented of existing integrated systems.

## Ponds and Wetlands

### High-Sediment Waters

Many urban stormwater treatment systems include sedimentation basin forebays (pond elements) followed by emergent SF wetlands (Strecker *et al*., 1992; Schueler, 1992). Figure 18.31, Chapter 18, provides an example of a stormwater treatment system that incorporates this idea. This series combination has the advantage of providing for easy removal of accumulated sediment, together with further processing and reduction of concentrations of dissolved pollutants in the marsh. Many stormwater wet-detention systems combine these ecosystem units in a single basin.

In the agricultural landscape, more complex arrangements of ecosystem units in series have been utilized. The nutrient–sediment control system (NSCS) developed by the U.S. Natural Resources Conservation Service (NRCS) is composed of five units in series: sedimentation basin, overland flow, FWS emergent marsh wetland, pond, and overland flow (Figure 24.13) (Wengrzynek and Terrell, 1990; U.S. Department of Agriculture, 1991; Higgins *et al*., 1993). This system is intended to intercept the TSS from row crops (i.e., potatoes), and the inlet basin will fill. For an example operation in Maine, accretion

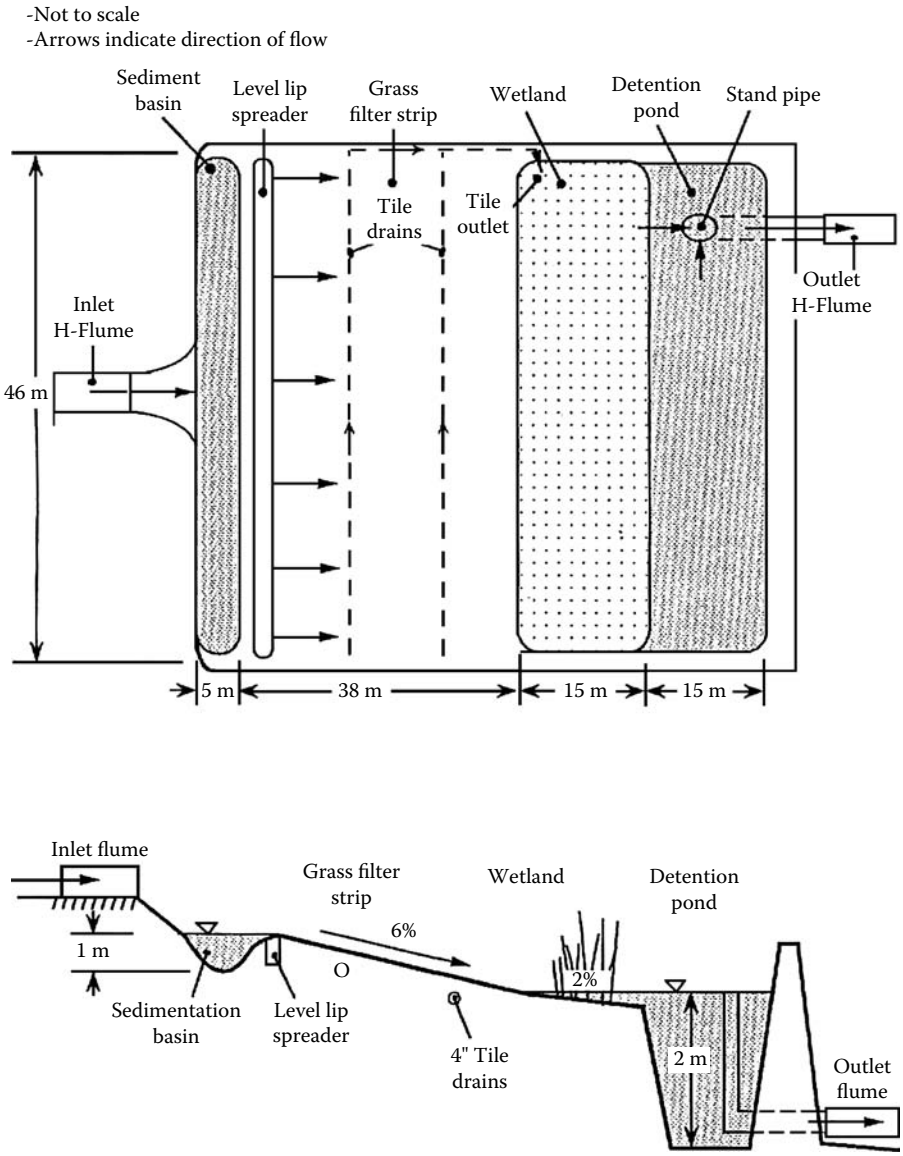

**FIGURE 24.13** Plan and profile views of an example of the NRCS nutrient–sediment control system. (From Higgins *et al.* (1993) In *Constructed Wetlands for Water Quality Improvement*. Moshiri (Ed.), Lewis Publishers, Boca Raton, Florida, pp. 359–367. Reprinted with permission.)

was about 3 cm/yr, and a 30-cm depth would require removal on about a ten-year cycle (Higgins *et al*., 1993).

Some continuous-flow applications may also entail high TSS in the entering water. For instance, the Tucson Sweetwater wetland receives filter backwash with high TSS, and this material must be removed from the inlet deep zones (see Figure 7.13, Chapter 7).

## Pond and Wetland Combinations

Wetlands possess the potential to be a valuable adjunct to treatment lagoons. They need not replace lagoons because those aquatic systems provide reasonable treatment for many water quality parameters such as BOD and TSS. A relatively common combination of natural technologies for municipal wastewater treatment found in the United States includes a facultative lagoon or pond for primary and secondary treatment, followed by a constructed FWS wetland. Kadlec (2003d) lists 21 such systems, and there are more being developed around the world (for example, see Browne and Jenssen, 2005; Polprasert *et al*., 2005; Herrera-Melian *et al*., 2006). This integrated system utilizes a minimum amount of fossil-fuel energies, generates minimal solids requiring disposal (infrequent pond-sediment removal), and is relatively inexpensive to construct. Almost any advanced wastewater treatment effluent standards are achievable as long as adequate land is available.

Facultative and aerated ponds are time-tested systems for treating wastewater to approximately secondary standards (Water Environment Federation, 2001). Modern improvements call for multiple cells of varying design, designated as advanced integrated wastewater ponds (Shilton, 2005). Table 24.3 provides a sense of the effluent concentrations that may be expected from anaerobic, facultative, and aerated ponds treating domestic wastewater. The general sense is that

**TABLE 24.3**
**Typical Effluent Concentrations from Lagoons Treating Domestic Sewage**

| Lagoon Type | TSS (mg/L) | BOD (mg/L) | Ammonia (mg/L) | Phosphorus (mg/L) | Fecal Coliforms (MPN/100 mL) |
|---|---|---|---|---|---|
| Facultative | 40–100 | 30–40 | 10–20 | 3–5 | 200–10,000 |
| Aerated | 20–40 | 30–60 | 8–15 | 3–5 | 30–100 |
| Partial-mix aerated | 20–40 | 30–60 | — | — | — |
| Anaerobic | — | 90–180 | — | — | — |

*Source:* Data from Crites and Tchobanoglous (1998) *Small and Decentralized Wastewater Management Systems.* McGraw-Hill, New York; Water Environment Federation (2001) *Natural Systems for Wastewater Treatment (WEF Manual of Practice FD-16).* 2nd edition, Water Environment Federation, Alexandria, Virginia; Mara (2005) *Pond Treatment Technology*. lagoons may not meet secondary (30 TSS, 30 BOD) standards in all cases. Pathogens, as measured by fecal coliforms, may be too abundant to meet human health standards (typically 200/100 CFU/100 mL in North America). Additionally, there is likely to be too much ammonia to meet ammonia toxicity standards for fish, which may require no more than 2–4 mg/L ammonia in the discharge. Finally, eutrophication of receiving waters may dictate phosphorus removal to 1.0 mg/L or below, which cannot be met with lagoon treatment alone.

Wetlands offer an alternative way to improve the quality of lagoon discharges. They are in use for reduction of TSS and BOD, nutrients nitrogen (N) and phosphorus (P), and pathogens (fecal coliforms, FC). Table 24.4 represents a collection of summary data from North American wetlands that are used in conjunction with lagoons. There are very large differences in size, loadings, and design purposes. A summary of removal percentages based on Table 24.4 shows that some of these wetlands are very successful in improving water quality, primarily those with lower loadings.

Facultative ponds utilize algae for the predominant removal functions. There is a strong connection between the phytoplankton (algae) produced in a lagoon and the TSS leaving that lagoon. These algal solids can cause lagoon TSS in the range 60–140 mg/L, which is well above secondary treatment standards. A FWS treatment wetland is one option for reducing lagoon TSS.

An interesting application of pond plus wetland technology is a stormwater/snowmelt system in Anchorage, Alaska. Snow removal from streets is accumulated in a snow dump, which contains the northern version of urban runoff constituents. In the summer, urban runoff is routed directly to the pond. In spring and early summer, the meltwater from the storage pile is conducted to the constructed pond (Figure 24.14). Water then overflows a low bank into the constructed wetland, from which it is discharged to a receiving stream. The wetland was constructed by excavating frozen blocks of peat and associated vegetation, and placing them in cross-rows in the constructed wetland basin. This herringbone structure sagged and collapsed during warm conditions, creating an array of interconnected peat berms and open water zones. These subsequently colonized with *Typha* and other local wetland plants.

### Confined Animal Feeding Operation Wastewater Management Systems

Wastes from confined animal feeding operations (CAFOs) are biodegradable, but they tend to have very high concentrations of oxygen-demanding substances. Many CAFOs presently discharge partially treated wastes to nearby lakes, creeks, streams, and rivers. There is a growing awareness of the need to control discharges from many of these sites to protect downstream water quality resources. Treatment of CAFO wastes has often been limited to ponds meant to trap and degrade manure solids and animal urine. These ponds do not typically treat the wastes to levels that can be safely discharged to receiving waters and often do not even provide enough treatment to safely irrigate croplands while protecting groundwater resources (Table 24.5). As discussed in Chapter 25, there has been a growing interest in building integrated natural systems to improve the quality of waters leaving these sites. A typical integrated system includes one or more pretreatment ponds and a constructed FWS wetland (see Figure 24.13).

## FWS and Infiltration

### FWS to Infiltration

Water from a FWS treatment wetland may be directed to an infiltration system for final effluent polishing or disposal. This alternative is used when there is no acceptable surface water body to accept treated effluent, and there is adequate water quality to protect the surficial groundwater aquifer for its designated uses. The unit ecosystem is a rapid-infiltration bed (Water Environment Federation, 2001), also known as a soil aquifer treatment system (Crites *et al*., 2006). Water is treated as it percolates downward through a soil matrix. Physical, chemical, and biological processes operate during this unsaturated flow to groundwater. Application is usually intermittent, and vegetation plays no role in the process. Desirable soil characteristics include high permeability, and that usually means sand. The depth to groundwater would be several meters, unless the percolate is collected in an underdrain system (Water Environment Federation, 2001).

(a) (b)

**FIGURE 24.14** An interesting application of pond plus wetland technology is this system in Anchorage, Alaska. Snow removal from streets is accumulated in a snow dump (a), which contains the northern version of urban runoff constituents, leading to the black appearance. The meltwater is conducted to a constructed pond (b, foreground), and then overflows a low bank into the constructed wetland (a, background).

Hydraulic loading rates are commonly in the range of 1–100 m/yr, with application periods of 1–9 days and drying periods of 5–20 days (Crites and Tchobanoglous, 1998). Passage through the soil results in BOD, TSS, and pathogen removal. Depending on soil sorption characteristics, there can be considerable reductions of metals and phosphorus. Nitrogen is removed by soil sorption of ammonia on the application part of the cycle and subsequent nitrification during the drying portion of the cycle. Design procedures are detailed in (Crites and Tchobanoglous, 1998; Water Environment Federation, 2001; Crites *et al*., 2006).

The sequence of pond–wetland–infiltration has been implemented at Lake Nebagamon, Wisconsin (Figure 24.15), and at Isanti-Chisago, Minnesota, for example (see Figure 25.17, Chapter 25). In both cases, the goal was disposal of treated water but with the expectation that further polishing would take place in the soil profile.

### Infiltration to FWS

There are also systems that reverse the order, using the sequence pond–infiltration–wetland. For instance, the Onaway, Michigan, system uses this sequence so that phosphorus control can be exerted prior to the wetland, which then serves as a polishing unit ecosystem (Figure 24.16). When this sequence is used, the sand beds provide nitrification, but

**FIGURE 24.15** The Lake Nebagamon, Wisconsin, infiltration beds developed into a constructed wetland that infiltrates the treated water from a lined constructed wetland.

there is not enough BOD to fuel denitrification because BOD has been removed in the aerated pond. However, the FWS unit ecosystem generates its own carbon supply and therefore provides denitrification for the sand-bed effluent.

### Overland Flow to FWS

Overland flow is a unit ecosystem that incorporates shallow sheet flow over a grassed slope. It is essentially a fixed-film biological treatment system in which grass and litter form the matrix (Water Environment Federation, 2001; Crites *et al*., 2006). The soils should be relatively impermeable, and the site slope should be in the range of 2–8%. Slope lengths vary from 20 to 80 m, and water delivery rates are on the order of 2–10 $m^3$/d·m of cross-width. Drying periods are part of the operation, with ammonia removal improving as the wet/dry ratio shrinks to about 0.25 (Crites *et al*., 2006). Design procedures are detailed in (Crites and Tchobanoglous, 1998; Water Environment Federation, 2001; Crites *et al*., 2006). Depending upon the carbon availability in the wastewater, denitrification may or may not be complete. Overland flow is one method of distributing water into a FWS wetland while providing pretreatment. The treatment wetland at the Orange County Eastern Service Area near Orlando, Florida, effectively uses overland flow as the inlet distributor (Schwartz *et al*., 1994) (Figure 24.17).

### Vertical Flow to FWS

Although infiltration and overland flow are sometimes acceptable alternatives to provide nitrification, the VF wetland (sand filter) with intermittent flow is often a more

**FIGURE 24.16** The Onaway, Michigan, infiltration beds. See Figure 18.29, Chapter 18, for a view of the constructed wetlands that follow. Aerated lagoons precede these beds.

**FIGURE 24.17** The inlet to the Orange County Eastern Service Area constructed wetlands near Orlando, Florida. The area in the foreground is a grassed overland flow zone. The shrub area in the background is the first unit of the constructed wetland.

compact unit ecosystem that can also provide that nitrification. However, the VF process also removes BOD and in fact nitrifies more effectively at low inlet BOD levels. Therefore, a follow-on FWS wetland, which can generate the carbon needed for denitrification, completes a logical sequence that both nitrifies and denitrifies.

One example of such an integrated process operates for the Lamb–Weston potato-processing facility in Connell, Washington (Kadlec *et al*., 1997; Burgoon *et al*., 1999; Burgoon, 2001). The first element of this treatment train is a parallel, 10-ha pair of FWS emergent wetland cells that function primarily as a trap for organic solids to decrease chemical oxygen demand (COD), and to foster the conversion of organic N to ammonium (Figure 24.18) (see also Figure 25.8, Chapter 25). This unit ecosystem is necessary because the incoming TSS is about 300 mg/L and would clog a VF unit quite quickly. The incoming COD is about 3,000 mg/L and would impede nitrification. The incoming nitrogen is largely organic, which must be mineralized before nitrification can occur. A 4-ha set of parallel VF wetland cells then nitrify this ammonium N to nitrate N. The VF wetland cells are followed by two 1-ha FWS wetlands to denitrify this nitrate N and reduce the ultimate mass load of N prior to effluent disposal. This treated water is stored in a 17-ha pond prior to ultimate disposal via slow-rate land application on 213 ha of hayfields. The irrigation water rate to the fields is 57 cm/yr, and a remaining nitrogen load to the hay is 360 kg/ha·yr, which are the desired rates for hay production. A pilot version of this system was operated with two inlet FWSs, one VF, and one FWS in series. The nitrogen species transformations are shown in Figure 24.19.

A similar combination VF–FWS is used at the Saginaw, Michigan, site to treat landfill leachate (see Figure 25.14, Chapter 25).

### SSF and Infiltration

Early implementations of SSF wetland technology assumed that the wetland system could arbitrarily be divided 50/50 between treatment and infiltration (TVA, 1993), although later studies have indicated this is not necessarily a good assumption (White and Shirk, 1998), and current design

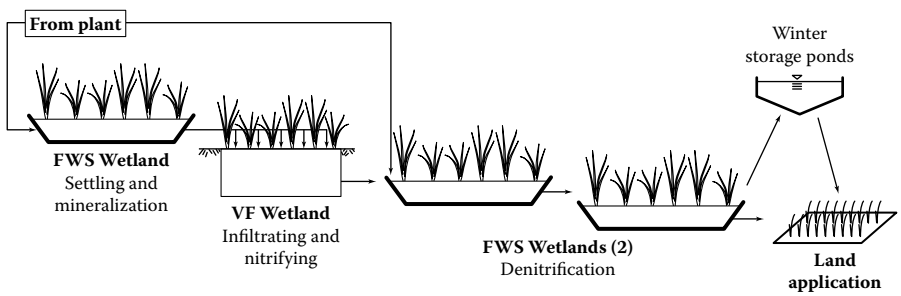

**FIGURE 24.18** Layout of the Lamb–Weston integrated natural system.

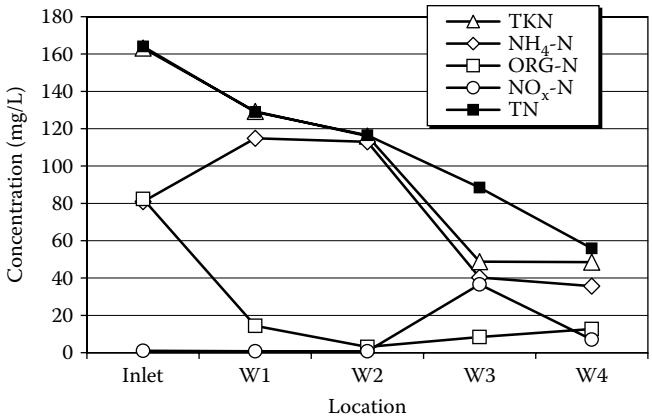

**FIGURE 24.19** Performance of the Lamb–Weston pilot integrated natural system.

guidelines recommend that infiltration systems be designed on soil morphology instead of prescriptive standards (U.S. EPA, 2002c).

Interactions between applied wastewater and the soil matrix are complex because a clogging layer develops at the soil/water interface (U.S. EPA, 2002c) in the soil infiltration system. This clogging layer both restricts flow and can aid in soil filtration processes such as pathogen removal. However, the cumulative organic loading to the soil matrix eventually leads to clogging of the soil and hydraulic failure of the infiltration system (Tyler and Converse, 1994).

The longevity of soil infiltration systems can be dramatically increased if the organic loading to the infiltration system is reduced (Tyler and Converse, 1994); if water is pretreated, the life of infiltration systems can be extended almost indefinitely because soil clogging develops at a much slower rate. Some regulatory agencies in the United States allow for reductions in infiltration area on the order of 25 to 50% if the water is pretreated to secondary standards prior to application to the soil infiltration system (Wisconsin Department of Commerce, 2000). Treatment wetlands have been used in this regard as a simple, low O&M treatment alternative (Axler *et al*., 2001). This is most likely to be a benefit where available land for replacement infiltration systems is limited or nonexistent.

### VF and HSSF Combinations

Although long regarded as separate technologies, combinations of VF and HSSF wetlands have in fact existed since the development of SSF wetland technology (Seidel, 1966). Both VF–HSSF and HSSF–VF combinations have been developed (EC/EWPCA Emergent Hydrophyte Treatment Systems Expert Contact Group and Water Research Centre, 1990; Brix, 1998; Cooper, 1999; Noorvee *et al*., 2005a) based on different treatment process objectives, and are considered standard process configurations. These combinations have been previously discussed in detail in Chapters 15, 20, and 21.

At the present time, two process configurations have been commonly employed:

*VF–HSSF combinations.* This approach dates back to the original work of Seidel (Seidel, 1966). VF wetlands (often two or more stages in combination) are used for TSS filtration, BOD removal, and nitrification; subsequent HSSF stages are used for effluent polishing (see Figure 15.9, Chapter 15).

*HSSF–VF combinations.* The design strategy with this approach is to use a large HSSF wetland as the initial stage to remove BOD and TSS, both of which can be removed in an anaerobic environment. This reduces the overall oxygen demand on the subsequent VF stage, which is designed primarily for nitrification (Brix, 1998).

Either process configuration is capable of producing a nitrified effluent. If total nitrogen reduction is a design goal, then recycle of the nitrified effluent back to the primary treatment tank is commonly employed (Laber *et al*., 1999). Individual unit processes may be designed as discrete elements using the procedures previously outlined in this book.

## SUMMARY

At the present stage of technology development, the performance envelope for Type *A* FWS and HSSF treatment wetlands can be fairly well defined based on the large number of operating, full-scale systems. Performance of these systems has been defined (based on available data) in Part I of this book. System modifications have been sought to increase that performance envelope.

Free water surface wetlands are rarely modified internally, partly because of their size and partly because of a desire to emulate natural wetlands. Their operational strategy may involve recycle or other steps to improve performance.

Type *B* engineered SSF wetlands remain an area of technology development. At the research scale, Type *B* approaches have been explored primarily to increase oxygen supply. Modified full-scale HSSF applications are much less common. The current spectrum of HSSF treatment wetlands encompasses both the Type *A* (passive) and Type *B* (engineered) design approaches. Any decision to use SSF wetland treatment technology must balance the requirements of land availability and simplicity versus the need for operator intervention and complexity, to meet regulatory goals.

Combinations of various wetland technologies have been presented throughout this book, and more specific applications have been provided in this chapter.

# 25 Wetlands by Application Group

The strategy of this book up to here has considered individual wastewater constituents by analysis of the available data and in terms of the types of wetlands that may be employed to reduce concentrations of those individual chemicals. That might be termed a horizontal approach because removal of, say, biochemical oxygen demand (BOD), is a crosscutting issue that affects many types of effluents. Primary emphasis has been on the reduction of specific contaminants, including BOD, total suspended solids (TSS), nutrients, metals, and hydrocarbons.

In this chapter, a "vertical" approach is taken, in which particular treatment wetland applications are considered as a group. This is done because some technology growth areas are very application specific. It is not necessary to repeat the many details already presented in two key application areas—metals and hydrocarbons—because each has had an entire chapter already (Chapters 11 and 13). Likewise, the general application area of stormwater runoff has been singled out for an entire chapter (Chapter 14). There remain several applications that deserve additional attention because they present unique features that can influence design. These include wetland treatment of animal waste, food wastes, landfill leachate, and chemical industry effluents.

## 25.1 ANIMAL WASTES

### Confined Animal Operations

Liquid animal wastes consist of manure, flushwater, and rainfall. The *Agricultural Waste Management Field Handbook* (USDA-NRCS, 1992) provides information on volumes of manure (feces and urine) and mass excretion rates of nutrients for different types of livestock. Average quantities of nitrogen, phosphorus, and $BOD_5$ in manure are given in Table 25.1. Solid wastes consist of manure and sometimes bedding material such as straw. These amounts are then diluted with water, and the amount of water added to the system usually exceeds the amount of manure. For cattle and dairy facilities in the United States, 160–200 L/d per cow are used for flushing requirements for freestall alleys (CH2M Hill and Payne Engineering, 1997). Swine flushing quantities are typically 60–95 L/d per adult animal. However, Tanner and Kloosterman (1997) use a lower water rate of 50 L/d per cow, and the French use an even lower range, from 5–15 L/d per cow (Liénard *et al.*, 2002).

Operators use a variety of methods to manage wastewater, including lagoons, ponds, storage structures, compost areas, filters, and sediment basins. Liquid wastes are typically collected and treated in one or more lagoons before being land applied. The organic matter and nutrients in manure are important resources that are recycled to the land, if possible, to foster crop production. Solid and slurry wastes usually have very high nutrient concentrations and are good soil amendments, but, in many cases, it is not feasible to collect and contain all animal waste. Some portions are leached from loafing lots, and spills occur. In other cases, the availability of cropped land does not accommodate the entire waste production.

A constructed wetland offers another option for polishing wastewater before it is recycled as flushwater, land applied, or ultimately discharged. As for other wastewater types, the goal is to prevent manure from being discharged to receiving waters. In natural recipients, the organic matter and nutrients promote algal growth and deplete dissolved oxygen, or in other words, promote eutrophication.

Wetland treatment can be implemented on farms in cold climates. Systems have been evaluated across Canada, from Alberta (Reimersma, 2001) to the Atlantic Provinces (Smith, 2003; Smith *et al.*, 2006). Other cold-climate applications have been reported in Germany (Kern and Carlow, 2000; Kern, 2003). These low-technology, solar-driven systems are passive and user-friendly, and thus farmers do not need to acquire the skills of wastewater treatment plant operators. The operation of a wetland system is closely related to current farming practices. The wetland system requires sunlight, nutrients, and water, but does not need to be harvested. The treatment wetland plants can tolerate relatively high concentrations of nutrients, but full-strength wastes should not be applied directly to wetlands because many wetland plants cannot tolerate the high nutrient levels.

The use of wetlands for treating concentrated animal wastes gained a measure of popularity in the early 1990s. The Brenton cattle operation in Iowa, which started in 1930, was the oldest system in North America found by CH2M HILL (1997). Other early sites include Sand Mountain, Alabama, started in 1989, and the Newton and Hattiesburg, Mississippi, systems, also started in 1989. In the mid-1990s, data collection efforts catalogued the performance of 68 wetland systems in North America (DuBowy and Reaves, 1994; CH2M Hill and Payne Engineering, 1997; Knight *et al.*, 2000). Design procedures are offered, which generally fall in the two categories of loading methods and rate constant methods (CH2M Hill and Payne Engineering, 1997).

Examples are included here to illustrate the breadth of applicability for several types of animal operations.

## Poultry

### Example: Auburn Poultry

Three systems of free water surface (FWS) constructed wetlands were prepared at the Alabama Agricultural Experiment Station's (AAES) Poultry Science Unit at Auburn University in Auburn, Alabama, in June 1992 (Rogers *et al.*, 1995; Hill and Payton, 1998). Each system consisted of two cells in series, one planted with *Phragmites* and *Scirpus*, a second with *Sagittaria lancifolia*, while the third series acted as an unvegetated control. Each wetland cell was 5.5 m wide, 30.5 m long with an average depth of 30 cm, and lined with 10 cm of bentonite clay. Subsystems of wooden dowels were tested within the open water system. The wetlands influent was taken from the first cell of the lagoon system fed by the caged layer poultry operation, and the wetland effluent flowed to a holding pond nearby. A hydraulic loading rate of 3.1 cm/d was applied to each system, which resulted in chemical oxygen demand (COD) and total Kjeldahl nitrogen (TKN) loading rates of 145 and 30 kg/ha·d, respectively. In order to determine plant porosity blockage and thus also to assist in calculation of detention time, water column displacement tests were performed. The measured values were 10.7% and 7.0% for *Phragmites* and *Sagittaria*, respectively. The detention time was calculated to range from 11.1 to 11.6 days. The concentration reductions are shown in Table 25.2, and ranged from 40–60% for the principal contaminants for the vegetated systems. It was expected that temperature would have positively

affected treatment of several of the parameters under study, but treatment showed little correlation to water temperature (Hill and Payton, 1998).

## Cattle

Wetlands are used to manage feedlot runoff, dairy cattle waters, and pasture waters. Two fairly distinct situations may be found in the use of treatment wetlands for cow operations: pastures and feedlots versus dairies. Pastures and feedlots are primarily event-driven, runoff control systems, whereas dairies are concerned with water originating in milking parlors, comprised of cleaning waters. The two are considered separately here.

Pasture runoff has only been recently considered for treatment. The studies of Tanner and coworkers in New Zealand have utilized modern design concepts and made extensive measurements, which form the beginnings of a performance knowledge base (Tanner *et al.*, 2003; Tanner *et al.*, 2005b). Because some pastures are tile-drained, there is sometimes the possibility of directing tile drainage to constructed wetlands (see Figure 14.8, Chapter 14). The density of animals on the contributing watershed is typically low, and therefore the concentrations of nutrients and other contaminants is relatively low (e.g., 10–20 mg/L nitrogen). Further, speciation of nitrogen favors nitrate as the dissolved form, rather than ammonia, because the infiltration through the vadose zone provides for nitrification.

Feedlots present a different situation because the density on the contributing watershed is high. Nitrogen is almost all in the form of organic and ammonia (TKN), and concentrations of all pollutants are high in the direct runoff. One of the earliest constructed wetlands was a two-cell FWS system built in 1930 at the Brenton Brothers feedlot in Dallas County, Iowa, which serves a 26-ha feedlot that typically has 7,000 head of cattle. The first wetland cell, of extremely irregular shape, comprises 25 ha and receives rain-driven runoff from the feedlot. Over a two-year study period, there were reductions of 87% BOD, 60% TSS, and 58% TKN. This system was one of the two included in the North American Livestock Database (CH2M Hill and Payne Engineering, 1997). Subsequently, other wetland systems have been tested, with good results. For instance, runoff from Iowa State University's 380 head beef cattle concrete feedlot was treated via solids settling, soil infiltration, and a small constructed wetland, in series (Lorimor *et al.*, 2003). Concentrations and nutrient mass flows were reduced by over 97% for TKN, 94% for total phosphorus, and 93% for TSS. No buildups in the system were observed over five years. The authors concluded that the passive treatment system could very effectively protect surface-water quality below open beef feedlots. In their review of vegetated systems for cattle runoff control, Koelsch *et al*. (2006) found that virtually all of the existing information was from non-CAFO (Confined Animal Feeding Operations) situations, i.e., dairies. These authors concluded that critical design factors included pretreatment, sheet flow, discharge control, siting, and sizing, together with maintenance of a dense vegetation stand.

### Example: Cattle

The Canadian livestock farming community is generally not required to meet the strict surface-water discharge regulations imposed on municipalities and industries. However, farming operations generate high levels of nutrients and bacteria that originate from manure storage and application areas, manure storage tank overflows, and feedlot runoff, and there is a need to intercept and reduce these contaminant loads. Demonstration of treatment wetland technology was the prime objective in constructing demonstration wetland systems in Manitoba in 1996. Full-scale wetland projects were constructed at two cattle feedlot operations in the Interlake Region of Manitoba (Pries and McGarry, 2001). The second constructed wetland, described here, was at an 1,800-head feedlot bordering Lake Manitoba in the Interlake area, commissioned in 1998. The treatment wetland was constructed to reduce the nutrient and solids loading to Lake Manitoba.

The project captures the feedlot runoff, stores it in a holding pond, and then treats the wastewater in constructed wetland cells operated during approximately 150 days each year from mid-May through mid-October. The 0.25-ha holding pond collects and stores contaminated runoff from the feedlot area during the late fall, winter, and early spring, and has a working volume of approximately 3,300 $m^3$. The average hydraulic retention time (HRT) in the pond during the wetland operating period is approximately two months. The stored water is pumped to the wetland cells; the topography does not allow for gravity flow.

The treatment wetland consists of two 0.5-ha cells operating in parallel with an average depth of 0.3 m and a working volume of 3,000 $m^3$. Flow to each of the wetland cells is controlled by gate valves. For normal operation, the gate valves at the weir box are opened to allow a maximum flow of about 100 L/min to each cell. The flow enters the wetland in the center of the width of an influent distribution deep zone, which distributes the water across the width of each cell. Treated water is discharged at the effluent level control structure with a weir for flow measurement. In dry years there may be no outlet discharge due to water removal through high rates of evapotranspiration.

The holding pond provided considerable treatment prior to discharging the contaminated stormwater to the wetland. Table 25.3 presents the average annual data from monthly samples for two years of operation. The wetland effluent $BOD_5$ was 15 mg/L or less throughout both years, and the TSS was also consistently less than 15 mg/L. Inflow ammonia averaged 2.1 mg/L, with excursions to 4.8 mg/L, but the effluent ammonia-nitrogen was less than 0.5 mg/L. Phosphorus reduction was consistent each year with lower concentrations in the effluent than was measured in the influent.

## Dairy Operations

Dairy operations can be major contributors of nutrients to the watersheds in which they are located. For instance, in a nutrition study, it was found that cows excreted 88.2% of phosphorus

**TABLE 25.3**

consumed daily: 68.6% in feces, 1.0% in urine, and 30.3% in milk (Morse *et al.*, 1992). Current and abandoned dairy systems in South Florida's Lake Okeechobee watershed have a demonstrated phosphorus pollution potential (Nair *et al.*, 1995). In Ireland, about 25% of the land area is devoted to dairy farming, and it is estimated that the percentage of pollution attributed to agriculture is approximately 32% in rivers and streams that are slightly to moderately polluted.

Most dairies produce two types of waste streams: "white" water, which is defined as the wastewater produced during cleaning and sterilization of the milking equipment, and "green" water, which is wastewater resulting from the washdown of the manure-spattered walls and floors of the milking parlor and the associated holding pen or staging areas. The combination of these two waste streams produces the "typical" milkhouse wastewater. Because each dairy is different, the ratio of white water to green water will vary. Some farms may have existing manure treatment lagoons, which may be used as pretreatment device for the wetland treatment system. A typical dairy waste treatment schematic is shown in Figure 25.1.

Constructed wetlands have been demonstrated to be effective add-ons to supplement the treatment afforded by farm dairy pond systems. Farm dairy ponds provide for the return of a significant proportion of the nutrient loading to the pasture via periodic desludging, but the water discharges are not sufficiently good to protect receiving water quality (Table 25.4; see also Table 25.3). This application has spurred considerable research over the past decade (Geary and Moore, 1999; Karpiscak *et al*., 1999; Newman *et al.*, 2000; Hunt and Poach, 2001; Shamir *et al.*, 2001; Kowalk, 2002; Ibekwe *et al.*, 2003; Forbes *et al.*, 2004a; Dunne *et al.*, 2005c; Smith *et al.*, 2006; Healy *et al.*, 2007). Cronk (1996) identified 40 dairy treatment wetlands in North America, established between 1989 and 1993. A database compilation in 1996 identified 60 constructed wetlands at 38 sites in North America (CH2M Hill and Payne Engineering, 1997; Knight *et al.*, 2000). However, a large number of systems have been built, starting in the late 1990s. For instance, by 2004 there were 12 FWS wetlands in the Anne valley of County Wexford in Ireland (Figure 25.2) (Carroll *et al.*, 2005). In general, these systems have large surface areas, averaging 120 $m^2$/cow, and provide excellent water quality improvement (Table 25.4).

Although dairy wetlands have primarily been FWS, horizontal subsurface flow have also been implemented (Tanner *et al.*, 1995a; Tanner *et al.*, 1995b; Mantovi *et al.*, 2003; Kern, 2003). Tanner and Kloosterman (1997) recommend HSSF as an add-on to FWS, presumably because of the potential for clogging of a gravel bed with direct lagoon discharges. The New Zealand wetland design guidelines suggest about 1.0 $m^2$/cow for this post-FWS application (Tanner and Kloosterman, 1997).

However, if a HSSF system is to be used as a "standalone" device, more area is required to achieve good pollutant reductions. In the United Kingdom, a HSSF wetland was used to treat influent with an average $BOD_5$ of 1,192 mg/L on a dairy farm in Drointon (Cooper *et al.*, 1996). An area of 250 $m^2$ for 160 cows (1.6 $m^2$/cow) proved unacceptable, and vertical flow wetlands were subsequently installed ahead of the HSSF system. A 95% reduction in $BOD_5$ was achieved (Figure 25.3). In Germany, an area of about 10 $m^2$/cow produced reductions of 91% COD, 86% total nitrogen (TN), and 99% fecal coliforms (FC), with better nutrient reductions in winter (Kern, 2003). A HSSF system in Italy dimensioned at 1.84 $m^2$/cow (at a measured 80 L/d per cow) was successful in reducing BOD from 451 mg/L to 28 mg/L, for a settled influent from Imhoff tank pretreatment (Mantovi *et al.*, 2003). Total nitrogen was reduced from 65 to 33 mg/L, due to mineralization of organic nitrogen, because ammonia removal was nonexistent. It should be noted that European dairy wetlands

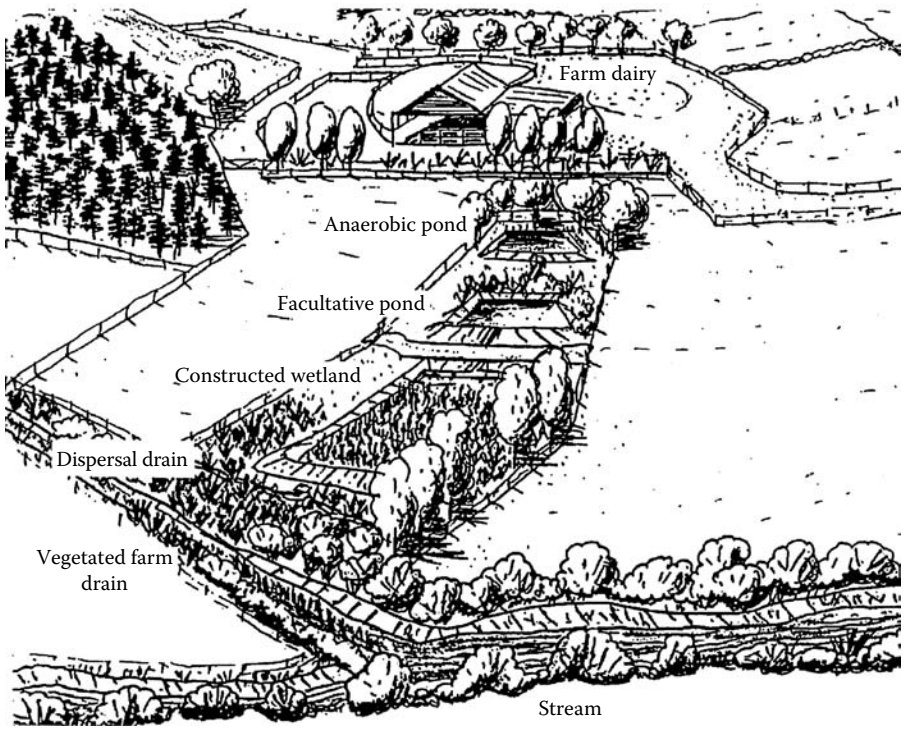

**FIGURE 25.1** Concept for a farm dairy treatment wetland system. (From Tanner and Kloosterman (1997) *Guidelines for Constructed Wetland Treatment of Farm Dairy Wastewaters in New Zealand*. do not usually have a lagoon for pretreatment, although that is the norm in North America and New Zealand. Therefore, direct comparisons are difficult.

Research is being directed to more highly oxygenated systems, such as forced aeration or vertical flow wetlands (Whitney, 2003). Vertical flow wetlands have high rates of oxygen transfer and are capable of handling high oxygen demands of milk-house wastes (Green *et al.*, 2002). Recommended vertical flow wetland criteria for dairy waters in France total 0.22–0.44 $m^2$/cow in two stages in each of two

trains (Liénard *et al.*, 2002). As for other VF systems, dairy VF wetlands are pulse loaded to induce hydrodynamic movement of air through the wetland bed.

The practitioner can find several design guidelines documents (CH2M Hill and Payne Engineering, 1997; Tanner and Kloosterman, 1997; Forbes *et al.*, 2004a). However, the supporting data is in the process of being strengthened at this time, as the various authors note, and improvements are to be expected as more operating data become available. Rate constants for dairy FWS can be found in the literature, in Payne Engineering and CH2M HILL (1997). In general, these are within the distributions presented in earlier chapters of this book, and indeed the dairy data were included in those determinations. McGechan *et al.* (2005) give rate constants for HSSF and VF dairy systems for nitrogen processing for mesocosms for dilute farm influents. However, loading specifications are more typically used to interpret data and for design. As an example, one set of median-loading recommendations for FWS systems is shown in Table 25.5. It should be noted that those loadings correspond to fairly large wetland areas, comparable to those used in the Irish systems in Table 25.4. Those dairy loading recommendations are comparable to, but somewhat less than, those recommended by U.S. EPA for municipal wastewaters.

Nitrogen reductions are in general less than for BOD and TSS. Dairy wastewaters differ from most municipal and domestic wastewaters in that they contain a relatively high amount of organic nitrogen. For instance, the database used in this book shows a median inlet organic nitrogen of 37 mg/L for animal treatment wetlands, whereas the median

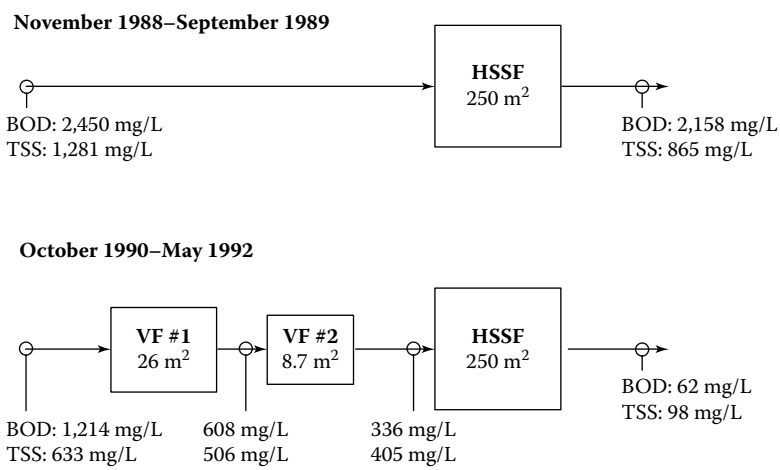

**FIGURE 25.3** Performance of the first and second iterations of the Drointon, U.K., reedbeds for farm waste treatment. In the first case, the BOD loading to the HSSF wetland was 255 kg/ha·d, and in the second case it was 35 kg/ha·d. (Based on Cooper *et al*. (1996) *Reed Beds and Constructed Wetlands for Wastewater Treatment*. WRc Publications, Swindon, United Kingdom.)

for municipal systems is 7 mg/L. As a consequence, there is a need to mineralize this organic nitrogen before it can be reduced by oxidative and other processes. This additional processing step slows overall nitrogen removal and is partly to blame for low removal rates. Mineralization of the organic nitrogen can increase the ammonia content of the water prior to its nitrification. Ultimately, the loss of total nitrogen suggests an implied oxygen supply that is limiting for nitrogen processing. The internal ammonia load created by mineralization of organic nitrogen adds to the incoming ammonia. The rates of nitrogen removal in animal wetlands are strongly suggestive of mechanisms other than traditional nitrification–denitrification. Oxidized nitrogen is rarely a significant component of influents or effluents from dairy water wetlands. This is speculatively due to an adequate carbon supply and rapid denitrification, and perhaps also due to Anammox or similar alternative processing mechanisms (see Chapter 9).

### Example: Dairy Farm Operations

A study on a three-cell integrated FWS system in County Wexford, Ireland, was conducted over a 2.5-year period (Dunne *et al.*, 2005a; Dunne *et al.*, 2005b). Water from farmyard management and dairy operations for a 42-cow facility were collected in a central storage tank before discharge to the wetlands. The three cells had a combined area of 4,265 $m^2$ (102 $m^2$/cow) and were maintained at a 30–40-cm depth. A 250-$m^2$ sedimentation basin preceded the treatment marshes. The vegetative cover was 80–90% during the growing season, and comprised of a mixture of *Carex riparia, Typha latifolia, Phragmites australis, Sparganium erectum*, and other emergent species. The flow rate to the wetlands averaged 7.6 $m^3$/d (180 L/cow·d), and was greatly augmented by rainfall (1,142 mm/yr) to produce an outflow rate of 31.1 $m^3$/d. As a result, there were considerable differences between mass reductions and concentration reductions (Table 25.6). Part of the observed concentration reduction was attributable to dilution. Nonetheless, this lightly loaded system produced very good removals, but with lesser performance in winter for ammonia and phosphorus. It is noteworthy that the implied maximum oxygen supply was about 4.8 gO/$m^2$·d, which is a feasible reaeration rate. It is also the case that the nitrogen supply places these wetlands in the group with agronomic control. BOD and TSS are reduced to what

appear to be background concentrations because there was little change in concentrations after the first two wetlands.

### Swine

Swine wastewaters are strong effluents that received only minimal treatment in past years. A very popular system in the southeastern United States is an anaerobic lagoon followed by a spray irrigation system. In North Carolina, there are 4,500 active and 1,700 inactive swine waste lagoons (Humenik *et al.*, 2004), but these are no longer permitted because of problems with overflow and leakage. Constructed wetlands are a logical add-on, and therefore investigations on their effectiveness were initiated, approximately in 1990, at Auburn University's Sand Mountain Agricultural Experiment Station in DeKalb County, Alabama (Hammer *et al.*, 1993a; McCaskey *et al.*, 1994). Another facility followed soon after (1991) at the Pontotoc, Mississippi, Experiment Station (Cathcart *et al.*, 1994). Based on early swine wetland data and the performance of municipal treatment wetlands, design recommendations quickly proliferated (USDA-NRCS, 1992; Hammer, 1994). Loading numbers of approximately 60–70 kg/ha·d for BOD were suggested. In fact, FWS swine wetlands are at the poor performance edge of the municipal concentration-loading band (Figure 25.4), and this loading now appears likely to produce 60–80 mg/L BOD in the wetland outflow. This may be due to the much higher concentrations in swine wastewater (Cronk, 1996). Research intensified in the mid-1990s, with projects in North Carolina and Indiana. Investigations were conducted from 1992 to the present at a continuous marsh site in the eastern coastal plain in Duplin County, and at a marsh–pond–marsh site in Greensboro at North Carolina A&T State University. The site descriptions and operational procedures are reported in a number of publications (Hunt *et al.*, 1994; Reddy *et al.*, 2001; Stone *et al.*, 2002; Poach *et al.*, 2003; Stone *et al.*, 2004). The Purdue University system at West Lafayette involved 16 FWS wetland cells operated in a designed experimental array (Reaves *et al.*, 1994). These studies all showed significant reductions in BOD, TSS, and total nitrogen, but the removal percentages were not outstanding (Table 25.7).

Because of the high ammonia levels in swine lagoons and wetlands, there has been concern that ammonia volatilization could be a problem. A study was conducted to address the concern that nitrogen removal was due to high ammonia volatilization. Poach *et al*. (2002; 2004) documented that less than 10% of the input nitrogen was lost by ammonia volatilization (see Figure 9.7, Chapter 9). However, as for other animal wastes, the organic nitrogen content is high, and a mineralization step must precede ammonia conversions. The process of denitrification is greatly assisted by the availability of organics and carbon, with the result that oxidized nitrogen is not present in the waters, and by the fact that redox potentials are generally quite low (Hunt *et al*., 2003; Szögi *et al.*, 2004). Nitrogen processing in swine wetlands is quite temperature dependent, as for other FWS systems. However, that does not preclude their use in cold climates during the unfrozen season, even as far north as Alaska (Maddux, 2002).

Subsurface flow wetlands have also been used to treat swine effluents in North America (Sievers, 1997) and elsewhere around the world (Lee *et al.*, 2004b). However, the high TKN concentrations also cause problems with respect to oxygen supply in HSSF systems. Therefore, vertical flow systems have also been piloted (Kantawanichkul *et al.*, 1999; Sezerino *et al.*, 2003). As an alternative to vertical flow, a fill-and-drain mode has been employed with good success (Behrends *et al.*, 2003; Rice *et al.*, 2005). This concept involves continuously pumping wastewater back and forth

between adjacent cells on a two-hour cycle. This vertical flow design provides aeration of the gravel substrate and exposes the internal biofilms to atmospheric oxygen. During the "drain phase" of the cycle, atmospheric oxygen causes enhanced oxidation of ammonia and organic matter. This mode of operation is described further in Chapter 24.

### Example: Swine

In 1995, six wetland systems to treat swine lagoon wastewater were constructed at the North Carolina A&T State University farm near Greensboro, North Carolina (Reddy *et al.*, 2001; Stone *et al.*, 2004). The wetland systems were configured into a marsh section, a central pond section, and another marsh section (marsh–pond–marsh). The marsh sections were approximately 10 m × 10 m, and the pond section was 10 m × 20 m. The marsh sections were planted with *Typha latifolia* and *Schoenoplectus americanus* in March 1996. Beginning in September 2000, the wetlands were loaded with specific total nitrogen at rates of 5, 14, 23, 32, 41, and 50 kg/ha·d. For one year, the wetland hydraulic loading rates were held approximately equal, with only the TN loading rate varying. The operating depths of the constructed wetlands were 15 cm for marsh sections and 75 cm for pond sections.

Mean TN and $NH_4$-N concentration reductions were 35 and 25%, respectively. However, the nitrogen performance was on the poor side of the scatter of performances for other FWS wetlands (Figure 25.5). The calculated first-order plug-flow rate constants ($k_{20}$) for TN and $NH_4$-N were 3.7–4.5 m/d and 4.2–4.5 m/d, respectively, which are considerably lower than the central tendencies given in Chapter 9. These are at about the 10th percentile for FWS wetlands. However, no allowance was made for the internal mineralization of organic nitrogen in the Stone *et al*. (2004) analysis.

## Zoos

The Wuhan Zoo, Wuhan City, China, is investigating the use of sedimentation systems and wetlands to reduce nutrient losses from the site to a lake. The project is conducted by the Research Centre for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing (D'Arcy, 2005). A reed bed has been operating for some years at Chester Zoo in the U.K., treating runoff from its Asian elephant enclosure (D'Arcy, 2005). A vertical flow treatment wetland is used at the Saint-Felicien zoo in Quebec (Pries, 1994). The seals of the Rheine zoo in Westphalia, Germany, have their water recycled back to their basin to cut costs that otherwise would arise by replacing used water with fresh drinking water (Dartmann *et al.*, 2000). The seals produce large amounts of residue that cloud the water, capable of impairing the visitors' view, especially in deep-water zones. A horizontal flow wetland system is used to filter and clarify the water.

## Aquaculture

Fish farming is an increasing activity worldwide, as wild supplies dwindle and dietary preferences change. Constructed wetlands have been explored as a means of controlling the associated pollution, notably for catfish, trout, and shrimp operations. However, other fish species have also been the object of treatment wetlands, such as milkfish (*Chanos chanos*) (Lin *et al.*, 2002a; Lin *et al.*, 2002b).

### Catfish

Channel catfish (*Ictalurus punctatus*) farming is the largest segment of aquaculture in the United States. Most of the nation's catfish is raised in Alabama, Arkansas, Louisiana, and Mississippi on 70,000 ha of catfish farms (Tucker, 1999). More farm-raised catfish is produced and sold in these states than all other U.S. aquacultured species combined. In fact, the farm-raised catfish industry enjoyed phenomenal growth over the past 37 years, from 2.6 million kilograms produced in 1970 to more than 275 million kilograms in 2006 (Harvey, 2006). Nearly all commercial aquaculture in the southeastern United States is conducted in earthen ponds. Good production from ponds is encouraged by using manufactured feeds

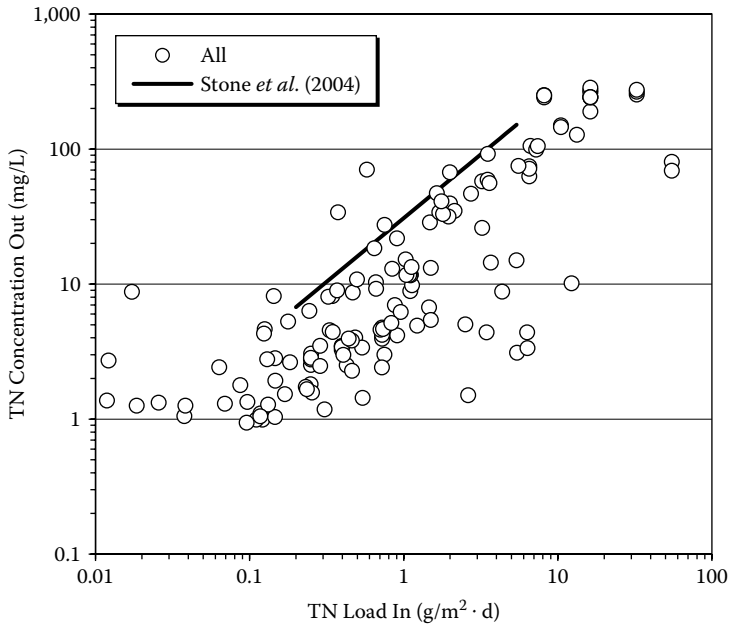

**FIGURE 25.5** Total nitrogen loading graph for the marsh–pond–marsh system at North Carolina A&T University Farm FWS swine wetlands at Greensboro, North Carolina, compared to the general FWS loading data. The line that represents their swine data (from Stone *et al.* (2004) *Ecological Engineering* 23(2): 127–133) is on the upper edge of the cluster of data.

or increasing the availability of natural foods by adding fertilizers. Less than 30% of the nitrogen and phosphorus added in feed or fertilizer is recovered at harvest. The remainder of the nutrient load is left in the pond and may be discharged when it rains or when ponds are drained between fish crops.

In the United States, aquaculture effluents are regulated under the National Pollutant Discharge Elimination System (NPDES) as part of the Federal Water Pollution Control Act of 1972. A study by the Southern Regional Aquaculture Center characterized catfish pond effluents from 45 ponds over a two-year period (Tucker, 1999). Effluent quality was poorest in the summer when fish-feeding rates and water temperatures are highest. Catfish pond effluents generally have higher concentrations of nutrients and organic matter than natural stream waters, but much lower concentrations than municipal and industrial wastewater.

As a result of successful demonstrations, the use of constructed wetlands for finfish production was thoroughly examined by Posadas and LaSalle (1997; 1998). Their report concluded that the use of constructed wetlands was not economically viable because of the added costs. Kouka and Engle (1994) estimated that wetland treatment would add $0.18/kg to the price of the fish, which is on the order of $1.75/kg (2006 USD) (Harvey, 2006).

### *Example: Catfish*

In 1992, a two-cell, 2,350-m$^2$ test wetland was implemented near Greensboro, Alabama (Schwarz and Boyd, 1995). Water from a production pond was passed through the constructed wetlands at HRTs of 1, 2, 3, and 4 days, with hydraulic loading rates of 77–91 L/d·m$^2$. Cell one was planted with California bulrush (*Scirpus californicus*) and giant cutgrass (*Zizaniopsis miliacea*), and cell two with maidencane (*Panicum hemitomon*). Concentrations of potential pollutants were much lower in effluent from the wetland than in influent from the channel catfish ponds. The mean mass removals were total nitrogen, 61%; biochemical oxygen demand, 62%; suspended solids, 87%; and total phosphorus, 75%. Overall performance of the wetland was not correlated with HRT, but that was clearly because hydraulic loading was held constant while depth was varied. Thus, this data supports the notion that removal is area specific rather than volume specific. The researchers observed that although pond overflow and water exchanges could be treated with reasonably sized wetlands, complete pond draining usually proceeds rather rapidly and would create unacceptably high hydraulic loads.

## Tilapia

"Tilapia" is the generic name of a group of cichlids endemic to Africa, consisting of three aquaculturally important genera (*Oreochromis, Sarotherodon,* and *Tilapia*). Worldwide harvest of farmed tilapia has now surpassed 800,000 metric tons, and tilapia are second only to carp as the most widely farmed freshwater fish in the world (Pompa and Masser, 1999). Positive aquacultural characteristics of tilapia are their tolerance to poor water quality and the fact that they eat a wide range of natural food organisms. Indeed, tilapia have been considered as part of a system to improve swine water quality, used in conjunction with wetlands (Dontje and Clanton, 1999). Biological constraints to the development of commercial tilapia farming are their inability to withstand sustained water temperatures below 10 to 15°C. The U.S. imports most of its

demand, but tilapia farms are beginning to appear, and with them the need to improve water quality.

In the mid-1990s, constructed wetlands were tested for treatment of tilapia wastewater at New Mexico State University, Las Cruces, New Mexico (Zachritz and Jacquez, 1993). Brown *et al*. (1999) used salt-tolerant plants (*Suaeda esteroa, Salicornia bigelovii,* and saltbush *Atriplex barclayana*) to remove nutrients from saline aquaculture wastewater in Tucson, Arizona. These were grown in sand in draining lysimeters and were irrigated to meet evapotranspiration and produce a 0.3 leaching fraction using aquaculture effluent generated from an intensive tilapia culture system. The system removed 98% and 94% of total and inorganic nitrogen, respectively. Behrends *et al*. (1999; 2002) utilized fill-and-drain SSF wetlands to treat wastewater from an experimental tilapia-rearing (*Oreochromis niloticus*) facility in Muscle Shoals, Alabama, with good success.

## Salmonids

Salmon and trout (family *Salmonidae*) are also farmed intensively in more northerly climates and have the same general water quality issues as catfish. In the Province of Quebec, for example, trout farm production increased from 40 tons/yr in 1976 to 1,900 tons/yr in 1996 (Comeau *et al.*, 2001). Trout farms effluents are typically 20 times more diluted than medium-strength municipal wastewaters and even below municipal secondary treatment criteria (Comeau *et al.*, 2001; Schulz *et al.*, 2003a). With respect to receiving-water-quality objectives, the most constraining element to remove from freshwater fish farms is phosphorus.

Evaluation of treatment wetlands to treat effluents began in the mid-1990s, with work at the Freshwater Institute in West Virginia (Summerfelt *et al*., 1999), and at Chisholm, Minnesota (Axler *et al.*, 1996). Subsequently, projects proliferated, involving both FWS systems (Michael, 2003) and HSSF systems (Comeau *et al.*, 2001; Naylor *et al.*, 2003; Schulz *et al.*, 2003a; Ouellet-Plamondon *et al.*, 2004; Schulz *et al.*, 2004; Lymbery *et al.*, 2006). In general, findings indicate that constructed wetlands are an ecologically attractive and economical method for treating salmon and trout farm effluents to reduce solids and phosphorus. Examples of wetland performance are given in Table 25.8.

## Shrimp

The production of crustaceans in pond culture is a major agricultural enterprise. In the United States, this is a fledgling industry, with 120 farms growing only about 3,800 metric tons of saltwater shrimp and freshwater prawns (USDA-NASS, 2006). In contrast, 647 farms grow 16,000 metric tons of crawfish. U.S. imports of shrimp totaled 560,000 metric tons in 2006, because shrimp farming is primarily a tropical activity, with major centers in China, India, Thailand, Indonesia, and South America (Harvey, 2006). Effluent waters from shrimp aquaculture can contain elevated levels of phosphorus, ammonia, nitrate, and organics. Regulation of the water quality of shrimp pond discharges has begun in many locations. Constructed wetlands offer an ecologically beneficial, low-cost treatment alternative, and, as a result, exploratory studies began in the mid-1990s (Sansanayuth *et al.*, 1996). It was observed by Gautier *et al.* (2001) that an engineered mangrove wetland produced good water-quality improvement for a shrimp farm effluent in Colombia. However, the use of natural wetlands is not always allowed, and thus research mostly focuses on constructed wetlands.

A 7.7-ha mesohaline (3–8 ppt) FWS-constructed wetland was used to treat 13,600 $m^3$/d of effluent from 8.1 ha of intensively farmed shrimp ponds near Port Mansfield, Texas, on the coast of the Gulf of Mexico (Badrinarayanan, 2001; Tilley *et al.*, 2002; Staff, 2006) The depth of water was maintained between 0.15 and 0.45 m, which provided a hydraulic retention time (HRT) in the wetland on the order of one day. Originally, the wetland was planted with ten species of salt-tolerant wetland plants, but by the second year of operation, the wetland had undergone self design. *Typha latifolia*

became the overwhelmingly dominant plant species, occupying nearly two thirds of the wetland area. Concentrations of total phosphorus (TP), total suspended solids (TSS) and inorganic suspended solids (ISS) were reduced by 31, 65, and 76%, respectively, during recirculation, and maintained satisfactory water quality. Parameterization of the *k–C** model for TSS or TP showed that mean target levels could be achieved when the ratio of pond surface to wetland surface was 12:1. Tilley *et al*. (2002) concluded that constructed wetlands can perform satisfactorily as recirculation filters in large-scale shrimp farms.

Similar results were obtained in a combination system in Taiwan (Lin *et al.*, 2003b; 2005). A FWS unit was followed by a HSSF unit, and integrated into a commercial-scale recirculating aquaculture system for intensive shrimp culture. This study investigated performance of the treatment wetlands for controlling water quality. Removals were TSS (55–66%), $BOD_5$ (37–54%), total ammonia (64–66%), and nitrite (83–94%) for recirculating water under high hydraulic loading rates (1.57–1.95 m/d). The area ratio of the demonstration wetlands to culture tank was 0.43. It was concluded that a constructed wetland was technically and economically feasible for managing water quality of an intensive aquaculture system.

## 25.2 FOOD-PROCESSING WASTEWATERS

### Sugar Refining

Wastewaters from sugar-processing plants have been treated in natural wetlands (Gambrell *et al*., 1987). The form of the BOD in these wastewaters is sucrose and its precursors and derivatives. It is therefore not surprising that removal follows the pattern established for BOD in municipal wastewaters. The *k-C** model does a good job of fitting the batch disappearance of soluble TOC (Figure 25.6). The rate constant is similar to that obtained from BOD data from numerous domestic wastewater wetlands (see Chapter 8).

American Crystal Sugar's Hillsboro, North Dakota, sugar beet refinery, built in 1973, generates about 260,000 $m^3$ of wastewater during the eight-month processing season. The plant uses a 64-ha FWS treatment wetland for advanced secondary since 1993 (Anderson, 1996). The major emergent macrophtye species include cattails (*Typha latifolia, Typha angustifolia*), bulrushes (*Scirpus acutus*), and common reed (*Phragmites australis*). American Crystal Sugar subsequently built a second 64.8-ha FWS wetland at their Drayton, North Dakota, plant in 1993.

Vertical subsurface flow wetlands were tested in the British Isles (Morris and Herbert, 1997). Three first-stage beds were followed by four second-stage beds, totaling 400 $m^2$ for the whole pilot system. Warm wastewaters during the beet processing season showed good removals of 87, 88, and 80% for COD, TSS, and ammonia nitrogen, respectively, at 2.5–7.4 cm/d hydraulic loading. Cooler temperatures in the nonprocessing season gave removals of 74, 88, and 93%, at 17.4–18.6 cm/d hydraulic loading.

Constructed vertical upflow SSF wetlands are used by Usina Costa Pinto S.A. in Piracicaba, Brazil, to treat wastewater from a sugar mill. Rice is planted in the several cells in series, situated in terraces on a modestly steep slope (Figure 25.7). The strong influent has BOD up to 10,000 mg/L, which is reduced by about 50%.

### Potato Processing

Potato processing produces wastewaters with high starch content. This material is highly biodegradable, and has been the target of constructed wetlands treatment since 1990 (de Zeeuw *et al.*, 1990).

Lamb-Weston's Connell, Washington, facility uses free water surface treatment wetlands as part of its wastewater

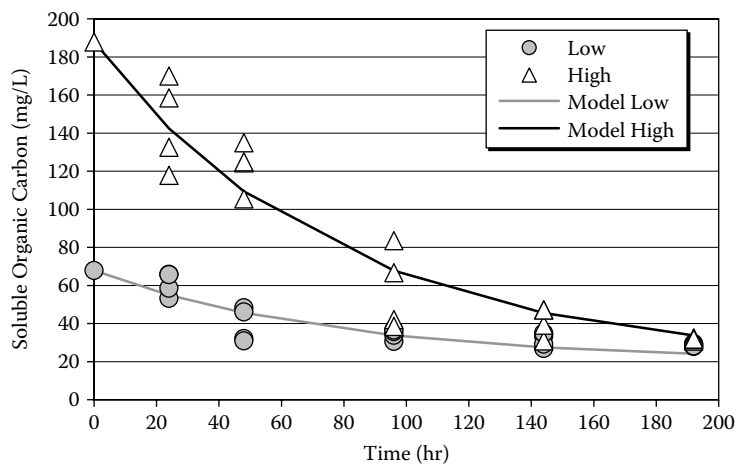

**FIGURE 25.6** Disappearance of soluble carbon in wetland microcosms dosed with sucrose. Data represent two levels of starting concentration, two levels of stirring, and two levels of supplementary nutrient addition. Model lines are for $k$ = 36 m/yr and $C^*$ = 20 mg/L. (Data from Gambrell *et al*. (1987) *Journal of the Water Pollution Control Federation* 59(10): 897–904; graph from Kadlec and Knight (1996) *Treatment Wetlands*. First Edition, CRC Press, Boca Raton, Florida.)

**FIGURE 25.7** Vertical flow rice wetlands at Piracicaba, Brazil. Very strong sugarmill effluents (up to 10,000 mg/L BOD) flow upward through the root zone.

treatment system to handle the approximately 5,300 $m^3$ of wastewater it produces each day (Burgoon *et al.*, 1999). The goal of the project is to remove TSS and COD and to reduce nitrogen to the amount needed for growing an irrigated fodder crop. Two pilot projects were conducted (Kadlec *et al.*, 1997). The first investigated FWS wetlands only and produced 60–70% reduction in COD with two to four days' detention. The second was a prototype for the full-scale system, consisting of a FWS–VSSF–FWS combination.

In the full-scale project, clarified wastewater is pumped to a 10-ha lined FWS treatment wetland (Figure 25.8), followed by a 4-ha vertical SSF flow system, then to a 2-ha denitrification FWS treatment wetland, and finally ends in a 500-mL storage pond (Burgoon *et al.*, 1999). Treated water is then used for seasonal irrigation on 250 to 500 ha of fodder crops. The first FWS wetland provides TSS and COD removal, whereas the VSSF component is highly effective at nitrification. The final FWS wetland provides denitrification utilizing a small amount of raw influent as a carbon source (Burgoon, 2001). The holding pond provides storage so that the water may be irrigated only during the growing season. The design hydraulic retention time is 6.6 days (summer) and ten days (winter).

### Milk Products

The addition of milk-processing water to domestic treatment lagoons has generated de facto data for milk BOD, which is high in colloids. In Gustine, California, FWS wetlands received lagoon wastewater that was dominated by milk-processing effluent (Walker and Walker, 1990). Wetland cells 2B and 6D were 11.6 m × 337 m, and operated at 10.5–12.2 days detention for several months, during which time influent BOD was 280–440 mg/L. These cattail-bulrush cells achieved 86–89% reduction, corresponding to $k$ = 48 m/yr and $C^*$ = 4.2 mg/L for an assumed $P$TIS = 5 (see Chapter 8). A relatively smooth reduction occurred along the flow direction (see Figure 8.7, Chapter 8).

The Eichten Cheese, Center City, Minnesota, system consists of a septic tank, subsurface flow constructed wetland,

**FIGURE 25.8** Potato wastewater wetland at Connell, Washington.

**FIGURE 25.9** Treatment wetland at the Kilmeadan cheese factory in Ireland.

and an infiltration bed (Wallace, 2002c). The wetland and infiltration bed are insulated with mulch, and the wetland has operated without freezing problems. An aeration system was placed in the wetland cell to increase the oxygen transfer rate, to deal with the extremely high BOD. $CBOD_5$ removal was 94%, whereas total nitrogen removal was 74%. The Kilmeadan cheese factory near Waterford, Ireland, employs a multicell FWS wetland to improve discharge water quality (Figure 25.9).

A pilot surface flow wetland system was constructed in 1996 near Quebec City (Serodes and Normand, 1999). This system consisted of four similar cells with vertical walls, each 12 m long and 1.2 m wide. The cells were planted with indigenous broad-leaved cattail (*Typha latifolia*) harvested from a local natural marsh. Water depths of 4, 6, 10, and 10 cm, allowed nominal hydraulic residence times of 3.3, 5, 10, and 10 days, respectively. The influent was produced by adding 1,250 mL of raw milk, 55 g of detergent, and 35 mL of commercial phosphoric acid to 600 L of fresh water. Immediately following its production, this effluent had a COD of 425 mg/L and levels of *ortho*-P and total P of 12 and 19 mg/L, respectively. The results showed that COD elimination was rapid because, at mid-course in the 3.3-day wetland, COD reduction was already in excess of 85%. The presence of a residual concentration (27–57 mg/L) was noted, which could not be lowered further by more detention.

Perdomo *et al*. (2000) examined the performance of two mesocosm cells in series, containing *Eichhornia crassipes* and *Typha* spp. in all three permutations. The influent was wastewater from a milk products processing plant and contained high concentrations of BOD, TSS, TN, and TP. At several weeks detention time, 99, 97, and 96% removals of COD, TSS, and ammonia were found for the cattail–cattail combination.

A combination system of two vertical stages and a final HSSF stage was used at Loubressac, France, to treat cheese effluents, including milk serum (whey). This acid water was partially neutralized and the COD reduced significantly (Reeb *et al.*, 2004).

### Meat Processing

Wetlands are in use for treating abattoir wastewaters in a number of locations. These waters contain significant quantities of blood and other sources of BOD and are well treated in the wetland environment.

Pioneering work was done in the 1980s by Van Oostrom and coworkers in New Zealand (Van Oostrom and Cooper, 1990), and Finlayson and coworkers in Australia (Finlayson *et al.*, 1990). (Figure 25.10).

The New Zealand tests began with multiple wetlands, including three SSF systems (*Schoenoplectus validus*, *Glyceria maxima*, and unplanted) and three FWS trenches, planted with mixtures of *Typha, Glyceria*, and *Schoenoplectus* (Van Oostrom and Cooper, 1990). The target was removal of ammonia, and less than 22% removals were found at 4–7 cm/d hydraulic loading. The low removals were attributed to lack of nitrification. Subsequently, these researchers targeted nitrate removal in FWS with floating mats of *Glyceria* (Van Oostrom and Russell, 1994). Their pilot system reduced oxidized nitrogen by 37% at 4.6 cm/d hydraulic loading. Further work with floating *Glyceria* improved oxidized nitrogen removal to 46% at 5.7 cm/d hydraulic loading (Van Oostrom, 1995). Additionally, there was 66% COD removal and 96% TSS reduction.

Subsurface flow wetlands were tested for improving anaerobically digested abattoir effluents in Pachuca, Mexico (Rivera *et al.*, 1997). Two beds in series were used, vegetated with *Phragmites australis* and *Typha latifolia*. The nominal detention time in the two 12 m × 50 m beds was 1.7 days. Removals were 89, 87, and 89% for $BOD_5$, COD, and TSS, respectively, but much less for inorganic nitrogen species and

**FIGURE 25.10** FWS wetlands at Rangiuru, New Zealand. Strong meat plant effluents from the Affiliated Freezing Farmers Cooperative (AFFCO) are treated here.

phosphorus. Gutierrez-Srabia *et al.* (2004) also operated SSF wetlands in the State of Hidalgo, Mexico, to improve slaughterhouse wastewater quality after sedimentation and lagoon pretreatment. Good reductions were achieved in a 10.6-day detention in the wetland, 74% for COD and 44% for TSS, but only 9% for ammonia. Weedon (2004) investigated VF wetlands for abattoir effluent and found excellent initial removals of various contaminants (>95%). However, clogging ensued, and removals dropped considerably (60–90%).

A combination of meat-plant lagoon effluent from Cargill Foods Ltd. and municipal lagoon effluent from the town of High River, Alberta, has formed the major source of input water for the 1,246-ha Frank Lake wetland since 1989 (White, 1997). An essentially dry lake bed was thereby restored to a hemi-marsh condition. Approximately 60% of the incoming phosphorus load has been removed and stored in sediments, thus reducing incoming TP from 8.2 to 2.5 mg/L. Additional constructed treatment wetlands are in design to improve the quality of the incoming water to Frank Lake.

### Beer, Wine, and Spirits

The Coors Brewery in Golden, Colorado, operates a FWS treatment wetland for unspecified purposes. Billore *et al.* (2001) described a four-cell SSF wetland to treat secondary effluent from Associated Alcohols and Breweries, Ltd., in Baraha, India. The pilot project operated at 6.6 days nominal detention time and was vegetated by *Typha latifolia* and *Phragmites karka*. The system achieved 48, 49, and 84% reductions in TSS, COD, and ammonia, respectively.

Both FWS and SSF wetlands are in use to improve the quality of winery effluents (Kerner and Rochard, 2004) (Figures 25.11 and 25.12). As of 2002, there were seven wineries using treatment wetlands to treat winery wastewater in

**FIGURE 25.11** Full-scale vertical SSF wetland for treating winery wastewater at Chateau Mont-Redon, Chateauneuf-du-Pape, France.

**FIGURE 25.12** The Grove Mill winery FWS wetland in the Waihopai Valley near Blenheim, Marlborough, New Zealand.

California (O'Brien *et al.*, 2002). Two have free water surface wetlands, four have subsurface flow wetlands, and one uses both free water surface and subsurface wetlands technology. Two additional subsurface wetlands are either under construction or in permitting. Targets for treatment are typically COD, TSS, ammonia, and nitrate. Performance of these constructed wetlands has been found to depend on the management at each winery. Results also show that wineries with a pretreatment system, prior to the wetlands, perform better than those without a pretreatment system.

Pilot work on SSF treatment of winery wastewater was performed in 1996–1997 (Grismer *et al.*, 2001; Shepherd *et al.*, 2001a), using wastewaters from the Fetzer Vineyards, Hopland, California. Results indicated excellent reductions in TSS and COD. COD in the range 2,000–5,000 mg/L was reduced to 20–60 mg/L in about ten days' detention, and TSS was reduced from 300–600 mg/L to 12–32 mg/L. A full-scale system was placed in operation in late 1998 and has had some success (Grismer *et al.*, 2003) (Table 25.9).

In Italy there are at least three systems involving combinations of SSF, VSSF, and FWS components (Masi *et al.*, 2002). Very good removals have been reported at low hydraulic loading rates of 1.3–3.7 cm/d (Table 25.10). Tests have also given good results in Germany (Müller *et al.*, 2002), and in France (Rochard *et al.*, 2002).

Attempts at parameterizing removal models for HSSF systems have met with mixed results (Sheridan *et al.*, 2006).

### Vegetables

Anchor Foods, located in Pecos, Texas, processes onion rings as well as cheese and vegetable appetizers for the frozen-food market (O'Brien *et al.*, 2002). Wastewater was originally routed to two lagoons and then disposed of through flood irrigation on adjacent land. In 2001, the plant added two small sedimentation basins and a free water surface treatment wetland totaling 1.4 ha. The effluent from the wetland system is then land applied through flood irrigation. The permitted flow rate is 760 $m^3$/d.

A two-bed SSF wetland was built at Gradisce, Slovenia, in 1991 to treat food-processing effluents (Vrhovsek *et al.*, 1996). At hydraulic loadings of 2.6–5.5 cm/d, removals were 92%

for COD and 86% for ammonia. Del Bubba *et al.* (2004) operated a pilot-scale reed bed for olive mill wastewater treatment. Ten-to-one dilution was required to maintain healthy vegetation and gave sustainable removal efficiencies, especially for COD ($74.1 \pm 17.6\%$) and polyphenols ($83.4 \pm 17.8\%$).

## 25.3 LANDFILL LEACHATE

Old and new landfills produce leachates, typically formed from infiltrating waters and the products of solid-waste decomposition. Those contaminated leachate waters are a potential threat to surface and subsurface receiving waters. A very wide spectrum of pollutants is possible, reflecting the character of the materials contained in the stack. The principal categories of undesirable substances are (1) volatile organic compounds (VOCs), (2) nutrients, notably nitrogen, (3) heavy metals, and (4) priority toxic organic compounds. Leachates are produced when rainfall and percolated groundwater combine with inorganic and organic degraded waste. In unlined landfills, leachates frequently discharge to groundwater or appear as surficial drainage around the base of the landfill. In modern lined landfills, leachates are collected from the lined cells and routed to treatment units.

The highly variable nature of solid waste, differences in age and decomposition, and the diversity of chemical and biological reactions that take place in landfills result in a wide range of chemical quality of leachates. From a review of an "average" landfill, concentrations of COD, volatile acids, and nitrogenous compounds increase in landfill leachate during the first few years of operation and then decline over 10 or more years. Table 25.11 provides typical ranges encountered in landfill leachates. There is, consequently, a strong distinction between waters coming from open, operating landfills and waters emanating from closed landfills. The fresh leachate from an active or newly closed landfill system can have very high levels of organics and nitrogen. After a period of many years, the concentrations in the leachates are likely to be much lower, and continue to decrease with time. Flows are generally low but may vary depending on management and minimization of percolation from rainfall.

One common option for disposal of leachate is to send it to a municipal treatment plant. Depending upon the character of the refuse, the leachate can contain a number of constituents not normally present in municipal or domestic wastewater. These primarily include metals, a spectrum of volatile organics, and toxic compounds. These substances are of concern to municipal treatment plant operators for two reasons.

**TABLE 25.11**
**Typical Landfill Leachate Characteristics Over Time**

| | Concentration (mg/L) | | |

**FIGURE 25.13** Marinha Grande, Portugal, HSSF leachate treatment wetlands. These are newly planted at the time of this photo.

First, the potential toxicity threatens the essential microbial populations that form the basis for processes such as activated sludge. Second, many of the potential contaminants are not treated by conventional processes, and pass through to the discharge point where they threaten compliance for the plant permit. Therefore, despite the low volumes of water involved compared to many treatment plant flows, the municipal treatment plant owners and operators do not want to accept landfill leachate. The leachate is usually of such small volume that pipelines to treatment plants are not economical, and the leachate must be trucked to the treatment plant. This is a costly procedure, requiring storage at the landfill site as well as transportation charges.

## Treatment Wetlands for Landfill Leachate

Natural wetlands are often the recipients of landfill leachates simply because many landfills are adjacent to wetlands or partially fill them. In such cases, the natural wetlands have been observed to improve water quality (Higgins and Lugowski, 1996; La Forge, 1997). Extensive studies of a very large wetland receiving leachate in Florida demonstrated that the ecosystem could easily absorb all leachate constituents (Schwartz *et al.*, 1999). Wetland treatment of the leachate is an attractive alternative method of water quality improvement (Loer *et al.*, 1999; Rew and Mulamoottil, 1999). The volumetric flow of leachate is often fairly small, compared to other wastewaters, such as domestic, animal, and industrial, or urban or agricultural runoff. Thus, long detention times are possible for small wetland–landfill area ratios. The use of constructed wetlands to treat these landfill leachates began to develop in the late 1980s through the mid-1990s, with both subsurface flow wetlands (Trautmann *et al.*, 1989; Staubitz *et al.*, 1989; Cooper and Hobson, 1989; Birkbeck *et al.*, 1990; Robinson, 1990) and surface flow wetlands (Mackie and Murphy, 1992; Martin *et al.*, 1993; Martin, 1994; Martin and Moshiri, 1994). Subsequently, wetland treatment of landfill leachates has been successfully tested at several locations (Figure 25.13). A brief review of existing work is given here.

Surface flow wetlands have been operating successfully in Escambia County, Florida, since 1990 (Martin *et al.*, 1993; Martin, 1994; Martin and Moshiri, 1994; DeBusk, 1999). Another warm-climate system exists near Mobile, Alabama (Martin *et al.*, 1999; Johnson *et al.*, 1999). Full-scale FWS constructed wetlands were implemented near Cambridge, Minnesota, which are operated only during the warm periods of the year (MPCA, 1995; Loer *et al.*, 1999; Kadlec, 2003e). A full-scale combination of a VF and a FWS wetland is in use at Saginaw, Michigan, for seasonal treatment of leachate (Kadlec, 2003e).

Cold-climate systems are functioning properly in Norway (Mæhlum, 1994; Jenssen *et al.*, 1994a; Mæhlum *et al.*, 1999; Mæhlum, 1999; Mæhlum *et al.*, 2002), as well as at several locations in Canada: Sarnia, Ontario (Higgins and Brown, 1999); Huneault, Ontario (Castonguay *et al.*, 1996; Sartaj *et al.*, 1999); Richmond, British Columbia (Birkbeck *et al.*, 1990; Hunter *et al.*, 1993); Sackville, Nova Scotia (Pries, 1994). More recently, a FWS system was placed in operation at Dartmouth, Nova Scotia (Galbrand, 2006).

A facility at Fenton, New York, has been operating since 1989 (Trautmann *et al.*, 1989; Grunder and Lauve, 1993). A facility in Tompkins County, near Ithaca, New York, has also been operating since 1989 (Staubitz *et al.*, 1989; Peverly *et al.*, 1993; Surface *et al.*, 1993; Sanford *et al.*, 1995a; Sanford *et al.*, 1995b; Sanford, 1999), which has utilized subsurface flow wetlands. There is also a nearby treatment wetland facility at Monroe County, New York (Eckhardt *et al.*, 1999).

Reedbeds are used to treat leachate in the United Kingdom (Cooper and Hobson, 1989; Robinson, 1990; Barr and Robinson, 1999; Robinson *et al.*, 1999), Slovenia (Urbanc-Bercic, 1994; Bulc *et al.*, 1997; Vrhovsek *et al.*, 2000; Sajn Slak *et al.*, 2004;

Bulc, 2006), Poland (Agopzowicz, 1991; Obarska-Pempkowiak *et al.*, 2005), and Sweden and Norway (Westholm, 2004; Keitliska *et al.*, 2005). Applications of treatment wetlands in warmer climates have also been reported (Aluko and Sridhar, 2005; Ferreira *et al.*, 2006).

Intensive research was conducted at a multicell pilot facility in New Hanover County, North Carolina (Rash and Liehr, 1999; Kozub and Liehr, 1999; Liehr *et al.*, 2000). Both surface and subsurface wetlands were tested with leachate lagoon effluent and mechanically pretreated leachate. The Water Environment Research Foundation has published a research report (Liehr *et al.*, 2000) on the pilot studies, which formed the basis of design for the full-scale New Hanover County facility. The full-scale facility consists of a free water surface wetland discharging to spray irrigation of a hay crop located on the landfill cap (CDM, 2001). A combination system involving several types of wetlands has been implemented near Des Moines, Iowa (Metro Waste Authority, 2005).

Recently, more intensive engineering has been added to wetland systems. Aeration and sedimentation (Mæhlum, 1999; Mæhlum *et al.*, 2002) and forced aeration within wetlands (Higgins and Brown, 1999; Wallace, 2001b; Nivala, 2005; Wallace *et al.*, 2006b; Nivala *et al.*, 2007) have produced favorable results. Wetlands have also been proposed for control of stormwater runoff from capped landfills (Mackie and Murphy, 1992). Cotreatment of municipal wastewater and leachate has been investigated, in which the wastewater actually provides dilution of the stronger leachate (Johansen and Brix, 1998). Vegetation response is an issue for very strong leachates and, consequently, there have been some botanical investigations as well as studies of other biota (Kylefors *et al.*, 1994; Bernard and Lauve, 1995; Bernard, 1999; Kelly-Hooper, 1999).

In addition to full-scale and pilot-scale system studies, there are numerous leachate treatability studies that have been undertaken. These involve the use of mesocosms or potted plants to gain an understanding of the possibilities for implementation of treatment wetland technology. However, they are usually of short duration, under more or less controlled conditions, and cannot be directly used in scale-up or design. These span a variety of wetland types: HSSF, VF, and FWS. The reader is referred to recent treatability studies (Kinsley *et al.*, 2002; Cao *et al.*, 2002; Silva *et al.*, 2003; Connolly *et al.*, 2004; De Feo *et al.*, 2005; Ujang *et al.*, 2005; Yang and Tsai, 2005; Sun and Austin, 2006; Kõiv *et al.*, 2006; Ling, 2006; Polprasert and Sawaittayothin, 2006; Rustige and Nolde, 2006; Sawaittayothin and Polprasert, 2006).

Ancillary benefits are difficult to ascribe to leachate systems. Benyamine *et al*. (2004) attempted to quantify such benefits for a multifunctional project near the municipality of Örebro, Sweden. The three goals of the project are to create an attractive recreational area, increase biodiversity, and manage pollution, with the major part of the project focused on increasing bird diversity. However, the leachate water treatment was designed primarily from an engineering perspective, and the biodiversity implications of the wetlands had a low priority. The success of the project could not be determined because of a lack of specific goals and data.

## Design Considerations

Design of leachate treatment wetlands can partially rely upon known wetland processes and performance, but unfortunately, the complexity of the leachate chemistry means that new concepts must be invoked. In other words, leachate treatment is not just about reducing TSS, BOD, and nutrients. Some of the important additional factors are as follows:

- Very small flows, which interact strongly with rainfall and evapotranspiration
- Survival of the wetland vegetation
- Very high amounts of ammonia to be removed
- Reduction of volatile hydrocarbons (BTEX, etc.)
- Reduction of trace toxicants (PAHs, PCBs, etc.)
- Removal of considerable amounts of iron
- Removal and storage of trace metals
- Sensitivity and protection of receiving waters

The reader will recognize that all of these subjects have been addressed in previous sections of this book, but leachate treatment moves into new territory compared to municipal wastewater treatment. Each of these peculiarities is explored further.

## Water Budget Considerations

Leachate is generated as a result of rainwater that falls on the landfill. Some of that rain runs off as surface flow, usually termed stormwater, and this water does not interact with the decomposing materials interior to the landfill. Another portion of the rainfall is evaporated and transpired by vegetation on the mound. The balance of the rainfall soaks into the mound and adds to the groundwater inside the mound. The relative proportion that soaks in is in part determined by the nature of the cap on the mound, if any. If the landfill is lined, then there is no other source of water adding to that groundwater mound. If the water table within the landfill is allowed to increase, at some point seeps will develop around the perimeter of the landfill. This seepage water carries pollutants acquired from the decomposing garbage. Given this scenario, it is possible to estimate the amount of leachate as a fraction of the precipitation received by the mound. Suppose a 10-ha mound receives 50 cm of rain annually, and one quarter of that soaks in, with the balance occurring as stormwater runoff and *ET*. The annual volume entering the mound would be 12,500 $m^3$, or 34 $m^3$/d. Next, consider a treatment wetland loaded at 1.0 cm/d, a very light loading that would produce about one month's nominal detention in a FWS wetland. The area would be 3,300 $m^2$, or 0.33 ha. Such a small wetland is very likely to fit within the project boundaries, without the acquisition of off-site property.

There are other ramifications of the relatively small flow. In cold climates, winter storage becomes possible in ponds of relatively small size. Therefore, it is possible to avoid the penalty of low microbial activity in cold waters. Another feature is that a treatment wetland interacts with rainfall and

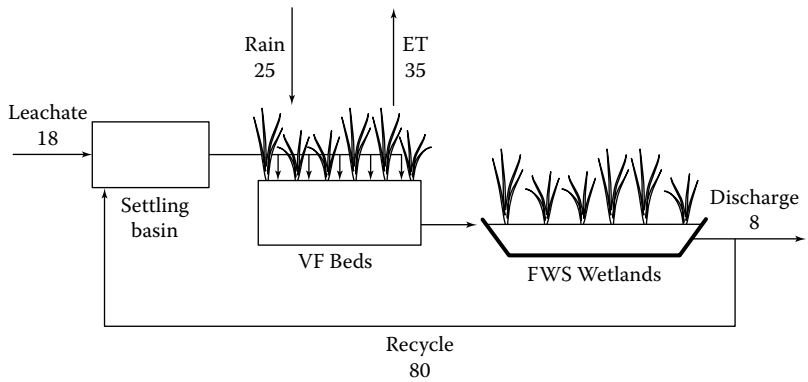

**FIGURE 25.14** Water flows during the operating season for the full-scale Saginaw, Michigan, leachate treatment wetland system ($m^3/d$). The values are averages for six years of operation, 2000–2005. Note that during periods of no rain, *ET* more than consumes the incoming water flow.

evapotranspiration (*ET*), which are seasonally not in balance. In arid climates, for instance, the warm period experiences high *ET* and low rainfall. If the wetland operates during that period, it will produce a net loss of water even to the point of having no discharge.

As an example, consider the performance of the Saginaw, Michigan, leachate treatment system (Kadlec, 2003c). This system operates only during the unfrozen season, approximately April through November. There is adequate storage in the landfill to accommodate any small winter water additions. The system consists of a $12 \times 12 \times 2$ m settling basin, a 600-$m^2$ VF wetland, and a 0.74-ha FWS wetland (Figure 25.14). On average, over the operational season of about six months per year, there is an excess of *ET* over rainfall of about 10 $m^3/d$. The incoming flows average 18 $m^3/d$, and so about half the water is lost on average. But, rainfall is episodic, and during inter-event periods, *ET* more than consumes the average inflow, leading to periods of zero discharge. During a six-year period of record, there was zero discharge 71% of the days during the warm operating season.

## Wetland Vegetation

Leachate water quality is potentially detrimental to a number of wetland plant species. In particular, ammonia levels can be exceptionally high (see Table 25.11). This narrows the choice of wetland plants to those that can tolerate elevated levels of ammonia, and even then steps may be needed to protect the plants. One such step is to recycle treated effluent to the front of the wetland, as shown in Figure 25.14 for the Saginaw, Michigan, system. The ammonia levels at various points in the system are shown in Figure 25.15. The averages for six years were raw influent: 335 mg/L, sedimentation basin outlet: 99 mg/L, vertical flow outlet: 22 mg/L, and FWS outlet: 2.5 mg/L. It is quite possible that wetland plants could not survive the raw influent—indeed, there were none to be

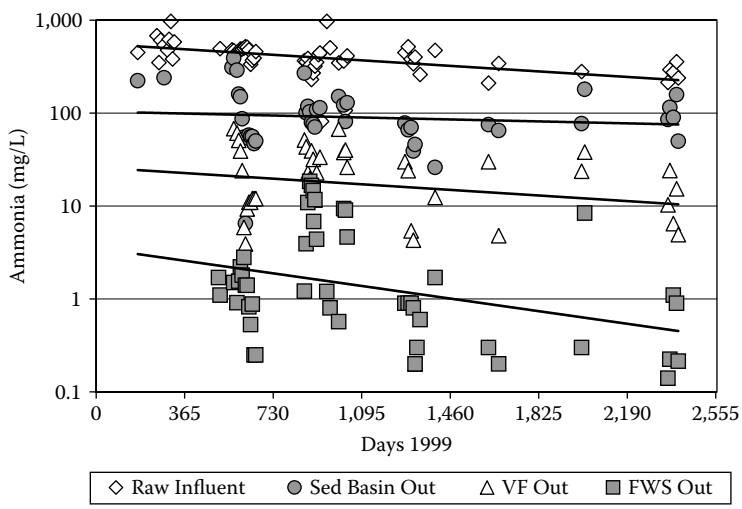

**FIGURE 25.15** Ammonia concentrations for the full-scale Saginaw, Michigan, leachate treatment wetland system, for six years of operation, 2000–2005. Note that during periods of no rain, *ET* more than consumes the incoming water flow.

found in the immediate vicinity of seeps prior to the project. The recycle plus the vertical flow unit reduced ammonia to 22 mg/L, which is an acceptable level for a wide variety of wetland plants.

### Ammonia Removal

High ammonia concentrations imply a need to remove very high fractions of the incoming load. Both "passive" and "active" wetland treatment systems have been used to treat landfill leachates (Kadlec, 1999b). Active wetland treatment systems typically employ some mechanism to boost oxygen transfer in order to oxidize the high concentrations of ammonia commonly found in landfill leachates (Vasel *et al.*, 2004). Single-unit constructed wetlands often cannot treat the high concentration of ammonia present in the leachate due in part to insufficient oxygen transfer but also due to the hydraulic inefficiencies of those single units. It has been shown in preceding chapters that oxygen transfer rates are of the order of 2–4 gO/m$^2$·d for FWS and HSSF systems, which constrains the capability of the wetland to microbially reduce ammonia. Preliminary evidence suggests that Anammox processes may or may not be present in leachate wetlands. Sun and Austin (2006) argued that completely autotrophic nitrogen removal over nitrite occurred in one of three leachate microcosms. However, Polprasert and Sawaittayothin (2007) found none of the microbes needed for such a process in their mesocosms. At this point in time, there is no known way to foster such advantageously efficient anomalous nitrogen processing, and this remains an area of wetland technology development.

Vertical flow wetlands are a proven technology for increasing oxygen transfer rates. They can be difficult to operate in cold climate conditions, and therefore the alternative of forced aeration can be considered to provide better oxygen availability (see preceding text).

However, no single unit can provide very high percent removals because of the constraint of hydraulic efficiency. If concentrations of hundreds of mg/L must be reduced to single-digit mg/L, reductions of 99+% are called for. Therefore, absolutely no short circuits can be tolerated, and must be prevented by multiple cells or multiple units.

The Saginaw system is an example of the use of VF and FWS to provide adequate oxygen transfer and multiple units in series (Figure 25.14). The VF units are loaded at about 15 cm/d, comprised of about 20% fresh feed and 80% recycle. The ammonia load removed is 11 gN/m$^2$·d, or 80% of the incoming ammonia, which has an implied oxygen requirement of 50 gO/m$^2$·d. The FWS units are comprised of two units in parallel, each compartmentalized by cross deep zones. These are loaded at 1,100 kg/ha·yr, which is in the zone of microbial control, and produces an outlet ammonia of 2.5 mg/L, or a 91% mass removal in the FWS wetland alone. This performance is in line with the expected performance of other FWS systems (see Figure 9.39, Chapter 9), and is represented by a first-order removal rate coefficient of 14 m/yr, which is the 60th percentile for FWS wetlands (see Table 9.31, Chapter 9).

The oxidation of ammonia in either an aerated HSSF bed or a VF bed leads to the production of oxidized nitrogen, as demonstrated in the leachate treatability study of Kinsley *et al.* (2002). Because of a deficiency of carbon after such aerobic treatment, it is necessary to supply the required carbon either by a chemical (BOD) addition (Yang and Tsai, 2005), or by reliance upon the carbon generated in a FWS wetland.

### Volatile Hydrocarbons

Perhaps the most challenging yet the most promising application of constructed wetlands is for the control of the large number of single organic compounds that are the subject of landfill leachate regulation. Very few of these have been studied with respect to wetland technology. Those that have been investigated show removals due to volatilization and biological degradation in the wetland environment (see Chapter 13).

The prospect of small pulses of individual organics at erratic frequency and variable concentration requires a broad-spectrum treatment device, which is always poised for the next event. A shallow wetland water body provides the opportunity for air stripping of volatiles. The efficiency is not as great as for mechanical devices, but the difference is more than compensated by the long detention times in the wetland. Half-lives (time to volatilize one-half the substance) range from two to four days for insoluble compounds such as benzene, toluene, and naphthalene (Mackay and Leinonen, 1975; Shugui *et al.*, 1994); and are less for more volatile compounds, such as vinyl chloride and chloromethane. Therefore, a long-detention, FWS wetland is effective in removal of volatile substances from leachate (Kadlec, 2003c). Because many of the organics are below detection on many occasions, another metric of their removal is needed. The hit frequency may be used, calculated as the fraction of samples that produced an above-detection result. For instance, out of 69 analytes tested at Isanti-Chisago, Minnesota, only 33 were ever detected in the raw water, and only 5 after the wetland (Table 25.12). The corresponding hit frequencies for those analytes that were detected were 0.16, 0.16, 0.12, 0.04, and 0.04. In other words, only 7% of the compounds were found in the wetland effluent (5/69), and those 5 were only detected in about 10% of the samples.

Clearly, the concepts of removal rate constants or loading charts are not applicable to forecast outlet concentrations for these occasional compounds, for which only left-censored data are available. However, it is possible to determine fractional removals for certain model compounds, such as benzene.

### Trace Toxicants

Heavier organics, such as polycyclic aromatic hydrocarbons (PAHs), are also trapped and degraded in treatment wetlands. PAHs partition very strongly to sediments. Because PAHs are not required for plant metabolism and growth, uptake is dependent on concentrations and supplies to the

pore water in the root zone. Only a small percentage of those sorbed substances are biologically extractable by plants (Gomez-Hermosillo *et al.*, 2000). In contrast, the sorbed PAH is readily biodegraded by microbial processes (Jackson *et al.*, 1996; Machate *et al.*, 1997). Accretion of trace organics is mediated by gross wetland sediment accretion, but additionally, both anaerobic and aerobic zones exist in the wetland that can provide slow degradation. Heavy organic contaminants partition selectively to organic substrates, which are present in great abundance in a FWS wetland. For instance, 14 base-neutral PAHs were found in the leachate at the Saginaw, Michigan, site, but none have been found in the wetland system effluent over the seven-year period of record of sampling.

### Iron

A variety of iron items are discarded in trash, and therefore iron is a common constituent in landfill leachate. Concentrations of several milligram per liter are common. Under the anaerobic conditions within the mound, this iron exists in reduced (ferrous) form, but when the leachate surfaces in the treatment system, conditions become oxidizing, and the iron converts to the insoluble ferric form. The precipitates are

oxyhydroxides, which are gelatinous masses that can quickly clog any SSF system. At the Jones County Landfill HSSF facility near Anamosa, Iowa, iron oxidation and precipitation was observed to plug the bed and aeration lines within 18 months of start-up (Hoos, 2003; Nivala, 2005). Thus iron removal is often necessary prior to any SSF unit (see Figure 16.18, Chapter 16).

The two steps needed to effectively remove iron are aeration and settling. Passive devices, such as cascades, may be used for aeration, and ponds can be effective in sedimentation of the iron floc and coprecipitates. For example, at the Isanti -Chisago leachate treatment system, extracted water was cascaded down the side of the landfill in a polypropylene "step aerator," intended to increase dissolved oxygen concentrations and oxidize ferrous to ferric iron (Loer *et al.*, 1999; Kadlec, 2003c). A sedimentation basin was the second component of the treatment train, to allow settling of metal hydroxide flocs following cascade aeration (Figure 25.16). Basin size and residence time were selected based on settling rate studies and other factors.

### Trace Metals

A large number of metals find their way into leachate, resulting from the even bigger spectrum of metallic objects that are discarded into the trash. Metals are removed by cation exchange to wetland sediments, precipitation as sulfides and other insoluble salts, and plant uptake. The anaerobic sediments provide sulfate reduction to sulfide and facilitate chemical precipitation. A number of design options are available to take advantage of these wetland mechanisms, and these have been discussed in Chapter 11. Good choices are peat filters, usually VF (Sartaj *et al.*, 1999), because their large storage capacity, and FWS wetlands, because they renew the storage media by creating new peat each year. SSF sand/gravel wetlands are not as good a choice because of limited sorption capacity and the inability to form new storage sediments without clogging the bed.

**FIGURE 25.16** The inlet cascade and settling pond of the Isanti-Chisago, Minnesota, leachate treatment system. The FWS wetlands are in the background.

### Receiving Waters

There is a key question as to what should be the method of discharge or disposal of the treated leachate. Discharge to surface waters is an option if the treatment wetland is designed to capture or destroy all potential pollutants, and it is commonly assumed that surface water is to be the recipient. Regulators are justifiably nervous about this option because there are so many potential toxicants. Therefore, the usual suite of municipal treatment parameters becomes a necessary but not sufficient list of treatment goals. Understandably, treatment wetland studies have frequently borrowed the list of study variables from municipal applications. Besides TSS, BOD, and ammonia, each new situation is likely to require that other pollutants are monitored and controlled by the wetland system. The additional parameters are likely to include specific hydrocarbons and metals, especially those suspected or confirmed of being present in the leachate. In any case, it is likely, in the United States, that any such discharge to surface waters will be subject to a whole effluent toxicity test. Even if the treatment wetland system is adequately designed, the monitoring costs can escalate to onerous levels.

Another option for disposal of the treated water is to irrigate the top of the (closed) landfill mound for the purpose of sustaining a cover crop. This option is practiced at the New Hanover County, North Carolina, treatment wetland system (grasses) (CDM, 2001) and at Ormoz, Slovenia (trees) (Sajn Slak *et al.*, 2004). These systems have been successful, but there are caveats. First, leachates tend to have high levels of dissolved solids (TDS), which often are dominated by high chloride content (salt). Therefore, the cover crop to be irrigated must have high resistance to salinity. Secondly, irrigation needs are seasonal, and added water may be unnecessary in some seasons of the year. During such periods, the cover crop may be overwatered, and runoff may occur. Most closed landfills in the United States will have a stormwater system that receives mound runoff, and the treated leachate will sometimes augment that flow. However, the added water will have been treated in the wetland system and in what amounts to an overland flow system atop the mound. In other seasons, *ET* (crop consumption) may serve to eliminate any runoff, effectively creating a zero-discharge system. Any treated water that infiltrates an imperfect mound cap will add to subsequent leachate flows, effectively creating recycle through the mound.

**FIGURE 25.17** The infiltration wetland at the Isanti-Chisago, Minnesota, leachate treatment wetland facility. This is a constructed wetland whose purpose is disposal of the treated water.

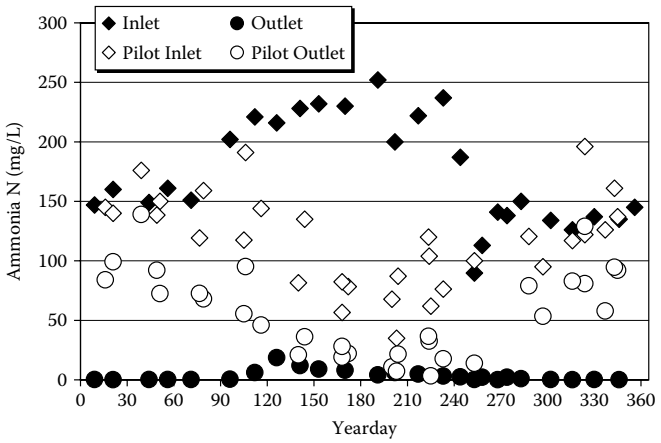

**FIGURE 25.18** Performance of the New Hanover County, North Carolina, FWS landfill leachate systems. The pilot project was 60 $m^2$ and operated at about 1.5 cm/d HLR for four years. The full-scale project is 21,000 $m^2$ and operated in its first year at 0.15 cm/d. Note that the influent concentration pattern of the full scale does not match that of the pilot.

Another, less frequent option is a groundwater discharge of the treated leachate. That option would usually require that there be no potable water usage from the receiving aquifer. A groundwater disposal option was implemented at the Isanti-Chisago, Minnesota, site (Figure 25.17), where the infiltrate system was a leaky constructed wetland. Local groundwater flows vented to downgradient wetlands of the region and were not tapped for human use.

### Scale-Up

There are well-known problems that properly limit the scale-up of mechanical plants of various sorts, and treatment wetlands are no exception. Conservative designs usually do not exceed a scale-up factor of the order of 10, or perhaps 100 if all variables seem to have been identified and are controlled in the larger system. This is an unwritten assumption in the many scale-up recommendations that have been promulgated for HSSF and VF wetlands treating municipal effluents. There is danger if the large-scale conditions do not closely match those of the small-scale prototype. Leachate treatment wetland technology is particularly susceptible to errors of scale-up because of the erratic composition time series and the known temporal drift in water quantity and water quality. Further, it has been noted that leachate wetlands will be strongly driven by rain and *ET*, which factors may be entirely different in a laboratory setting.

The New Hanover County, North Carolina, treatment wetland system provides an example of such scale-up pitfalls because there was a long-term pilot project preceding the full-scale project (Liehr *et al.*, 2000; CDM, 2001). The FWS pilot project was loaded at an HLR of 1.4 cm/d, which was not much affected by rain and *ET*, which were about equal. The pilot project achieved 50% reduction (127 to 63 mg/L) of ammonia over a four-year period of record. There were considerable drops in inlet ammonia during the warmest times of the year (Figure 25.18). Tracer testing showed the pilot wetland behaved as two TIS, and channels down the side of the wetland were visible. The full-scale project was 350 times larger and built with cross-deep zones. It operated in its first year at an HLR of 0.14 cm/d (10 times lower than design or the prototype), and reduced ammonia from 150 to 3 mg/L. The differences are attributable to: (1) lower hydraulic loading, (2) higher ammonia in summer high-removal period, (3) greater hydraulic efficiency, and (4) much greater effects of rain and *ET* at the very much lower HLR. In fact, the rate coefficients for ammonia are not much different if all factors are accounted. However, if "rules of thumb" are applied, there can be serious design mistakes.

## 25.4 INDUSTRIAL WASTEWATERS

Industrial wastewater is here a loosely defined category, including waters that are not from domestic, municipal, animal, or food product processing. A good many such treatment examples have already been discussed in connection with organics and metals. In this section, the focus is upon particular industries rather than particular contaminants. Only a few example categories have been chosen for illustration.

### Wood Leachates

Solid waste from the wood-processing industry includes wood chips, process trimmings, shredded bark, and sawdust from various saws, planes, and other process machinery. These materials, when stored unprotected outside and exposed to precipitation, will produce a leachate that is often characterized by a high carbon content, high oxygen demand, strong color, an array of dissolved metals, and low levels of nitrate, ammonia, and nitrogen (Frankowski, 2000). The carbonaceous component can contain high amounts of

tannins and lignins. Accordingly, researchers at the University of British Columbia have conducted mesocosm and pilot-scale studies to determine the effectiveness of FWS wetlands to treat these leachates. Based on successful lab treatability studies, Frankowski (2000) operated a set of six (6 m × 18 m) pilot-scale wetlands, treating wastewater with COD = 5,600 mg/L (BOD = 1,730 mg/L). The carbonaceous compounds included 500 mg/L of volatile fatty acids (VFA) and 870 mg/L of tannins and lignins, and the water had a pH of 3.8. At a hydraulic loading rate of about 3 cm/d (*n*HRT seven days), these cells were able to reduce COD (43%), VFA (14%), tannins and lignins (39%), and rainbow trout toxicity (49%). Continued operation (Masbrough, 2002) showed improved removals of COD (51%), VFA (69%), tannins and lignins (42%).

Based on the presumption that the concentrations of this wastewater were too high, a set of mesocosms were operated with the same waste diluted approximately 10:1 (Tao *et al.*, 2004). Further, this study explored the effect of changing detention time, with the expected result that increasing detention improved treatment. Process studies linked the performance to microbial activity (Tao and Hall, 2004; Tao *et al.*, 2006).

## Pulp and Paper Wastewaters

The pulp and paper industry converts wood products into cellulose pulp and paper. Raw wood and wood chips are converted to pulp (cellulose fibers) by mechanical grinding (groundwood) or through chemical degradation and leaching (sulfite and Kraft processes). Pulp mill effluents are complex mixtures of wood-derived organics. Raw wastewater from pulp and paper mills typically receives primary treatment through settling, either in ponds or in primary clarifiers. Secondary treatment is provided at most pulp and paper mills, but to meet reduced effluent limitations, some pulp and paper mills are being required to provide treatment beyond the secondary level. The goals of additional treatment depend on site conditions such as effluent quality and permit limits. Goals may include further reduction of $BOD_5$, TSS, nitrogen, phosphorus, color, and whole effluent toxicity. Constructed and natural wetland treatment systems have been tested at a number of pulp and paper mills to provide such advanced secondary or tertiary treatment (CH2M Hill, 1994; NCASI, 2004).

There is a difference in the character of the BOD between paper and municipal effluents. Lignin-based compounds that survive the pretreatment processes are not found in domestic wastewater, and are harder to degrade than starches and sugars. Nevertheless, wetlands have proven to be effective in the reduction of this specialized form of BOD. Data from six operating systems indicate that the *k*-values for degradation may be comparable to those for domestic wastewater.

Observations of pollutant assimilation in a partially vegetated facultative treatment pond at the Australian Paper Manufacturer's Maryville Mill in Victoria, Australia, led to the first published treatability experiments using wetland plants to treat pulp- and paper-mill wastewaters (Allender, 1984). In the experiment, five emergent wetland plant species were established in 4-L tubs. Researchers measured concentrations of lignosulphonate, color, total suspended solids, biochemical oxygen demand ($BOD_5$), and foaming tendency in FWS basins with and without plants over a very long holding period (three weeks). The presence of wetland vegetation was shown to enhance pollutant removal, but microbial populations were found to be responsible for most of the assimilation (CH2M Hill, 1994).

### Weyerhaeuser

In 1985, Weyerhaeuser Company began an initial pilot study using eight HSSF wetland mesocosms (2.6 $m^2$), 60 cm deep, to assess the effect of wetland vegetation. The wetland cells with plants were found to have higher removal efficiencies for ammonia-nitrogen, organic nitrogen, and phosphorus. Longer retention times resulted in higher removal efficiencies for most measured parameters (TSS, BOD, $NH_4$-N, Org-N, P). In the last stage of this study, the mesocosms were modified and replanted to study the effects of substrate depth. Table 25.13 presents the results of this experiment (Thut, 1993). The area of the shallow (15-cm) wetland was 2.7 times that of the deep (40-cm) wetland, and therefore utilized approximately 2.7 times the substrate and plant biomass. Thut (1993) ascribed the higher removal percentages for $BOD_5$, ammonia, and phosphorus in the 15-cm substrate depth to two reasons: (1) higher dissolved oxygen levels, and (2) the greater amount of plant biomass (both below- and aboveground).

Subsequently, a large HSSF pilot was placed in operation (Thut, 1993), with moderately good results. However, hydraulic issues were experienced, with a 15-cm head differential along the flow direction. The inlet zone became flooded (Figure 25.19), while the outlet zone became devoid of wetland plants because of too much dry gravel at the top of the profile (see, for example, Figure 21.14, Chapter 21).

**TABLE 25.13**
**Effect of Substrate Depth on Pollutant Removal in HSSF Wetlands Polishing Pretreated Pulp-Mill Effluent at a 15-Hour Retention Time**

| | Substrate Depth | |
|---|---|---|
| **Parameter** | **15 cm** | **40 cm** |
| TSS | 49% | 55% |
| $BOD_5$ | 46% | 28% |
| $NH_4$-N | 96% | 42% |
| Org-N | 31% | 33% |
| Phosphorus | 27% | 14% |

*Source:* Data from Thut (1993) In *Constructed Wetlands for Water Quality Improvement*. Moshiri (Ed.), Lewis Publishers, Boca Raton, Florida.

**FIGURE 25.19** The inlet zone of a HSSF wetland-treating pulp-mill effluent.

As a result of such difficulties, Weyerhauser went on to build a 27-ha FWS full-scale system, the only constructed full-scale facility. Eight flow paths with a total of 33 cells were used to treat 60,000 $m^3$/d of secondary water. Over a two-year period, about 80% of the TSS were removed (69 to 16 mg/L), and 48% of the BOD (27 to 14 mg/L). However, if a background BOD concentration is acknowledged, the high HLR (16 cm/d) means the removal rate coefficient of about 45 m/yr was near the central tendency for other types of BOD.

### Other Pilot Studies

In the early 1990s, several pilot projects were conducted. Boyd *et al*. (1993) attempted treatment of lightly pretreated raw wastewater with sprayed, inoculated SSF wetlands and found reductions of BOD from 1,200 to 300 mg/L. Hammer *et al*. (1993b) attempted color removal in HSSF mesocosms, with very little success. Tettleton *et al*. (1993) studied three FWS pilot wetlands (1,320 $m^2$) that received well-pretreated influents at HLR of 10 to 45 cm/d. BOD reduction was poor, at 6–7%; only nitrate reduction was moderately good, at 64–80%.

#### *Pope & Talbot*

The Pope & Talbot company began experimenting with constructed wetland treatment systems in 1990 at its Halsey, Oregon, mill (Moore *et al.*, 1994; Hatano *et al.*, 1994). Ten 0.14-ha wetland cells were constructed, one of which was a VSB cell; the remaining nine were FWS cells. Seven of the FWS wetland cells were supplied with pretreated pulp mill effluent, whereas two were fed clean water. TSS was reduced by 55–80% at an HLR = 24 cm/d, but $BOD_5$ was reduced by only 6–45%. Slight color removal was noted in the FWS wetland cells.

#### *Champion*

Champion International Corporation operated a pilot wetland system receiving secondary-treated effluent over two years at its Pensacola, Florida, bleached kraft mill facility. This pilot system consisted of six FWS wetland cells designed with varied length-to-width ratios, fractions of open water, and retention times (Knight *et al.*, 1994). A variety of contaminants were assessed, including biochemical oxygen demand ($BOD_5$), total suspended solids, ammonia, and color. The results of this study indicated that the cells with the longest L:W ratios (10:1) performed better than the other cells (L:W ratios of 5:1 and 2.5:1). The data from this study also showed that the inclusion of deep zones decreased the volumetric $k_V$ for aspect ratios of 5:1 and 10:1, whereas areal *k*-values were generally improved by the deep zones. No acute toxicity to cladocerans (*Ceriodaphnia dubia*) or fathead minnows (*Pimephales promelas*) was detected in any of the FWS wetland effluent samples. In contrast, all influent samples were toxic to cladocerans, and two out of three influent samples were chronically toxic to fathead minnows.

## Fertilizer Manufacture

### ICI Lambton

Imperial Chemical Industries Canada (ICI) operated a phosphate fertilizer plant at Courtright, Ontario, for many years, leaving behind a large gypsum waste pile, well-laced with phosphorus. Leachate from this and other "gyp stacks" is very high in sodium, calcium sulfate, and other chemicals. At this plant, leachate is subjected to pretreatment, including liming, and then passed through a series of ponds prior to discharge to the Detroit River. A decision was taken to convert the 12.5-ha terminal pond into a wetland, with both deep water and bench areas, to be fringed by appropriate upland plantings. Construction commenced in autumn 2002 and was completed in spring 2003. Ancillary benefits were a high priority, and the system contains nesting boxes, raptor perches, and basking logs for wildlife. Public access is facilitated with a parking area and three viewing and information kiosks. The area quickly developed to support a wide variety of indigenous trees, shrubs, and wetland vegetation.

### Simplot Brandon

Simplot Canada Limited has owned and operated a nitrogen fertilizer manufacturing facility in Brandon, Manitoba, since 1966. The original designs and operating procedures

**FIGURE 25.20** The Simplot wetland at Brandon, Manitoba.

of the facility in the 1960s and 1970s did not provide for treatment of process wastewaters or containment of leakages and spills. Plant wastewater, leakages, and spills were conveyed via unlined surface drainage ditches to an adjoining slough, which ultimately drained into the Assiniboine River. The result was nitrogen contamination of the unconfined groundwater aquifer below the facility. The waters that vent and travel to the river have about 200 mg/L of ammonia and a comparable amount of nitrate.

Simplot's engineered wetland was constructed in autumn 2002, consisting of a 4-cell, 22-ha FWS constructed wetland (Figure 25.20). A clay layer, located between 1 and 3 m below the surficial topsoil, provided for water retention. No liner was required, saving costs. Seeding of vegetative propagules (seeds, rhizomes) occurred in selected portions of the cell basins. Propagules were obtained from surface soils in ditches adjoining municipal road allowances in which nuisance aquatic macrophytic growth occurred. The species in the wetland cells include cattail, bulrush, arrowhead, and sedges. All species are native, and none are rare or endangered.

The system is designed to allow for gravity flow. The average annual flow in 2004 was 280 $m^3$/d. A steady reduction in both total nitrogen and ammonia was observed as water flowed through the wetland. A 39% reduction in TN and an 82% reduction in ammonia were measured in 2004. At that time wetland operations were still in the start-up phase, with very modest initial vegetative growth.

The day-to-day management of the wetland has been limited to Simplot's Environment Group at only one to two hours per week. Monitoring of the wetland is conducted via weekly tours, which involve recording water levels at each of the 12 control gates and taking samples where there is flow through the gates.

## SUMMARY

Although the majority of applications of treatment wetlands remain as municipal and domestic systems, there is a growing number of other application areas. A few of those other applications have been singled out in this chapter as examples of the growth of wetland technology. There is some removal of nearly every organic compound tested in wetland treatment systems, whether full scale, pilot scale, or microcosm. This includes organics from very important generators: pesticides, petrochemicals, paper and food wastes, and landfill leachates. In each of these categories, there are multiple studies that have initiated the design database. What is known thus far shows great promise for wetlands technology for organics control, especially in those situations where these passive systems can be fit into the landscape and accumulated organics will not pose a threat to wetlands biota. Animal wastewaters are similar to municipal effluents, but generally more concentrated. Therefore, with appropriate pretreatment, the application of treatment wetland technology to animal wastes is an easy extrapolation.

Perhaps the most challenging yet the most promising application of constructed wetlands is for the control of the large number of single organic compounds that are the subject of landfill leachate regulation. The prospect of small pulses of individual organics at erratic frequency and variable concentration requires a broad-spectrum treatment device, which is always poised for the next event.

Importantly, it is not possible or prudent to scale a wetland from one technology to another because of the flow and composition differences. Therefore, it is critical to examine each pollutant individually and apply removal forecasts based on a calibrated mechanistic model.

# Appendix A: Lists of Basis Wetlands

This book is based on the analysis of data from many wetlands, and the associated experiences of cost and implementation. The appendix summarizes those wetland cells and systems that have contributed to this basis of analysis, by name and country (and by state when appropriate). Tables in the various chapters provide extensive referencing, dictated by availability of publications. In some instances, we have relied upon project reports and our own data compilations of published and unpublished results.

It is certain that differences in sampling and laboratory protocols have contributed significantly to the data scatter for wetland performance parameters. There is no simple way to evaluate data quality from the various wetlands, and any attempt to screen the data would be highly suspect in and of itself, as it would be a reflection of the bias of the reviewer. The periods of record vary, with some systems possessing many years of information. In general, very short periods of record, i.e., days or weeks, have been excluded. Laboratory microcosm studies are not included here because conditions are generally too far removed from field environments. We concluded early in the process of information analysis that there are no single "definitive" studies that are superior to others, despite the hopes of individual investigators. In fact, focusing on one study leads to the loss of understanding of intersystem variability and the full loading spectrum that has been explored by the greater number of wetlands.

The lists given here are intended to assist the reader in regionalizing a search for further information relevant to treatment wetlands in a particular climatic zone. However, the lists are not geographically balanced because treatment wetland technology is not geographically uniform, and data are not always accessible despite large numbers of systems in a given region.

The three main types of treatment wetlands are considered separately. Of the total of 950 basis wetlands, 488 are FWS, 362 are HSSF, and 100 are VF. It is understood that these proportions are not indicative of the entire universe of operating systems, but it is believed that the sample sizes are sufficient to characterize the three variants of the technology.

The systems listed in Tables A.1, A.2, and A.3 provided data that were utilized to determine *k*-rates, temperature coefficients, or background concentrations. This is by no means a definitive listing of treatment wetlands, but does provide the reader an indication of systems with significant monitoring data.

# Appendix B: Tracer Testing and Flow-Pattern Modeling

The large majority of information on the contaminant removal capabilities of treatment wetlands has been in the form of a relatively continuous time series of inlet and outlet concentrations, under conditions of known flow. There is a second realm of data acquisition and analysis that revolves around the spike addition of substances to the wetland. A wide variety of substances have been used to trace the progress of water through treatment wetlands. These have included the salt ions lithium, bromide, chloride, iodide, and fluoride; the fluorescent dyes rhodamine RWT and B fluorescein; and tritiated water. Most often, these are pulse injected into the wetland inlet, and the concentration response is determined at the wetland outlet. The purpose of hydraulic tracer testing is to determine the distribution of detention times for the wetland.

Detention time distributions (DTDs) for treatment wetlands have been extensively investigated at many wetland sites, and thus there exist numerous examples of the functional forms that are characteristic of wetlands. Single-shot tracer injection with effluent concentration monitoring is usually employed (Kadlec and Knight, 1996). Because the tracer does not (theoretically) interact with wetland soils or biota, it serves as a marker of the water with which it enters. Typical distributions are bell shaped, with some tracer exiting at short times, and some exiting at longer times.

This evidence is conclusive: imperfect flow patterns pervade the universe of treatment wetlands. It is necessary to account for this in design, and it is accomplished via nonideal flow models. In turn, the understanding and development of nonideal flow models derive principally from tracer testing. The purpose of this appendix is to expand on the practicalities, pitfalls, and results of wetland tracer testing.

One of the principal results derived from tracer testing is presented in Chapter 2—the volumetric efficiency of the wetland, i.e., how much of the nominal wetland water volume is involved in its flow. It is the ratio of tracer detention time to nominal detention time: $e_V = \tau/\tau_n$.

Another principal result is the dimensionless variance of the outlet response, $\sigma_\theta^2$, which is briefly discussed in Chapter 6. This measure of the spread of the distribution of detention times may be used in a number of ways as an aid to pollutant removal performance. The dimensionless variance may be used to determine the parameters in DTD models, such as the tanks-in-series (TIS) model. Or, it may be used to compute the DTD efficiency of the wetland (Persson *et al.*, 1999):

$$e_{DTD} = \left(1 - \sigma_\theta^2\right) \tag{B.1}$$

This efficiency is unity for plug flow (PF), and zero for perfect mixing. As shown by Kadlec and Knight (1996), the DTD efficiency is an approximate interpolator between the performance of one TIS, as measured by $F_{1TIS}$, and PF performance, as measured by $F_{PF}$.

$$F = \frac{C - C^*}{C_i - C^*} = e_{DTD}\ F_{PF} + (1 - e_{DTD})\ F_{1TIS} \tag{B.2}$$

For plug flow,

$$F_{PF} = \frac{C_{PF} - C^*}{C_i - C^*} = \exp\left(\frac{-k_A \tau}{h}\right) \tag{B.3}$$

For *N*TIS,

$$F_{TIS} = \frac{C_{TIS} - C^*}{C_i - C^*} = \left(1 + \frac{k_A \tau}{hN}\right)^{-N} \tag{B.4}$$

where

$C$ = outlet concentration, mg/m$^3$
$C_i$ = average inlet concentration, mg/m$^3$
$C^*$ = background concentration, mg/m$^3$
$F$ = fraction remaining to background
$k_A$ = intrinsic reaction rate constant, m/d
$N$ = number of tanks
$\tau$ = detention time, d

The root-mean-square degree of fit of the approximation for Equation B.2 ranges 1–6% for $1 \le (k_A\tau/h) \le 3$.

Persson *et al.* (1999) go on to suggest a combined measure, the hydraulic efficiency ($\lambda$), that reflects the excluded volume and the mixing pattern of constructed wetlands. This measure is defined as the product of the volumetric efficiency and the DTD efficiency:

$$\lambda = e_V \cdot e_{DTD} \tag{B.5}$$

This is useful for ranking wetlands for their combined efficiency, but is not directly useful for parameter estimation. The two pieces are needed separately for quantitative estimates of performance. For a TIS model, the combined hydraulic efficiency is given by a very simple result:

$$\lambda = \frac{\tau_p}{\tau_n} \tag{B.6}$$

where

$\tau_p$ = tracer peak time
$\tau_n$ = nominal hydraulic detention time

Persson *et al*. (1999) have explored both real wetland systems and, via calibrated two-dimensional dynamic modeling, simulated situations. They found $0.11 < \lambda < 0.90$. The same parameter has been evaluated for other hypothetical wetland situations (Jenkins and Greenway, 2005).

## IDEAL FLOW REACTORS

Wetlands can be thought of as a cross section between two theoretically ideal reactors: the plug flow reactor and continuously-stirred tank reactor (CSTR). The plug flow (PF) reactor represents a situation where there is no internal mixing within the reactor, and water parcels move in unison from the inlet to the outlet. The CSTR represents the ideal of perfect mixing: water entering the system is instantaneously mixed throughout the reactor.

### Nominal Hydraulic Detention Time

PF and CSTR reactors behave very differently in response to the input of a conservative tracer. To discuss tracer behavior, it is useful to review the concepts of hydraulic detention time from Chapter 2. For a free water surface (FWS) wetland, the nominal wetland water volume is defined as the volume enclosed by the upper water surface, and the bottom and sides of the impoundment.

$$\tau_n = \frac{V_n}{Q} = \frac{(LWh)_n}{Q} \tag{B.7}$$

where

$\tau_n$ = nominal hydraulic detention time, days
$L$ = wetland length, m
$W$ = wetland width, m
$h$ = water depth, m
$LWh_n$ = nominal wetland volume, $m^3$
$Q$ = flow rate, $m^3/d$

For a subsurface flow (SSF) wetland, it is that enclosed volume multiplied by the porosity of the clean (unclogged) bed media.

$$\tau_n = \frac{V_n}{Q} = \frac{\varepsilon(LWh)_n}{Q} \tag{B.8}$$

where

$\varepsilon$ = bed media porosity, dimensionless

Dimensionless time, $\theta$, can be used instead of nominal hydraulic detention time, $\tau_n$, when comparing tracer response curves:

$$\theta = \frac{t}{\tau_n} \tag{B.9}$$

where

$t$ = elapsed time in days

### Tracer Response in PF and CSTR Reactors

A spike input of tracer entering a PF reactor will move through the system with zero mixing. As a result, the tracer spike will exit the reactor unchanged at $\tau_n$ ($\theta = 1$). In a CSTR reactor, the tracer impulse is instantaneously and uniformly distributed among the tank contents (Levenspiel, 1972). As flow continues to enter the tank, tracer-contaminated water is displaced, resulting in a declining tracer output curve with a long tail. Figure B.1 displays both types of ideal reactors and their associated tracer response curves.

### Real-World Tracer Movement

It is well documented that the flow patterns through treatment wetland systems are nonideal and do not conform to either the PF or CSTR ideals (see Tables 6.1 and 6.2, Chapter 6). In SSF wetland systems, dispersion and mixing occurs within the bed as water flows between the gravel particles or sand grains. In SSF wetlands, roots may create preferential flow paths near the bottom of the wetland cell (Liehr *et al*., 2000). In FWS wetlands, water near the surface is less subject to bottom drag and moves faster than the flow that is deeper in the water column. Water must detour around plant bases, which act as stagnant pockets that exchange water with adjacent flow channels by diffusion. Open water zones are subject to wind-driven mixing. The bottom topography may form deeper pathways, further contributing to short circuiting.

These combined phenomena produce a distribution of transit times for water parcels. The combined effect of these processes can be demonstrated by passing an inert tracer through the wetland. An impulse of the tracer, added across the flow width, moves with water through the wetland as a spreading cloud. Many treatment wetlands have been tracer tested, and all exhibit a significant departure from plug flow (Kadlec, 1994a; Stairs and Moore, 1994; King *et al*., 1997). Figure B.2 displays the movement of a bromide tracer impulse through an aerated horizontal subsurface flow (HSSF) wetland, as inferred from a $4 \times 4$ lateral and longitudinal array of sampling ports (Nivala, 2005). Similar two-dimensional profiles are shown in Figure 6.14 in Chapter 6.

Real-world flow patterns, such as the ones illustrated in Figure B.2, can be approximated using a variety of different flow models. The simplest, and most widely used, is to assume that the wetland can be represented as a series of CSTRs. This model, the TIS model, is addressed in the next section of this appendix.

## THE TANKS-IN-SERIES FLOW MODEL

The TIS flow model bridges the gap between the idealized extremes of the PF and CSTR reactor types. In the TIS model, the wetland is represented by a number of CSTRs in series, as shown in Figure 6.19 in Chapter 6. The flow enters

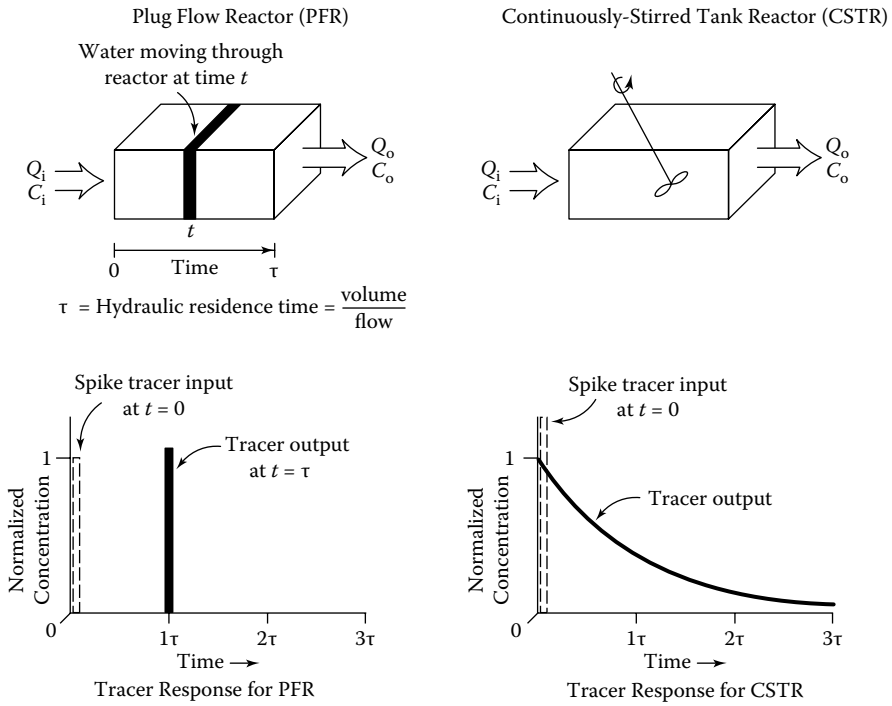

**FIGURE B.1** Comparison of ideal reactors.

the first CSTR, is mixed, and then flows into the next CSTR. The number of tanks in the series, *N*, is an important parameter in the description of the movement of both reactive and nonreactive substances.

When $N = 1$, this TIS model simplifies to the CSTR ideal reactor. As the number of CSTRs increases, the flow comes closer to approximating plug flow (Crites and Tchobanoglous, 1998), as shown in Figure B.3. If there are an infinite number of tanks in series, the internal mixing goes to zero, and the TIS model simplifies to the ideal PF reactor. Thus, the tracer response curve generated by the TIS model is a function of *N*.

It is important to note that *N* is a mathematical fitting parameter. It does not represent the physical configuration of the wetland. A treatment wetland with three cells will not have $N = 3$.

### Tracer versus Nominal Hydraulic Detention Times

The number of tanks ($N$) that best represents the hydraulic characteristics of the wetland is not known *a priori*. If an impulse tracer test is conducted, the wetland will generate a tracer response curve at the outlet (or other monitoring location), similar to the ones shown in Figures 6.15–6.17, Chapter 6.

The tracer detention time, $\tau$, can be calculated from the tracer output data (Equation 6.36, Chapter 6):

$$\tau = \frac{1}{M_o}\int_0^\infty tQCdt$$

where

$C(t)$ = tracer exit concentration, g/m$^3$ = mg/L
$M_o$ = mass of tracer in outflow, g
$\tau$ = tracer detention time, d
$t$ = time, d
$Q$ = average flow rate, m$^3$/d

The tracer detention time, $\tau$, is often less than the nominal detention time $\tau_n$. This is because not all the wetland volume is involved in the flow path, as was assumed in the calculation of $\tau_n$. As discussed in Chapter 2, the volumetric efficiency, $e_V$, is an important parameter relating $\tau$ and $\tau_n$. For FWS wetlands, $e_V$ can be defined as follows (Equation 2.5):

$$e_V = \frac{V_{active}}{(LWh)_n} = \frac{\varepsilon\eta h}{h_n}$$

where

$e_V$ = wetland volumetric efficiency, dimensionless
$V_{active}$ = active wetland volume, m$^3$
$\varepsilon$ = fraction of volume occupied by water, dimensionless
$\eta$ = gross areal efficiency, dimensionless
$h$ = water depth, m
$h_n$ = nominal water depth, m
$LWh_n$ = nominal wetland volume, m$^3$

It is then clear that

$$\tau = e_V\tau_n \tag{B.10}$$

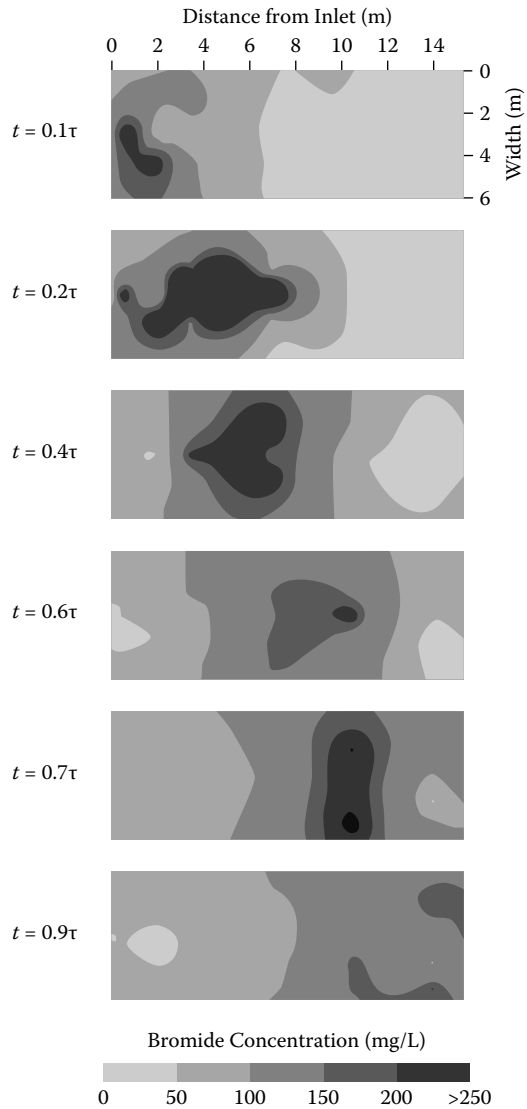

**FIGURE B.2** Tracer movement in a HSSF wetland. Time-series tracer contours were plotted from influent/effluent data along with 18 internal sampling points using Groundwater Modeling System (GMS) software. During this study, the effluent tracer concentration was modeled as 6.2 TIS. (From Nivala *et al*. (2004) *Hydraulic investigation of an aerated, subsurface flow constructed wetland in Anamosa, Iowa*. Poster presentation at the 9th International Conference on Wetland Systems for Water Pollution Control, 26–30 September 2004, Association Scientifique et Technique pour l'Eau et l'Environnement (ASTEE), Cemagref, and IWA, Avignon, France.)

Table B.1 lists volumetric efficiency results from tracer testing efforts at the Orlando Easterly treatment wetland (Martinez and Wise, 2003b), where 15 of 17 FWS wetland cells were tracer tested.

## The Detention Time Distribution

Calculation of the tracer detention time, τ, tells us a useful characteristic of the treatment wetland, namely, the average time water spends in the wetland. However, observation of tracer response curves, such as the ones shown in Figures 6.15–6.17, Chapter 6, clearly indicates that water is moving at different speeds within the wetland. Thus, the tracer response curve illustrates the entire range of detention times observed in the wetland. This range of detention times is termed as the *detention time distribution*, or DTD.

The DTD can be defined as

$$f(t)\Delta t = \text{fraction of incoming water that stays in the wetland for a length of time between } t \text{ and } \Delta t \tag{B.11}$$

where

$f$ = DTD function, $d^{-1}$
$t$ = time, d
$\Delta t$ = time increment, d

The exit tracer concentration is related to the DTD function. For an impulse tracer entering a system, the concentration curve, $C(t)$, can be related to the DTD function, $f(t)$, by

$$f(t) = \frac{QC(t)}{\int_0^\infty QC(t)dt} \tag{B.12}$$

where

$C(t)$ = exit tracer concentration, $g/m^3$ = mg/L
$Q$ = water flow rate, $m^3/d$

The numerator is the mass flow of the tracer in the wetland effluent at any time $t$ after the time of the impulse addition. The denominator is the sum of all the tracer collected and thus should equal the total mass of tracer injected. Equation B.12 represents the observed DTD function.

If flow rate is constant, $Q$ may be deleted from the numerator and denominator, and Equation B.12 simplifies to

$$f(t) = \frac{C(t)}{\int_0^\infty C(t)dt} \tag{B.13}$$

The tracer concentration can be measured at interior wetland points as well as at the outlet. Equation B.12 or B.13 may then be used to determine the distribution of transit times to that internal point. In this broader sense, the DTD becomes a function of internal position, $f(x,t)$.

The TIS model described in Figure B.3 is defined as a number ($N$) of equally sized, perfectly mixed tanks arranged in series. The number of tanks can be any integral number between 1 and ∞. The response of this series of tanks is

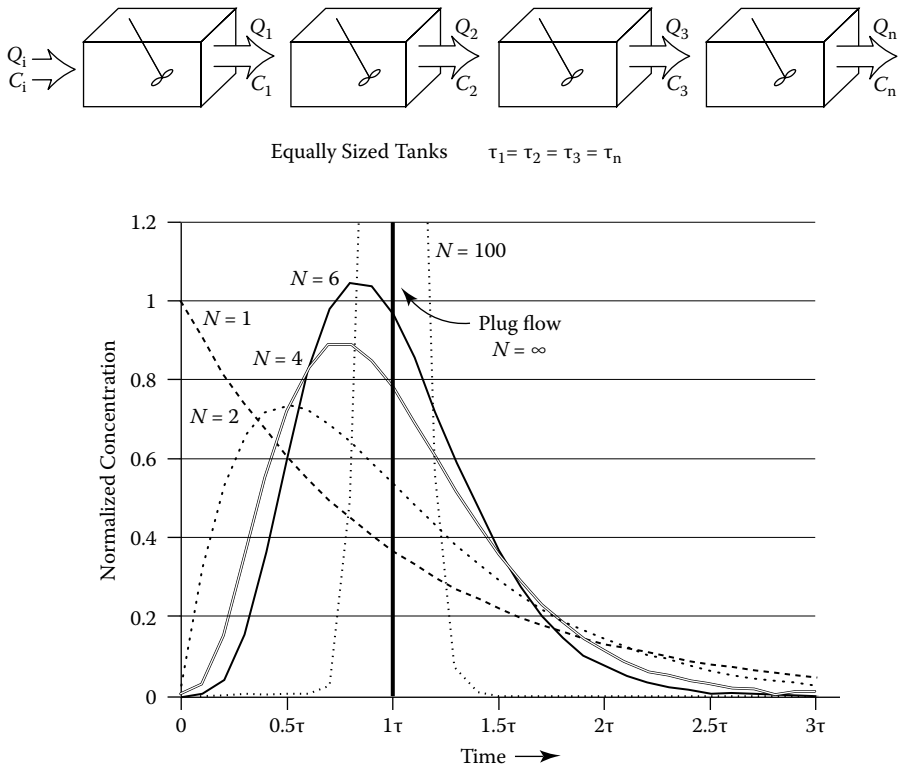

**FIGURE B.3** Response of a closed vessel to a unit impulse of an ideal inert tracer as a function of the number of tanks in series. (Adapted from Levenspiel (1972) *Chemical Reaction Engineering.* First Edition, John Wiley and Sons, New York.)

**TABLE B.1**

*Source:* Based on Martinez and Wise (2003b) *Journal of Environmental Engineering (ASCE)* 129(6): 553–560.

calculated from the dynamic tracer mass balance equations for the tanks:

$$V_j \frac{dC_j}{dt} = Q(C_{j-1} - C_j) \qquad j = 1, 2, \ldots, N \quad \text{(B.14)}$$

where

$C_j$ = tracer concentration in unit $j$, mg/L = g/m$^3$
$t$ = time, d
$V_j$ = volume of unit $j$, m$^3$

Equation B.14 is easily rearranged:

$$\tau_j \frac{dC_j}{dt} + C_j = C_{j-1} \qquad j = 1, 2, \ldots, N \quad \text{(B.15)}$$

where

$\tau_j$ = tracer detention time in unit $j$, d

Because all the units are of equal volume, the tracer detention time of the entire system is $\tau = N\tau_j$. If a unit impulse of concentration is fed to the series of tanks as a feed concentration condition, the resulting effluent concentration from the *Nth* tank is the tracer concentration response according to the model. Thus, Levenspiel (1972) demonstrates that the DTD curve for the TIS model can be represented by

$$f(t) = \frac{N^N t^{N-1}}{\tau^N (N-1)!} \exp\left(\frac{-Nt}{\tau}\right) \quad \text{(B.16)}$$

### Moment Analysis

The moments of the DTD define the key parameters that characterize the wetland, the two most important being the actual detention time and spreading of the concentration pulse due to mixing (variance of the pulse). The *nth* moment about the origin is defined by

$$M_n = \int_0^\infty t^n f(t) dt \quad \text{(B.17)}$$

The zeroth moment represents the definition of the fractional character of the DTD function. Because the term $f(t)\Delta t$ represents the fraction of tracer that spends between time $t$ and $t + \Delta t$ in the system, the sum of these fractions is unity:

$$\int_0^\infty f(t) dt = 1 \quad \text{(B.18)}$$

The first absolute moment is the tracer detention time $\tau$. This value defines the centroid of the exit tracer concentration distribution:

$$\int_0^\infty t\, f(t) dt = \tau \quad \text{(B.19)}$$

It is sometimes useful to work with a dimensionless time variable, defined as the actual time divided by the tracer detention time:

$$\theta = \frac{t}{\tau} \quad \text{(B.20)}$$

A second parameter that can be determined directly from the residence time distribution is the variance ($\sigma^2$), which characterizes the spread of the tracer response curve about the mean of the distribution, which is $\sigma^2$. This is the second central moment about the mean:

$$\int_0^\infty (t-\tau)^2\, f(t)\, dt = \sigma^2 \quad \text{(B.21)}$$

where

$\sigma^2$ = DTD variance, d$^2$

The variance of the DTD is created by the mixing of water during passage, or, equivalently, by a distribution of the velocities of passage. This can be lateral, longitudinal, or vertical mixing. This measure of dispersive processes may be rendered dimensionless by dividing by the square of the tracer detention time:

$$\sigma_\theta^2 = \frac{\sigma^2}{\tau^2} \quad \text{(B.22)}$$

The new parameter is $\sigma_\theta^2$, the dimensionless variance of the tracer pulse.

For the TIS model, it is possible to define simple relations between the parameters of the distribution and these moments. For instance, the TIS conceptual model (which produces a gamma distribution) has a dimensionless variance, given by

$$\sigma_\theta^2 = \frac{\tau - \tau_p}{\tau} \quad \text{(B.23)}$$

$$\sigma_\theta^2 = \frac{1}{N} \quad \text{(B.24)}$$

### Gamma Distribution Fitting

Virtually the entire early literature on tracer testing of wetlands and ponds utilized (archaic) parameter estimation methods that reflected the computational tools available when they were developed around 35 years ago. The most common method involves computation of the first and second moments of the experimental outlet concentration distribution (Equations B.19 and B.21) via numerical integration.

## TABLE B.2

A serious failing of the moment method of parameter estimation is that it emphasizes the "tail" of the response much more than the central portion—i.e., the peak area. Minor concentration anomalies on the tail of the concentration response curve may yield spurious parameter values. Often, a better procedure is to utilize a robust parameter determination routine, such as a search to minimize the sum of the squared errors between the selected DTD function and the data.

From Figure B.3, it is easy to see that the shape of the DTD is quite sensitive to changes in $N$ when $N$ is small. Note the change in magnitude and shape as the number of tanks increases from the ideal CSTR ($N = 1$) to 2 TIS and from 2 to 6 TIS. Because most wetland systems operate as a few (3–8) TIS, it is advantageous to be able to change $N$ from a discrete integer variable to a continuous (noninteger) variable. This enables the modeler to utilize fractional values of $N$, increasing the flexibility with which a dataset can be fit with a model. The gamma distribution $f(t)$ is defined as:

$$f(t) = \frac{N^N t^{N-1}}{\tau^N \, \Gamma(N)} \exp\left(\frac{-Nt}{\tau}\right) \qquad \text{(B.25)}$$

The gamma function $\Gamma(N)$ is defined by

$$\Gamma(N) = \int_0^\infty \exp(-x) x^{N-1} dx \qquad \text{(B.26)}$$

Equation B.25 represents a DTD function that may be fit to data. The GAMMADIST function is available in Microsoft Excel™ and returns values of $f$ for the time $t$ and the parameters $N$ and $\tau$.

The SOLVER application in Microsoft Excel™ allows the modeler to simultaneously solve for the variables $N$ and $\tau$ that minimize the difference between the observed DTD (Equation B.13) and the predicted DTD (Equation B.25). Examples of results of this approach are shown in Figures 6.13 and 6.15, Chapter 6.

As an illustration of the potential problems of the old moment analysis procedure and the ability of the sum of the squared errors (SSQE) minimization, consider the data set for the lithium tracer test of Cell 2 of the Everglades Nutrient Removal Project, Florida, FWS wetland (Figure B.4). Computations are illustrated in Table B.2. SSQE fits the peak area of the response, whereas moment calculations fit the tail. Moment analysis produces a higher tracer detention time (12.95 days versus 11.17 days) and a lower number of TIS (2.74 versus 5.47). The moment parameters produce a poorly appearing "fitted" gamma curve. The bulk of the tracer, and hence the important part of the response, is contained in the peak zone. Accordingly, the SSQE minimization analysis of tracer data is recommended, rather than moment calculations.

Here, the goodness of fit is measured via the root mean square (RMS) error between model and data DTD values. The range $0 < \theta < 4$ is chosen to eliminate repeated zero errors associated with the tail of the distribution. The RMS error is divided by the peak height of the distribution to provide shape scaling. The RMS error for the moment fit in Figure B.4 is 24.5%, whereas the SSQE fit yields an RMS error of 9.2%.

## TRACER TEST OBSERVATIONS

Treatment wetlands have been built to many different specifications and in many geometric layouts. Tracer tests for many have produced similar results, without evidence of pathological hydraulic behavior. Here, examples are given to illustrate commonly encountered features.

### FWS Wetland Systems

The results of an illustrative set of tracer test results for FWS wetlands is given in Table 6.1, Chapter 6. The average recovery for those 35 systems was 84%, the mean $N$TIS = 4.1, and the median $N$TIS = 3.6. More detailed information for a FWS system is informative.

The Tres Rios, Arizona, demonstration project conducted over 20 tracer tests of FWS wetlands used to polish municipal effluent. The Tres Rios Demonstration Constructed Wetland Project consisted of three discrete sites totaling 5.8 ha, of which 4.3 ha comprised two demonstration-scale free water surface (FWS) wetland facilities: a hayfield riparian site (H1 and H2) and a cobble site (C1 and C2). Wetland H2 was a 1.28-ha with a typical detention time of four days. Basin H2 had approximately 25% of its surface area as open-water deep zones, obtained using two large internal deep-zones with waterfowl islands. The primary vegetation consisted of two species of bulrush, *Scirpus validus* (soft-stem bulrush) and *Scirpus olneyi* (three-square bulrush). Tracer results have been discussed in Whitmer *et al.* (2000) and Keefe *et al.* (2004b).

The data from one of the bromide impulse tests are shown in Figure B.5, and the conditions for the test are given in Table B.3. The nominal detention time was 75 hours. A typical bell-shaped response is seen, with the first tracer appearing at the outlet at 16 hours. The tracer recovery was 88%, which indicates relatively conservative behavior. Three methods of analysis are illustrated: TIS from moments, TIS from least squares, and delayed (shifted) TIS from least squares. The RMS goodness of fit improves in that order (Table B.3). Depending on the fitting technique, the volumetric efficiency ranges 71–76%, indicating that most of the wetland water is involved in flow. The dimensionless variance is 0.237, corresponding to overall TIS = 4.2. However, if the shifted TIS DTD was used, the wetland behaved similar to a plug flow unit of 16 hours detention, combined with 38 hours detention in 2.8 TIS. The TIS moment fit of the DTD appears good only for the tail of the DTD.

The conversions for first-order, zero-background removal are given in Table B.3. In general, the plug flow approximation is not good, except for very low removals ($Da = 1$).

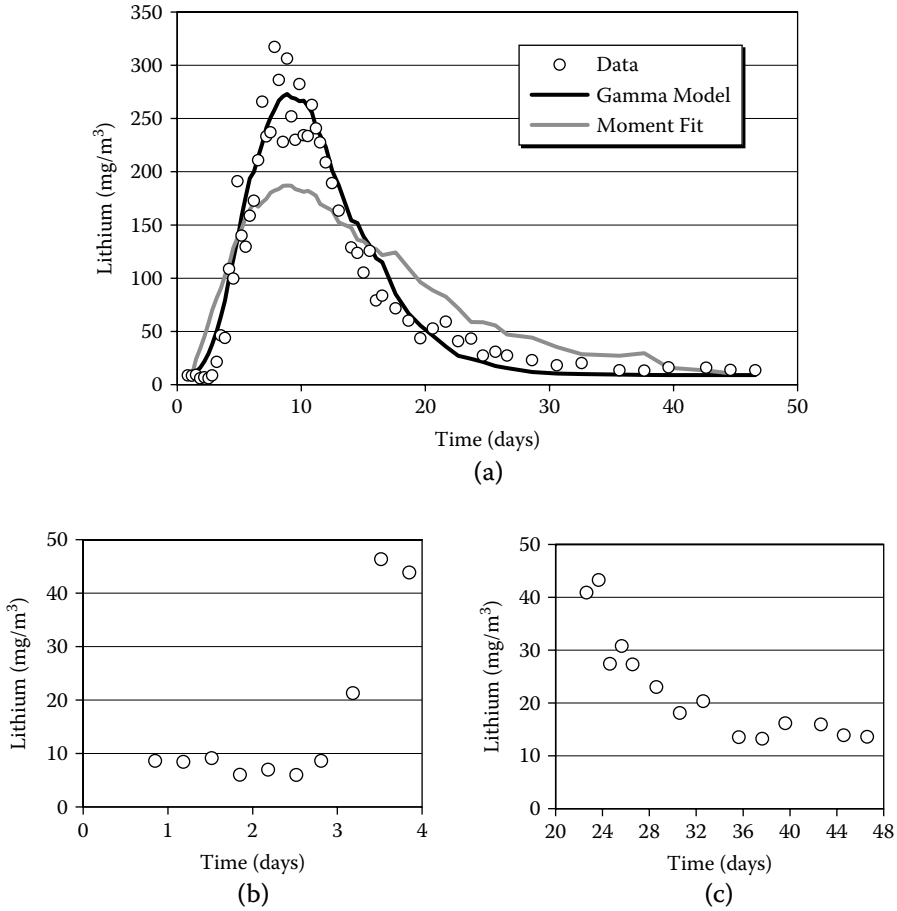

**FIGURE B.4** Tracer response for Cell 2 of the ENRP project, together with the least squares fit to a gamma function. The lower panels display expansions of the starting and ending periods of the test.

## HSSF Wetland Systems

The results of an illustrative set of tracer test results for HSSF wetlands are given in Table 6.2, Chapter 6. The average recovery for the 37 systems was 92%, the mean *N*TIS = 11.0, and the median *N*TIS = 8.3. More detailed information for a HSSF system is informative.

The HSSF wetland system at Minoa, New York, consisted of three flow paths with two cells in series in each, totaling 0.67 ha. The average design flow was 600 $m^3$/d, corresponding to a nominal detention time of three days. The substrate was 10–15 cm of 6-mm pea gravel on top of 75 cm of 20 mm gravel, and the cells were vegetated with *Phragmites australis* and *Scirpus validus*. Tracer results have been discussed in Marsteiner *et al*. (1996) and Marsteiner (1997). For the test example, the full flow was directed to cell 1.

The data from one of the bromide impulse tests are shown in Figure B.6, and the conditions for the test are given in Table B.3. The nominal detention time was 20.6 hours. A typical bell-shaped response is seen, with the first tracer appearing at the outlet at 9.6 hours. The tracer recovery was 98%, which indicates conservative behavior. Three methods of analysis are illustrated: TIS from moments, TIS from least squares, and delayed (shifted) TIS from least squares. The RMS goodness of fit improves in that order (Table B.3). Depending on the fitting technique, the volumetric efficiency ranges from 75–79%, indicating that most of the wetland water is involved in the flow. The dimensionless variance is 0.089, corresponding to overall TIS = 11.2. However, if the shifted TIS DTD was used, the wetland behaved similar to a plug flow unit of 9.6 hours' detention, combined with 11 hours' detention in 6.9 TIS. The TIS moment fit of the DTD appears good.

The conversions for first-order, zero-background removal are given in Table B.3. In general, the plug flow approximation is not good, except for very low removals (*Da* = 1).

## Event-Driven Wetland Systems

Tracer analysis of event-driven systems is complicated by two factors: the flow is not steady, and all the tracer may not be flushed out of the wetland by a single event. Despite these difficulties, it has been shown that the hydraulic flow patterns are similar under event-driven and continuous flow (Werner and

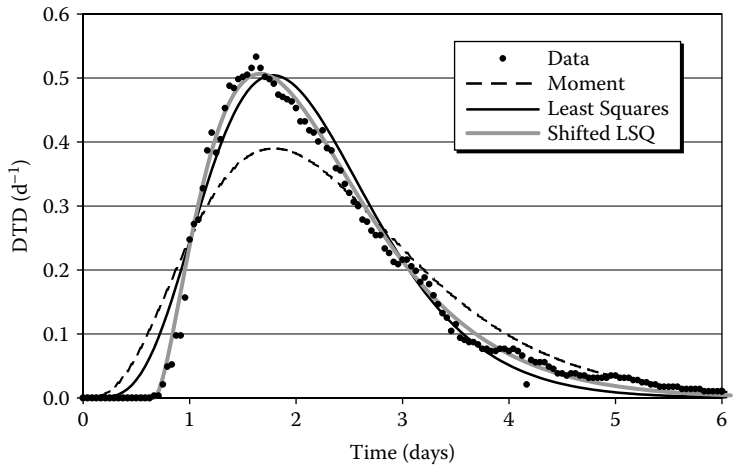

**FIGURE B.5** FWS tracer test results for Tres Rios Hayfield wetland 2, together with three different TIS fits. Conditions are given in Table B.3.

Kadlec, 1996). Methods for dealing with unsteady flows and depths have been outlined by Holland *et al*. (2004; 2005).

It is instructive to examine the hypothetical response of a 4-TIS wetland to a tracer addition to an inflow that terminates before flushing the wetland. A nominal detention time of three days is selected, corresponding to a fixed inflow of 500 $m^3$/d and a full-flow volume of 1,500 $m^3$. During the tracer test, the wetland receives 500 $m^3$/d for a period of three

**FIGURE B.6** Tracer test results for a HSSF wetland at Minoa, New York, together with three different TIS fits. Conditions are given in Table B.3.

days, but then the inflow stops. It is presumed that the wetland outflow is governed by a weir structure. The tracer concentration response at the system outlet is shown in Figure B.7. Two artifacts of the test results are apparent. First, there is a delay as the water level builds up in the wetland, with low outflows as the height over the weir increases. If there were no outflow, it would take three days to fill the wetland to the new depth. After the inflow ceases, the wetland drains back down to the elevation of the weir. Outflows decrease back down to zero over the next few days. There is residual tracer in the wetland, corresponding to a recovery of 68% (32% remaining). As a second result, the concentration near the outflow point, which has become stagnant, remains at an elevated value until another event again causes outflow.

Such distortion of the DTD makes it difficult to ascertain the hydraulic parameters of the wetland. A flow-weighted time, proportional to the volume of water that has exited the wetland, removes these two artifacts. On that basis, the response changes to the shape characteristic of continuous flow systems. There are alternative choices for scaling, as discussed by Werner and Kadlec (1996), who provide the mathematical background for rescaling to the volumetric approach.

## Variability in Tracer Results

As for any other treatment wetland performance parameter, there is variability in the volumetric and DTD efficiency results. That variability may be caused by seasonal variables, such as litter or algal density; or it may be caused by meteorological factors, such as wind, evapotranspiration (*ET*), or rainfall. A set of six warm-season tests on FWS wetland EW3 at Des Plaines, Illinois, gave $e_V = 0.70 \pm 0.13$ and $e_{DTD} = 0.62 \pm 0.10$ (Kadlec, 1994). Results from the Tres Rios, Arizona, demonstration wetlands ($N = 3$) showed a narrower range for $e_{DTD}$, with a typical coefficient of variation of 0.03–0.06.

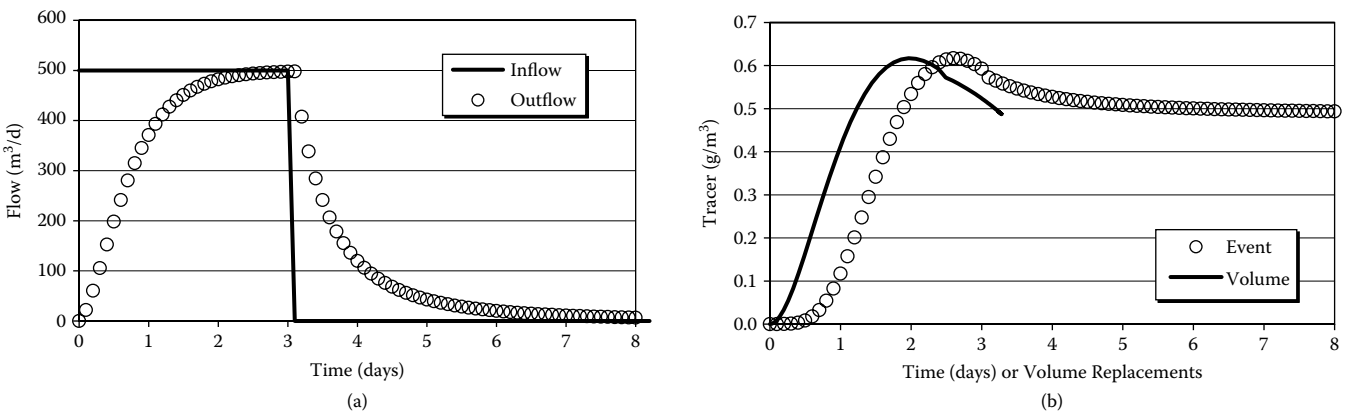

**FIGURE B.7** Tracer response for a hypothetical stormwater wetland. The inflow is presumed to last for three days (a), during which the system fills to a new operating depth. The tracer is not completely flushed (b), resulting in a residual concentration. The solid line shows a rescaling of "time" to a cumulative volume outflow basis.

**FIGURE B.8 (A color version of this figure follows page 550)** Progress of Rhodamine WT dye tracer through a FWS wetland, cell 4 of the ENRP in Florida. The dye was introduced along the upper boundary, and flow proceeds from the top to the bottom. Note the short-circuit along the left-hand side, which is partially redistributed by the central cross canal. (Photo courtesy T. DeBusk.)

However, there was wider variability for $e_V$, with a typical coefficient of variation of 0.13–0.33. Thus, it appears that the coefficient of variation for efficiency results may be in the range 5–30% for FWS systems.

## COMMON ABERRATIONS

Although it is tempting to think that the entire wetland water volume is swept by the flow in a moderately uniform manner giving rise to a gamma DTD, deviations from that pattern are commonly found. Two pathological situations are the existence of short-circuits from inlet to outlet and the existence of deadwater zones that are not swept by flow.

### Short-Circuiting

When part of the water follows a fast, preferential path through the wetland, the result is termed channeling or short-circuiting. On the ground, these fast flow paths may result from bathymetry, such as deeper channels from inlet to outlet (see Figure B.8). The tracer detention time will be less than the nominal. A pathological case is illustrated in Figure B.9, Lakeland, Florida, cell 1 (Keller and Bays, 2001). The recovery was 106%. The nominal detention time was 17.3 days; the tracer detention time was 5.8 days, for a volumetric efficiency of 33%. The dimensionless variance was 0.66, corresponding to *N*TIS = 1.5. The DTD curve for this wetland was clearly bimodal, indicating two flow paths. When the DTD is fit with a two-path

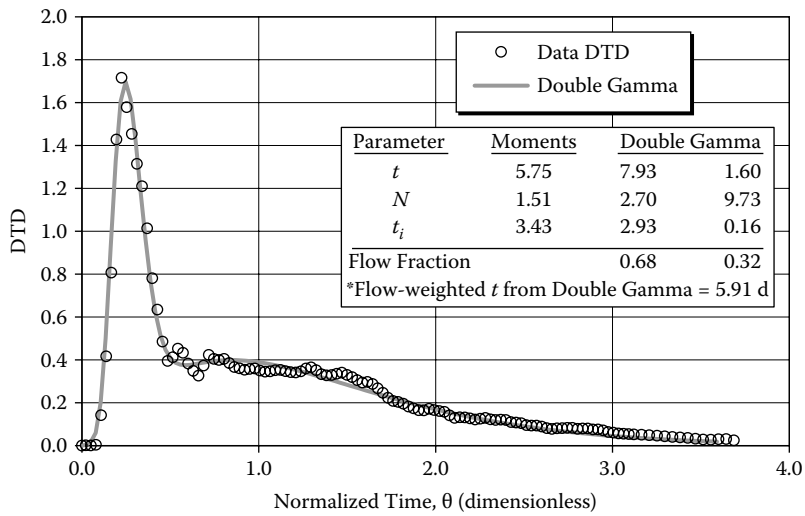

**FIGURE B.9** Tracer response for a short-circuited FWS wetland, Cell 1 at Lakeland, Florida.

model, the fit is excellent (see section titled Other Flow Models). About a third of the water had a mean detention time of 1.6 days, whereas the remaining two thirds had a mean detention time of 7.9 days. Cell 1 contained large internal areas of linear spoil mounds parallel to the direction of flow and, therefore, presumably, was highly channelized between these areas.

### Dead Zones

Wetlands often contain parcels of water that are not in the main flow path and are not flushed by flowing water. Such zones may be due to water trapped in a mass of algae or a dense clump of vegetation or litter in the FWS wetland. In a HSSF wetland, there may be dead-end pores. Tracer enters and departs these zones by diffusion, which is usually a slow process compared to flow. As a consequence, the tracer response will exhibit a long tail corresponding to the tracer that parked temporarily in the dead zones. An example from Sacramento, California, is shown in Figure B.10, along with a TIS fit (Nolte and Associates, 1998b). The nominal detention time for this test was 5.5 days, the tracer detention time was 5.3 days, and the recovery was 97%. If the moment method is used to fit the data, the tail region controls, and the peak zone is poorly represented. Alternative methods of analysis are discussed in the section on wetland–tracer interactions that can account for the dead zones, but at the expense of additional modeling parameters. The implications for pollutant removal are discussed in the section on pollutant removal effects.

## EXTENSIONS TO THE TIS FLOW MODEL

The simplest TIS model, and the gamma distribution that represents it, does not allow for some of the very real phenomena that may be encountered. DTD may result from velocity profile effects rather than mixing. When that is the case, it has a zero portion for short times, up to the shortest travel time experienced by rapidly moving water. For instance, that rapid path is typically associated with surface water layers in unvegetated areas of a FWS wetland. In HSSF wetlands, the rapid paths are the most direct routes between the media particles, as opposed to paths that wander off to the side to move around particles. In either case, there is a nonzero minimum of the travel time. This concept is discussed in detail in the engineering literature (see for example, Levenspiel, 1972). Another set of unaccounted processes includes water gains and losses, in the form of seepage, rainfall, and evaporation. These factors may be included by modifying the TIS model structure.

### TIS Plus a Delay

The TIS model has been described earlier (in the section on the TIS flow model) as an example of the use of least squares fitting of DTDs. As noted, it is a two-parameter fit, using detention time $\tau$, and number of tanks $N$. It does not suffer from a constraint of small degrees of nonideality and can cover the entire range from one well-mixed unit to a plug flow. Drawbacks are the inability to describe either the breakthrough delay or long tail resulting from retardation.

The tanks plus a delay have been utilized as a model for dealing with the breakthrough delay evidenced in most tracer response curves. This model may also be easily coded in a spreadsheet, but there are three parameters: the delay time $t_D$, the detention time $\tau$, and the number of tanks $N$. Many authors recommend the inclusion of this component of the response (Kadlec *et al*., 1993; Kadlec and Knight, 1996; Chazarenc *et al*., 2004; Marsili-Libelli and Checchi, 2005).

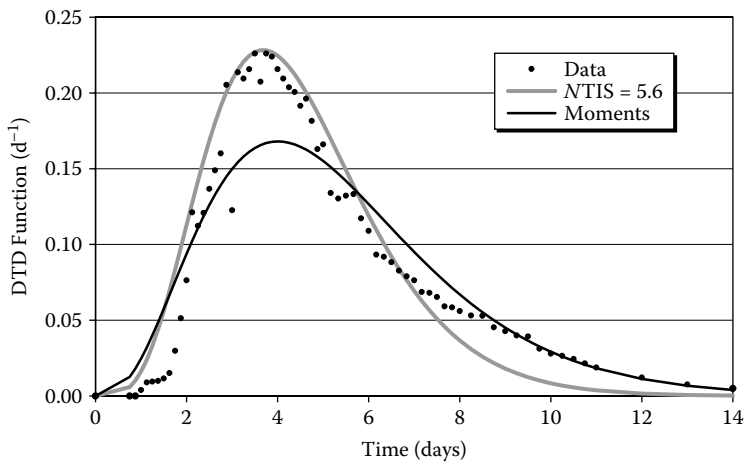

**FIGURE B.10** Tracer test result from the Sacramento, California, wetland Cell 7. The least squares TIS model does not account for the long tail of the experimental curve. The moment method fits the tail, but misses the peak area. (Data from Nolte and Associates (1998a) *Sacramento Regional Wastewater Treatment Plant Demonstration Wetlands Project*. 1997 Annual Report to Sacramento Regional County Sanitation District, Nolte and Associates.)

$$f(t)\begin{cases} = \dfrac{1}{t_i\,(N-1)!}\left(\dfrac{t-t_D}{t_i}\right)^{N-1} e^{\left(-\frac{t-t_D}{t_i}\right)} & t > t_D \\ = 0 & t < t_D \end{cases} \quad \text{(B.27)}$$

where
$t$ = detention time, d
$t_D$ = delay time, d
$t_i$ = mean detention time in one tank, d

### Infiltration

Some wetlands may safely infiltrate water into the ground. For example, the Tres Rios, Arizona, cobble site wetland, C1, infiltrated 60–80% of the incoming water (Kadlec, 2001c). Similarly, the Imperial, California, wetlands also leaked a considerable fraction of the incoming water, 40–60% (TTI and WMS, 2006). The tracer test theory does not usually include this leak effect on the water mass balance.

For illustration, let the model framework be the TIS concept discussed previously. The volume, depth, and planar area are considered to be the same for each unit. The leak rate is also assumed to be the same in each unit. For simplicity, the effects of rain and *ET* will be omitted from this analysis. The steady-flow water mass balance equation for the *jth* well-mixed unit is

$$Q_{j-1} = Q_j + L \qquad j = 1, 2, \ldots, N \quad \text{(B.28)}$$

where
$L$ = leak from unit $j$, $m^3/d$
$N$ = total number of units in the TIS model, integer
$Q_j$ = overland flow from unit $j$, $m^3/d$

Leakage acts to reduce the flow as water moves from inlet to outlet. Equation B.28 may be solved sequentially to determine the flow exiting each unit:

$$Q_j = Q_i - jL \qquad j = 1, 2, \ldots, N \quad \text{(B.29)}$$

where
$Q_i$ = inlet flow rate, $m^3/d$

The total leakage is

$$NL = \alpha Q_i \quad \text{(B.30)}$$

where
$\alpha$ = total fraction of inlet flow that is lost through leakage, dimensionless

At constant water volume in each unit, the tracer mass balances are

$$V_j \frac{dC_j}{dt} = Q_{j-1}C_{j-1} - (Q_j + L)C_j \qquad j = 1, 2, \ldots, N \quad \text{(B.31)}$$

where
$C_j$ = tracer concentration in unit $j$, mg/L = $g/m^3$
$t$ = time, d
$V_j$ = volume of unit $j$, $m^3$

Equations B.28 and B.31 combine to give

$$\tau_j \frac{dC_j}{dt} + C_j = C_{j-1} \qquad j = 1, 2, \ldots, N \quad \text{(B.32)}$$

where

$$\tau_j = \frac{\tau_{in}}{\left[N - \alpha(j-1)\right]} \qquad j = 1, 2, \ldots, N \quad \text{(B.33)}$$

The individual unit detention times $\tau_j$ are based on the combination of surface flow and leakage leaving the *jth* unit and its water volume. The nominal system detention time based on inlet flow $Q_i$ and the total system water volume is

$$\tau_{in} = \frac{NV}{Q_i} \quad \text{(B.34)}$$

If there is no leakage, then $\alpha = 0$, and $\tau_j = \tau_{in}/N$.

$$\tau_{an} = \tau_{in}\left(\sum_{j=1}^{N} \frac{1}{N - \alpha(j-1)}\right) \quad \text{(B.35)}$$

where
$\alpha$ = water loss fraction, dimensionless ($\alpha = 1 - R = 1 - Q_o/Q_i$)
$j$ = tank number counter, dimensionless
$N$ = total number of tanks, integer
$\tau_{an}$ = actual nominal detention time, d
$\tau_{in}$ = flow-based inlet nominal detention time, d

The effect of leakage on the measured detention time can be quite large for high values of $\alpha$, especially for high values of *N*TIS (Figure B.11). For example, if half the incoming water is lost, the true detention time for a 3-TIS wetland will be 23% greater than the inlet nominal detention time. The use of an average flow rate will always give an overestimate of the actual detention time.

The tracer is lost to leakage, and so the recovery will be less than 100%. The lowered surface outflow leads to a low and late peak (Figure B.12). However, the shape of the response is not affected, and hence the analysis of the response will give the same dimensionless variance (same number of TIS).

### Rain and Evapotranspiration

The loss or gain of water to or from the atmosphere does not carry tracer in or out of the wetland. However, *ET* does cause the water to slow as it passes through the system, and rain causes it to accelerate. Because there is normally level control at the outlet, the depth remains unchanged, but the linear

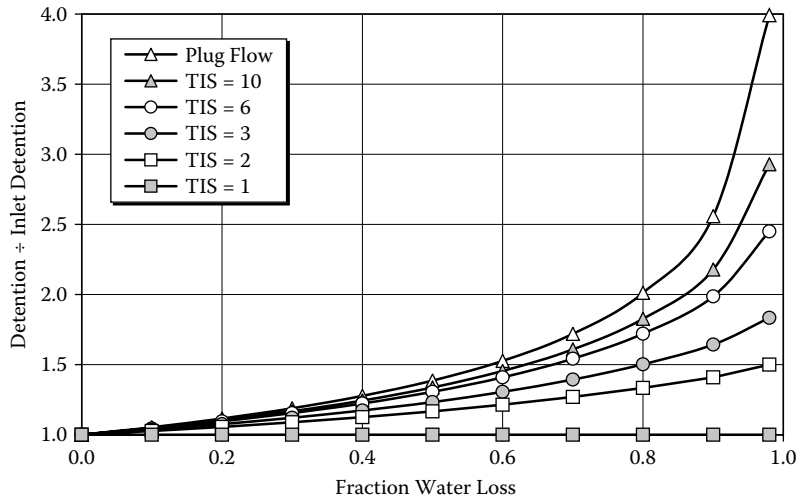

**FIGURE B.11** Detention times in leaking wetland systems, expressed as a ratio to the nominal detention time, computed from the inlet flow rate. The fractional water loss is the total for the entire wetland.

velocity of the remaining water is altered. Accordingly, for *ET*, the detention time is increased (see Chapter 2), and dissolved constituents become more concentrated. Conversely, for rain, the detention time is decreased, and dissolved constituents become diluted. The effects on tracer response have been discussed by Chazarenc *et al*. (2003; 2004), who present the theoretical result for detention time in plug flow systems with *ET* (Chapter 2, Equation 2.8):

$$\tau_{an} = \tau_{in}\left(\frac{\ln(R)}{R-1}\right)$$

where

$R$ = water recovery fraction, dimensionless ($R = Q_o/Q_i$)
$\tau_{an}$ = actual nominal detention time, d
$\tau_{in}$ = flow-based inlet nominal detention time, d

This plug flow formula works equally well for rainfall gains. However, this is not the case for a TIS system, in which the influence of precipitation and *ET* is greater. The actual detention time (tracer detention time) in a TIS wetland is

$$\tau_{an} = \tau_{in}\left(\frac{1}{N}\sum_{j=1}^{N}\left(\frac{1}{1-\frac{\alpha j}{N}}\right)\right) \qquad \text{(B.36)}$$

where

$\alpha$ = water loss fraction, dimensionless
($\alpha = 1 - R = 1 - Q_o/Q_i$)
$j$ = tank number counter, dimensionless
$N$ = total number of tanks, integer

In the limit, as $N$ becomes very large, Equation B.36 reduces to Equation B.35.

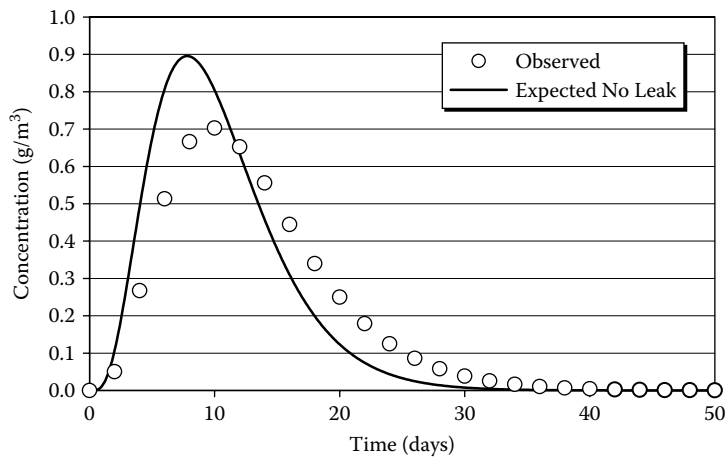

**FIGURE B.12** The effect of leakage on a tracer response for 4 TIS. The line is the forecast result for no leakage loss. The circles represent the result for 50% water loss due to leakage.

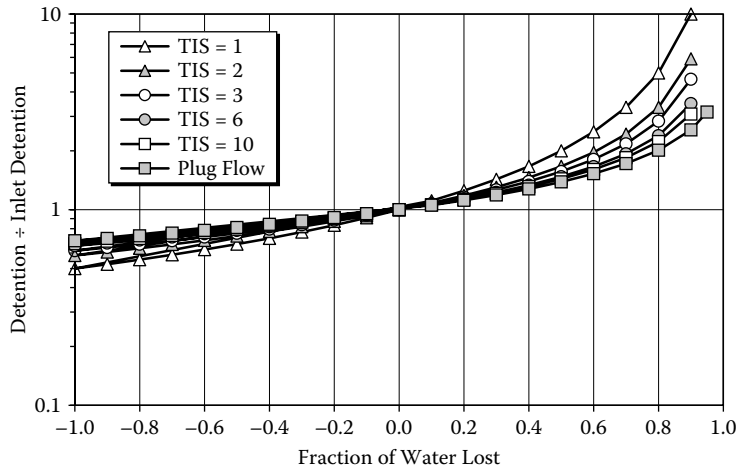

**FIGURE B.13** Detention times in wetland systems with rain or evapotranspiration, expressed as a ratio to the nominal detention time computed from the inlet flow rate. The fractional water loss or gain is the total for the entire wetland.

The effect of *ET* on the measured detention time can be quite large for high values of $\alpha$, especially for low *N*TIS (Figure B.13). For example, if half the incoming water is lost, the true detention time for a 3-TIS wetland will be 57% greater than the inlet nominal detention time. The use of an average flow rate will always give an underestimate of the actual detention time for *ET* and an underestimate for rain cases. The error is large for relatively large amounts of *ET*.

None of the tracer is lost to *ET*, so the theoretical recovery should be 100%. The combination of the evaporative concentration and lowered outflow leads to a high and late peak (Figure B.14). The combination of rain dilution and increased outflow leads to a low and early peak. However, the shape of the response is not affected, and hence the analysis of the response will give the same dimensionless variance (the same number of TIS).

## WETLAND–TRACER INTERACTIONS

In the foregoing, it has been assumed that the wetland water body can be considered as vertically uniform and that the tracer does not interact with any of the solids or biota in the system. In some cases, these assumptions are not warranted.

### Wind

If the wetland contains significant areas of open water, wind can be a factor in tracer movement. In ponds, field studies with drogues and computational fluid dynamics (CFD) modeling (HYDRO-3D) have shown that surface velocities may be 30-fold greater than deep-layer velocities and that the velocity profile is most affected in the top 10–15 cm (Guganessharajah, 2001). Lloyd *et al.* (2003) implemented windbreaks around a shallow pond (1.1 m deep), thus isolating the system from

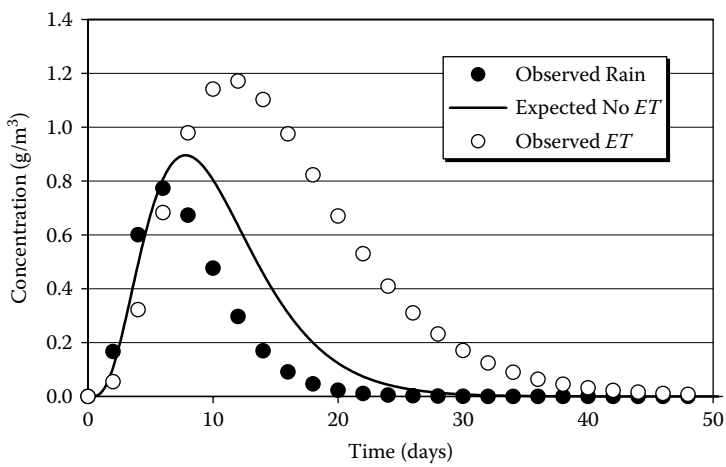

**FIGURE B.14** The effects of *ET* and rain on a tracer response for 4 TIS. The line is the forecast result for no *ET* loss. The open circles represent the result for 50% water loss due to *ET*. The closed circles represent the result for 50% water gain from rain.

winds that averaged only 0.8 m/s. The volumetric efficiency was increased from 50% to 74%, and the dispersion number was decreased from 0.66 to 0.40.

In laboratory flume experiments, with wooden dowels representing plants, Stephan *et al*. (2004) showed that tracer response curves differed in shape depending on whether the wind was with or against the flow. Wind acting on surface layers drives a surface current in the wind direction and promotes vertical mixing via recirculation in the water column. Therefore, Stephan *et al*. (2004) found that the tail of the response curve was shortened for a wind of 2.4 m/s blowing against the flow direction. The volumetric efficiency was higher with the tail wind (83%) than with the head wind (74%).

Stairs (1993) found that a tail wind of 5.7 m/s caused a very early peak concentration in the response compared to more quiescent conditions for an unvegetated FWS wetland.

There are no sufficient experimental results on vegetated operating FWS systems to formulate quantitative measures of wind effects at this point in time.

### Ice

Tracer tests for frozen conditions were conducted by Smith *et al*. (2005), who concluded that flow conditions "appeared to be good in both ice-covered and unfrozen conditions." The shapes of the tracer responses were very similar, and the volumetric efficiencies were nearly the same, for ice-free and under ice conditions.

### Degradation and Loss

Recovery of tracer is an extremely important quality check for the measured DTD. Failure to recover 100% of the tracer may mean that the tracer adsorbed or was degraded during passage through the wetland. Organic compounds, including the fluorimetric dyes often used for water tracing in mineral systems, are notorious in this respect: they disappear in wetlands. Noninteractive, inorganic substances are to be preferred, lithium ions and bromide ions being two of the more popular ones. Batch microcosm tests can help to establish the degree of interaction between a specific tracer and the wetland in question. Interactive, disappearing tracers produce serious errors in the inferred mixing parameters.

The use of a sorbing tracer can distort the tracer response curve and lead to errors in calculating hydraulic characteristics. An irreversibly sorbing tracer such as rhodamine WT may cause the peak time to be shorter than it really is, whereas a reversibly sorbing tracer will cause a flattening of the DTD and an unrepresentative extension of the tail. Dierberg and DeBusk (2005) reported that the recovery of rhodamine WT declined as the initial concentration of the impulse was reduced.

It is possible that molecular tracers may degrade during travel through the wetland. This is especially true for the organic dyes, such as rhodamine. These may be subject to photolytic decomposition, or to the action of microbes that use the tracer as a carbon source. Irreversible sorption has the same effect, because it removes the tracer from the water, with no chance of return. Additionally, it is possible that the tracer is permanently removed by plant uptake, at least on the time scale of a tracer test. Although such losses cannot be entirely prevented, it is possible to assess its potential effects on the results of the test.

We begin by supposing that the removal is first-order and apportioned equally in all portions of the water column. Therefore, each parcel of water traversing the wetland will lose tracer exponentially with respect to its travel time. We also suppose that the DTD is given by a gamma function, according to Equation B.25. If the rate coefficient is $k$, then the fractional concentration of the tracer exiting with a given parcel between time = $t$ and time = $t + dt$ is

$$\frac{C(t)}{C_i} = g(t)e^{-kt} = \frac{1}{t_i\,\Gamma(N)}\left(\frac{t}{t_i}\right)^{N-1} e^{\left(-t/t_i\right)}e^{-kt} \qquad \text{(B.37)}$$

where

$C$ = tracer outlet concentration, mg/L
$C_i$ = tracer inlet concentration, mg/L
$k$ = tracer loss rate coefficient, 1/d
$t$ = detention time, d
$t_i$ = mean detention time in one tank, d
$N$ = number of tanks

This equation is still a gamma distribution with the same $N$ as that for the nondestructive case. However, the detention time ($t = Nt_i$) has been shortened:

$$\tau_{app} = N\frac{t_i}{1+kt_i} = \frac{\tau_{act}}{1+k\dfrac{\tau_{act}}{N}} \qquad \text{(B.38)}$$

where

$\tau_{act}$ = actual detention time, d
$\tau_{app}$ = apparent detention time, d

Because the apparent detention time has been shortened, the volumetric efficiency will appear to be reduced accordingly. However, the number of TIS is not affected. If the distribution of Equation B.25 is averaged over all parcels, the mass recovery of tracer is given by

$$\text{Fraction recovery} = \left(1-k\frac{\tau_{app}}{N}\right)^N \qquad \text{(B.39)}$$

An example of the effect of tracer loss is given in Figure B.15. This effect is illustrated in the work of Bowmer (1987).

### Retardation

The tracer may also be retained in the wetland, but not lost. This can occur because of the presence of dead zones, either large or small scale, that gain the tracer by diffusion, retain it until the pulse has passed, and then release it back to the flowing water. Reversible sorption on any of several wetland solids can lead to the same phenomenon. Tracer is sorbed on

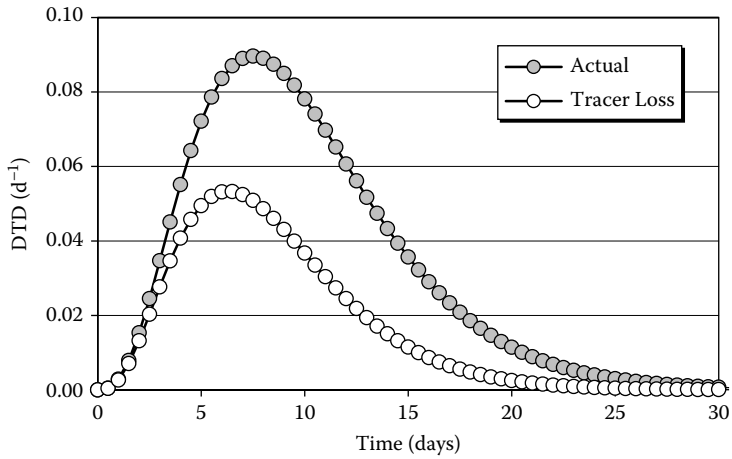

**FIGURE B.15** The effect of tracer loss on the DTD for a wetland with $N = 4$. The actual detention time was ten days, the measured tracer detention was 8.4 days, and the mass loss of tracer was 50%.

the rising limb of the tracer pulse and released on the falling limb.

There are several wetland "compartments" that can serve to store inert solutes. The wetland sediments or media may reversibly sorb the tracer, and this possibility may be qualitatively checked with laboratory tests. However, there may be several other types of "parking places" in the wetland environment. These include stagnant pools of water, pore water associated with litter or clumps of filamentous algae, and the upper layer of soil pore water. Side pools are accessible by wind-driven cross currents. Litter and biomass pore waters are accessible by diffusion. Topsoil pore waters are accessible by diffusion and transpiration flows. All of these mechanisms have two common features: the presence of a storage location, and exchange with the main streams of water. At a simple level, a common model can be used for all.

There are two components to the dynamic model needed to track a tracer with the possibility of storage. The one-dimensional mass balance for tracer for the flowing water is

$$\frac{\partial C}{\partial t} + u\frac{\partial C}{\partial x} = \Phi(C_s - C) \tag{B.40}$$

and the mass balance for storage is

$$\Omega\frac{\partial C_s}{\partial t} = -\Phi(C_s - C) \tag{B.41}$$

where

$C$ = tracer water concentration, mg/L
$C_s$ = tracer storage concentration, mg/L
$t$ = time, d
$u$ = actual water velocity along flow path, m/d
$x$ = distance along flow path, m
$\Phi$ = exchange flow with storage, $(m^3/d)/m^3$
$\Omega$ = storage ratio, $m^3/m^3$

These equations are those used to track pulses of constituents in chromatography, in which delays are due to adsorption. If there is equilibrium between storage and moving water, then $C_s = KC$. We may then add Equations B.40 and B.41, and write

$$(1+\Omega K)\frac{\partial C}{\partial t} + u\frac{\partial C}{\partial x} = 0 \tag{B.42}$$

The factor $(1 + \Omega K)$ is represented as $\rho$, the retardation factor for the system. In ideal circumstances, there would be no storage, and $\rho$ will be 1. However, that will rarely be the case in real wetland environments. The best we can hope for is that $\rho$ is close to unity, and, luckily, this is often the case (see, for instance, Richardson *et al*., 2004).

Equations B.40 and B.41, either in continuous form or discretized, form the basis for the stage models of wetland tracer response. In continuous form, they have been termed the zones of the diminished mixing (ZDM) model, which has been calibrated to many FWS and HSSF wetlands (Werner and Kadlec, 2000a; 2000c). In discrete form, it is termed the finite stage model (Mangelson, 1972; U.S. EPA, 2000a). These will be discussed in more detail in the next section; here, the purpose is to determine the possible effects of storage and exchange on the parameterization of a tracer test.

The cases of water-dead zone storage and solid sorption are somewhat different in that dead water would normally be included in the calculation of nominal detention time, whereas solid sorption storage would not.

For the case of solid sorption storage, the effect of storage is to delay and broaden the tracer response curve. This means that the tracer detention time is lengthened compared to the nominal, and the number of TIS is reduced.

For the case of water storage in dead zones, the effect of storage is to accelerate and broaden the tracer-response curve. That means that the tracer detention time is shortened compared to the nominal, and the number of TIS is reduced.

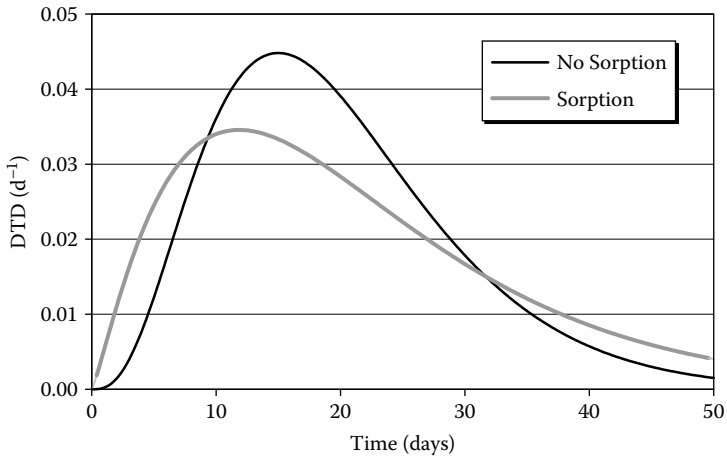

**FIGURE B.16** The effects of reversible sorption on a tracer response for 4 TIS. The "no sorption" line is the forecast result for no sorption. The "sorption" line represents the result for 50% augmentation of water column storage on the solids.

### An Example

These ideas are illustrated by considering a FWS wetland receiving 50 $m^3$/d of water. It is assumed that the system contains an estimated 1,000 $m^3$ of water, computed from stage and bathymetric data. The nominal detention time is easily seen to be 20 days. We further suppose that the system behaves similar to 4 TIS. Equations B.40 and B.41 may be used to assess the effects of added sorption storage on the form of the tracer response. For illustration, suppose that sorption storage provides 50% augmentation of the storage in the water column and the exchange rate of tracer is 50% of the water flow rate. It is found that the measured tracer detention time would be 21.7 days and the system displays behavior characteristic of 2.2 TIS. The nonsorbing and sorbing tracer response curves are shown in Figure B.16.

The illustration is continued for the dead water case. Suppose that dead water storage provides 50% of the storage in the water column and the exchange rate of tracer is 50% of the water flow rate. It is found that the measured tracer detention time would be 13.8 days, and the system displays behavior characteristic of 1.7 TIS. The non-dead-water and dead-water tracer response curves are shown in Figure B.17.

## OTHER FLOW MODELS

Whereas the TIS model described previously is the most popular flow model, other flow models are also used in the wetland literature.

### Plug Flow with Dispersion

Another model uses a dispersion process superimposed on a plug flow model (PFD). Mixing is presumed to follow a convective diffusion equation. Although the PFD model has been advocated for wetlands (e.g., Pardue *et al*., 2000; Wang, 2006), it is doubtful whether it is the most appropriate

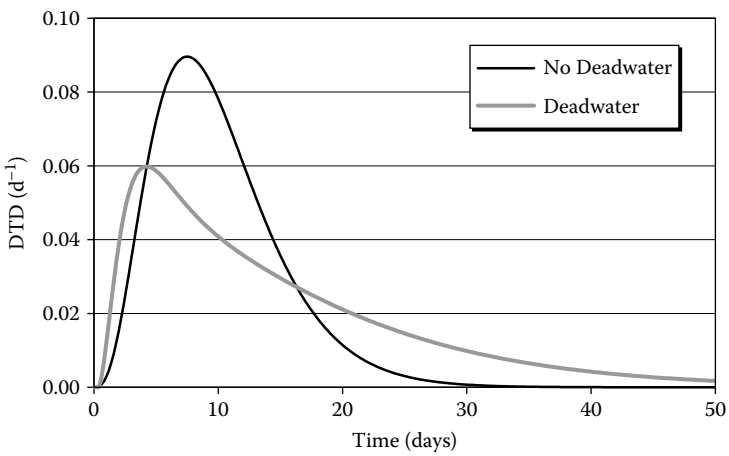

**FIGURE B.17** The effects of dead water storage on a tracer response for 4 TIS. The "no dead water" line is the forecast result for no dead water. The "dead water" line represents the result for 50% of water column in dead zone storage.

model of comparable complexity. The dispersion coefficient describes eddy transport of water elements both upstream and downstream. In FWS wetlands, such mixing may not occur because flow is often predominantly laminar.

A one-dimensional spatial model is chosen because analytical expressions are available for computation of pollutant removal for one-dimensional cases (Fogler, 1992). A two-dimensional version requires a two-dimensional velocity field, which are virtually nonexistent for treatment wetlands. The tracer mass balance equation includes both spatial and temporal variability:

$$D\frac{\partial^2 C}{\partial x^2} - \frac{\partial (uC)}{\partial x} = \frac{\partial C}{\partial t} \qquad \text{(B.43)}$$

where
$u$ = actual water velocity, m/d
$D$ = dispersion coefficient, $m^2/d$
$x$ = distance from inlet toward outlet, m

The appropriate wetland boundary conditions for this mass balance are known as the *closed-closed* boundary conditions (Fogler, 1992). These imply that no tracer can diffuse back from the wetland into the inlet pipe or up the exit structure at the wetland outlet. These are different from the *open-open* boundary conditions that are appropriate for river studies. There are analytical, closed form solutions to the latter case, which have led to their repeated misapplication to wetlands (Bavor *et al*., 1988; Stairs, 1993). There are no closed-form solutions for tracer responses for the wetland case, but numerical solutions to the closed-closed tracer mass balance have been available for more than three decades (Levenspiel, 1972). It is possible to calculate the dispersion constant that fits a particular dataset, although there are issues of accuracy. This model is not advocated here, because the PFD model is only infrequently applicable to treatment wetlands.

The dimensionless parameter that characterizes Equation B.43 is the Peclet number (Pe), or, its inverse, the wetland dispersion number ($\mathfrak{D}$).

$$\mathfrak{D} = \frac{D}{uL} = \frac{1}{\text{Pe}} \qquad \text{(B.44)}$$

where
$\mathfrak{D}$ = wetland dispersion number, dimensionless
$D$ = dispersion coefficient, $m^2/d$
$L$ = distance from inlet to outlet, m
Pe = Peclet number, dimensionless
$u$ = superficial water velocity, m/d

A primary interesting result from the model is the dimensionless variance, which can be written in explicit form for the PFD model:

$$\sigma_\theta^2 = 2\mathfrak{D} - 2\mathfrak{D}^2(1 - e^{-1/\mathfrak{D}}) \qquad \text{(B.45)}$$

The principal problems with the PFD model to wetlands have to do with meeting the assumptions implicit in the model. Levenspiel (1972) notes as follows:

> In trying to account for large extents of backmixing with the dispersion model we meet with numerous difficulties. With increased axial dispersion it becomes increasingly unlikely that the assumptions of the dispersion model will be satisfied by the real system.

The condition of an "intermediate" amount of axial dispersion (or less) should be met in order to apply the PFD model, which is nominally taken to be $D < 0.025$ (Levenspiel, 1972) and corresponds to about 20 TIS. The DTDs for FWS wetland systems are characterized by a large amount of apparent dispersion, with $0.07 \le D \le 0.35$ (Kadlec, 1994). Therefore, generally, neither FWS nor HSSF wetlands are within the acceptable mixing range, although HSSF systems may sometimes be marginally within the range (see Tables 6.1 and 6.2, Chapter 6). However, a bigger obstacle to accepting the PFD model consists of the concentration profiles that are predicted for reactive constituents, because they predict features not seen in treatment wetlands.

The first-order concentration reduction produced by the closed-system PFD model is available in explicit form and is well known (see, for instance, Fogler, 1992):

$$\frac{(C - C^*)}{(C_o - C^*)} = \frac{4b\, e^{(\text{Pe}/2)}}{(1+b)^2 e^{(b\text{Pe}/2)} - (1-b)^2 e^{(-b\text{Pe}/2)}} \qquad \text{(B.46)}$$

$$\begin{aligned} &\text{(a)} \quad b = \sqrt{1 + 4\frac{Da}{\text{Pe}}} \\ &\text{(b)} \quad Da = k\tau / h \\ &\text{(c)} \quad \text{Pe} = uL / D \end{aligned} \qquad \text{(B.47)}$$

where
$D$ = dispersion coefficient, $m^2/d$
$L$ = distance from inlet to outlet, m
$u$ = average superficial water velocity, m/d

This result is typically credited to Wehner and Wilhelm (1956).

Note that there are also two parameters in this reaction model: the rate coefficient $k$ (or, equivalently, the Damköhler number $Da$), and the dispersion coefficient $D$. This formulation has been advocated for wetlands and ponds (Reed *et al*., 1995; Crites and Tchobanoglous, 1998; Shilton and Mara, 2005; Crites *et al*., 2006). However, the longitudinal profiles that this model predicts for large degrees of mixing are not realistic.

## PFD Longitudinal Profiles

Longitudinal profiles may be used to test the validity of alternative modeling assumptions. For instance, the PFD model

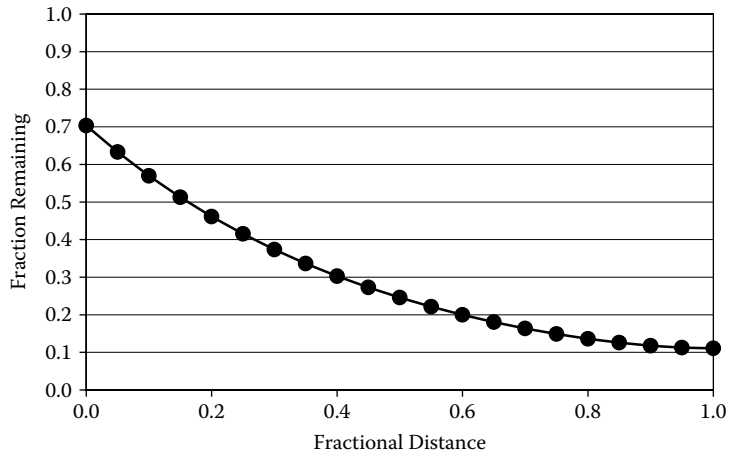

**FIGURE B.18** Fractional amount of reactant remaining for the first-order PFD model for closed-closed boundary conditions. The dispersion is $D/uL = 0.20$, and the reaction rate is $Da = k\tau h = 3.0$.

forecasts the concentration profile through the wetland by

$$\frac{C(x)}{C_i} = \frac{2e^{(x\mathrm{Pe}/2)}\left[(1+b)e^{(b\mathrm{Pe}(1-x)/2)} - (1-b)e^{(-b\mathrm{Pe}(1-x)/2)}\right]}{(1+b)^2 e^{(b\mathrm{Pe}/2)} - (1-b)^2 e^{(-b\mathrm{Pe}/2)}} \tag{B.48}$$

where

$x$ = distance in flow direction, wetland, m
$C(x)$ = concentration at length x, g/m$^3$

The longitudinal concentration profile is predicted to display an instantaneous drop at the wetland inlet. For $\mathfrak{D} = 0.2$ and $Da = 3$, the decrease at the inlet is 30% (Figure B.18). For larger $\mathfrak{D}$ (more dispersion), the instantaneous drop is even larger, increasing to 55% at $\mathfrak{D} = 1.0$. This unrealistically large concentration drop at the very start of the gradient has not been observed in wetland practice and, hence, the PFD model is not an acceptable alternative for most treatment wetland situations.

Interestingly, this predicted profile has only infrequently been examined in any of the literature pertaining to applications to ponds or wetlands, although the PFD model has been extensively utilized. In a pond environment, the situation is often one of considerable mixing because of wind and recirculation currents, and the concept of a sudden concentration change on entry is not unlikely. But in a treatment wetland, this model conceives of swirls that move back into the inlet region. That is a most unlikely scenario in a vegetated wetland environment.

### Parallel Paths

The parallel paths model has been described previously as an example of a method for dealing with the long tails evidenced in some tracers. This model may also be easily coded in a spreadsheet, but there are five parameters: the flow split, plus the detention time, and the number of tanks along both paths. Some authors recommend the two-path response model (Keller and Bays, 2001; Chazarenc *et al*., 2003; Wang, 2006; Wang *et al*., 2006). However, if a two-path model is warranted, then there is something seriously wrong with the wetland. It is the wetland that needs improvement, not the model.

### Finite and Infinite Stages

The breakthrough delay and the long tail may be described by a model that incorporates a plug flow component and side-tank storage in a series of units (Figure B.19). A single stage of

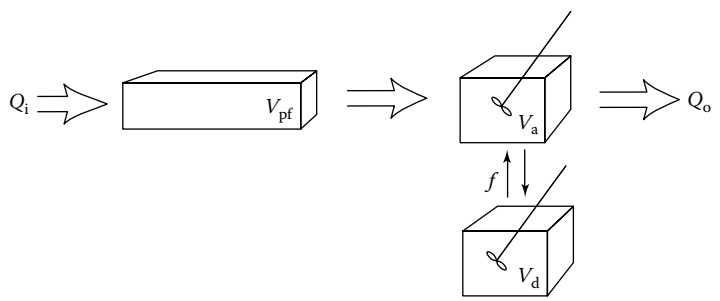

**FIGURE B.19** A single stage of the finite or infinite stage model. A plug flow unit is followed by a well-mixed unit that exchanges material with a side-storage unit.

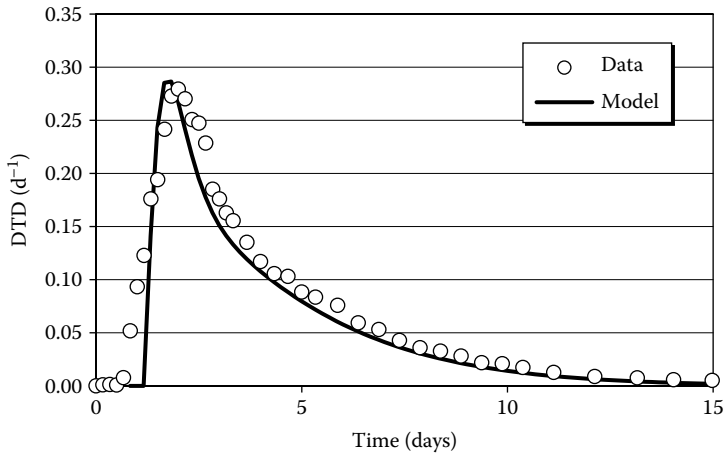

**FIGURE B.20** Finite ($N = 3$) stage model of the tracer response of ENRP cell 4. The tracer detention time was 3.4 days. The plug flow fraction was 20%, active volume 40% and dead volume 40%. The exchange flow ratio was 0.4.

this model consists of a plug flow unit (of volume $V_{PF}$), followed by a well-mixed unit (of volume $V_a$) that exchanges material with a side-storage unit (of volume $V_d$). There are five parameters in this model: the number of stages, the detention time, the fraction plug flow, the fraction active well-mixed, and the exchange flow ratio. The exchange flow between $V_a$ and $V_d$ is $f$, and the ratio to the through-flow is $f/Q$. The finite stage model comprises a small number (2–5) of these stages in series. The infinite stage model utilizes a large number (~100) of the stages.

The concept of the finite stage model was advanced by a number of early authors (Hovorka, 1961; Mangelson, 1972; Levenspiel, 1972). Buffham *et al.* (1970) set forth a family of models that rest on the concept of water elements being delayed a number of times during passage through a packed bed. These are based on the abstraction that water would flow uniformly through the bed (plug flow) if it were not that elements are detained at points during their travel, and elements so detained eventually rejoin the main flow after a time delay.

The finite stage model can provide an excellent fit of data from both ponds and wetlands (Mangelson, 1972; Nolte and Associates, 1998b). An example of the fit is given for cell 4 of the ENRP (Figure B.20). In this case, the response model is supported by the visual tracer study (see Figure B.8), in which the main flow path and side storages may easily be seen.

Werner and Kadlec (2000c) showed that the model could assume a limiting form for a very large number of stages. They termed this the zones of diminished mixing (ZDM) model, which contains four parameters: the detention time, the fraction dead zones, the fraction bypassing, and a dispersion number for the main flow path. Martinez and Wise (2003a) used the infinite stage model via the code of Runkel (1998), which is called OTIS (one-dimensional transport with inflow and storage).

Stage models, by virtue of their one-dimensional character, are not capable of providing a good fit in situations where there is clearly more than one flow path (Martinez and Wise, 2003a). Stage models do not lend themselves to an easy representation for computing pollutant removal. Thus, although they often can do an excellent job of representing the tracer response, they are of limited use in wetland evaluation and design.

## Computational Fluid Dynamics (CFD)

Many treatment wetlands are not linear in their design and assume irregular shapes with irregular bathymetry. Flow distribution may be at a point along the inlet boundary rather than distributed across the width of the wetland. Additionally, vegetation density may not be spatially uniform. Under such circumstances, the internal flow patterns are variable in at least two dimensions, lateral and longitudinal. As with all other models, vertical averaging has always been utilized, although that assumption is questionable under many wetland circumstances. Flow modeling involves solution of mass and momentum balances on a two-dimensional grid, together with a tracer mass balance. This procedure has been utilized, for example, by Walker (1998), Persson *et al.* (1999), Koskiaho (2003), Wörman and Kronnäs (2005), Jenkins and Greenway (2005), Kjellin *et al.* (2006), and Lightbody *et al.* (2007). Several software packages are available for this purpose, including RMA4, MIKE-21, HYDRA3, and HYDRUS2D.

The advantage of CFD modeling is the ability to explore the consequences of alterations in the basin morphology on the volumetric and DTD efficiencies of a system. For instance, the use of point inlets and outlets has the conceptual potential to create dead zones in the corners of a rectangular wetland. This may be tested with CFD, and indeed, the corners are predicted to be excluded from the flow (Figure B.21). The CFD simulations of Koskiaho (2003) indicate that the flow can miss both the inlet and exit corners in rectangular wetlands. For this case, there are field data to confirm the predicted effect (Stairs, 1993; Stairs and Moore, 1994). The FWS wetland had an aspect ratio of L:W = 3:1 and was

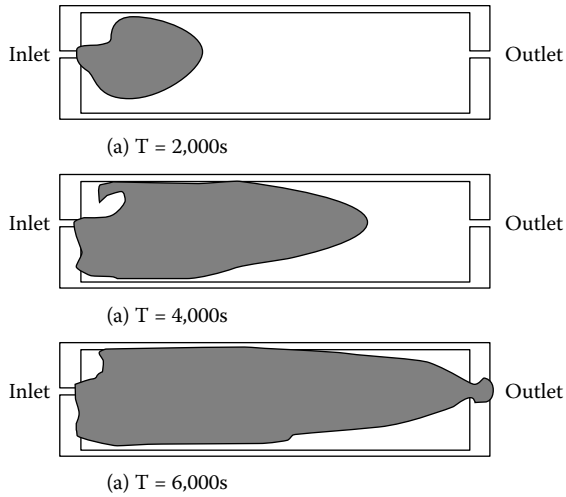

**FIGURE B.21** The penetration of new water into a FWS wetland according to a 2-D simulation model. Note that there may be recirculation and that corners do not "see" the new water. (From Walker (1998) *Ecological Engineering* 10(3): 247–262. Reprinted with permission.)

operated with and without a distribution header across the inlet. Tracer testing indicated a volumetric efficiency of 84% with the header, and 66% without. With the header, *N*TIS = 4.5, and without, *N*TIS = 3.3. The field data indicate an overall hydraulic efficiency $\lambda = 46\%$ for no header and $\lambda = 65\%$ with a header. The simulation results of Persson *et al*. (1999) and Jenkins and Greenway (2005) provide reasonable forecasts of overall hydraulic efficiency $\lambda$ of about 40–45% for unvegetated ponds of similar aspect ratio.

## PREDICTIONS FROM TIS AND CFD FLOW MODELING

The goal for treatment wetland design is to be able to predict the efficiencies of wetlands based on their morphology. Simulation results have been used to provide a few first indications of such relationships.

### Unvegetated Systems

Flat-bottom systems without plants have often been investigated. The effect of length-to-width ratios for ponds on dispersion has been reported by several researchers, and a summary of results is presented by Shilton and Mara (2005). Although the various pond regressions are for deep water environments compared to FWS wetlands, there is a trend, in all investigations, for the dispersion number ($D/uL$) to decrease as L:W increases. In other words, longer and narrower ponds display characteristics closer to plug flow, although still displaying behaviors characterized by a small number of TIS. Jenkins and Greenway (2005) present simulation results for unvegetated FWS wetlands with point inlets and outlets, which may be expressed as

$$e_V = 1 - e^{(-0.3L/W)} \tag{B.49}$$

Thackson *et al*. (1987) presented a similar correlation for data from shallow ponds that substantially agrees with these simulation results (Walker, 1998; Jenkins and Greenway, 2005). Likewise, the *N*TIS value is high for high values of L:W. Therefore, for unvegetated FWS wetlands, there is essentially no advantage in L:W ratios being greater than ten. However, it must be noted that these results are for point inlets and outlets, which are not efficient and probably should not be used.

### Vegetated Systems

The presence of vegetation will markedly change the hydraulics of the wetland by creating less dispersion and higher efficiencies (Kadlec, 1994). For example, the simulation results of Persson *et al*. (1999) showed that the full vegetation of the South Gippsland, Australia, wetland would have increased $e_V$ from 0.39 to 0.69 and *N*TIS from 5.7 to 15, compared to its existing condition. That existing condition was a channel from inlet to outlet, with only fringing vegetation.

The three principal variables associated with vegetation are: (1) percent cover, (2) stem density, and (3) orientation of patches. When vegetation is oriented in the flow direction, typically along the wetland edges, it is termed *fringing vegetation* (Persson *et al*., 1999; Jenkins and Greenway, 2005). When the orientation of patches is across the flow direction, it is termed *banded vegetation*. The simulation results of Jenkins and Greenway indicate that the use of banded vegetation is more efficient than fringing vegetation because of the shortcircuiting issue caused by the flow resistance in the fringes. Results from field studies in Florida (periphyton field cell tracer tests, unpublished data) and California (New River wetlands test results, unpublished data) tend to validate these simulation studies (Figure B.22).

If the vegetation density of a fringe is increased, then more flow is forced down the central channel, and efficiency drops. This was the simulation result of Jenkins and Greenway (2005), and the field result of Dal Cin and Persson (2000) and Stern *et al*. (2001).

### Bathymetry

Deep channels in the direction of flow cause shortcircuiting, whereas deep zones across the flow direction have little effect on flow patterns. The channelization effect is intuitively bad, and has been borne out in both simulation and field studies. It does little or no good to create the channel with meanders, that is, a serpentine deep channel from inlet to outlet (Persson *et al*., 1999).

The use of transverse deep zones in treatment wetlands has been advocated as promoting internal water redistribution and thus the improvement of volumetric and DTD efficiencies (Knight and Iverson, 1990; Knight, 1992; Knight *et al*., 1994; Knight *et al*., 2004). However, simulation results suggest that $e_V$ is little changed by deep zones (0.80 versus 0.81), and $e_{DTD}$ only modestly improved (0.96 versus 0.92) for the Gippsland,

**FIGURE B.22 (A color version of this figure follows page 550)** Rhodamine dye dispersing through an inlet deep zone, with a spikerush band providing resistance to shortcircuiting. (From CH2M Hill (2003a) *PSTA Research and Demonstration Project, Phases 1, 2, and 3 Summary Report*. prepared for the South Florida Water Management District (March 2003).)

Australia, wetland (Persson *et al*., 1999). At the Tres Rios, Arizona, site, 12 FWS wetlands were operated as triplicates of 0, 1, 2, and 3 internal deep zones, and tracer tested (Whitmer, 1998). Analysis of that data via least-squares parameter estimation provided values for $\tau$ and $N$. The resulting efficiencies are shown in Table B.4 for the 12 research wetlands. There was essentially no difference in volumetric efficiency or $N$TIS due to the number of deep zones, and hence none in hydraulic efficiency ($\alpha = 0.05$) (Kadlec, 2007).

Knight *et al*. (1994) operated a set of six treatment wetlands receiving treated paper-pulp-mill effluent for two years. Two internal deep zones comprising 25, 35, and 45% of the area were included in three of the six (Table B.5). Although there was variability in flow (different HLRs) and aspect ratios (2.5, 5, and 10), the authors concluded that there was improvement in nitrogen removal performance due to deep zones. Tracer data from that project are here reanalyzed, and characterized by a tanks-in-series (TIS) detention time distribution. The effect of deep zones was to decrease the number of TIS. However, for the two larger cell pairs, the volumetric efficiency was improved by deep-zone addition (Table B.5).

## Hummocks and Islands

Any wetland feature that protrudes from the water causes a reduction in wetland water volume and surface area compared to the wetland in its absence. Therefore, there is a penalty for such features in terms of the detention time or hydraulic loading. The argument has been made that islands (hummocks are small islands) promote better flow distribution and thus increase the DTD efficiency of the system (e.g., Thullen *et al*., 2005); however, field tests at Tres Rios do not support that contention (city of Phoenix, unpublished data).

According to CFD simulations for shallow ponds, this effect is present in wetlands without vegetation (Persson *et al*., 1999). However, CFD results for the Ekeby, Sweden, FWS wetland led to the conclusion that "According to the simulations, the constructed deep zones and islands had only

**TABLE B.4**

a minor effect on the residence time distribution" (Kjellin *et al*., 2006). The effect of islands in unvegetated systems is to divert flow toward corner zones that would otherwise not be accessed by the flowing water. However, in vegetated systems, the flow is predominantly directed by the vegetation, and not the bathymetry.

Underwater features, such as cross-flow benches or "speed bumps," have been utilized for the expressed purpose of redistributing flow. According to CFD simulations, this is effective for unvegatated systems (Persson *et al*., 1999). The field experience of Simi and Mitchell (1999) was that speed bumps and deep zones promoted mixing, such that a FWS wetland of L:W = 2 behaved approximately as *N*TIS = 2.

### Peninsulas and Sinuous Flow

Because of the strong effect of the length-to-width ratio that prevails for unvegetated FWS wetlands, it has been surmised that it is very advantageous to utilize high L:W for vegetated systems. Very often, the site boundaries do not allow linear wetlands of great length and, consequently, the strategy of folding the wetland several times is used to lengthen the L:W ratio. Such "back-and-forth" flow paths require the use of internal divider berms separating the passes of the flow path. This configuration is sometimes referred to as a sinuous path system in wetlands, but the equivalent in ponds is the use of baffles. Baffles improve the efficiencies of ponds, according to both CFD and field data. Vega *et al*. (2003) used simulation to predict that a pond of 2:1 aspect would show an improvement of $e_V$ from 74 to 84%, and *N*TIS from 3.94 to 5.5, for the addition of two baffles (18:1 with baffles). Lloyd *et al*. (2003) measured an increase in $e_V$ from 42 to 50%, and *N*TIS from 1.46 to 1.57, for two baffles in a pond of L:W = 4:1 (35:1 with baffles). Thus, improvement is found for the use of sinuous paths for unvegetated systems. However, pond systems often have low *N*TIS and low volumetric efficiency compared to vegetated wetlands.

The L:W ratio increases as the square of the number of passes. Sinuous and nonsinuous vegetated wetlands were run side by side at Listowel, Ontario, but unfortunately, no tracer tests were run (Herskowitz, 1986). However, there were improvements in pollutant removal performance for the sinuous systems. A tracer test was run on a FWS wetland of overall aspect L:W = 1:1, with three divider berms creating a four-pass back-and-forth flow pattern at Hillsdale, Michigan. The nominal flow aspect ratio was thus 16:1. Recovery was 70%, and *N*TIS = 4.3, but the volumetric efficiency was only 20–30%. Evidently flow followed small channels within each pass and failed to reach the majority of side areas.

In contrast, a side-by-side tracer test of a one-pass and a three-pass system of the same overall aspect (5:1) showed major differences (CH2M Hill, 2003a). Recoveries were similar but low (45 and 46%). The nonsinuous system (L:W = 5:1) had *N*TIS = 9 and $e_V = 0.88$, whereas the sinuous system (L:W = 45) had *N*TIS = 25 and $e_V = 0.58$. As a consequence, the hydraulic efficiency of the sinuous system was lower ($\lambda = 0.56$) than that of the nonsinuous system ($\lambda = 0.78$).

These studies are insufficient to draw conclusions about the efficacy of sinuous designs, but do provide preliminary indications that the length-to-width advantage may be overridden by the creation of numerous corner dead zones. Additionally, the divider berms occupy a portion of the footprint and so contribute to a loss of wetland area.

### Compartmentalization

Efficiencies may be increased by subdividing the wetland into a number of cells in series. This has the effect of lowering wind fetch and thus preventing large-scale recirculation. Compartmentalization also causes the water to be collected at each cell outlet, thus blending the high- and low-speed flow elements and then redistributing them.

On a theoretical basis, the effect on detention time is simply to break up the total detention time into pieces proportional to the volumes contained in the component cells:

$$\tau = \sum_{j=1}^{n} \tau_j \tag{B.50}$$

where
$n$ = number of compartments
$j$ = detention time in the *jth* compartment, d

However, the effect on the DTD efficiency is a bit more complicated. For cells in series, the variance of the tracer response for the system is the sum of variances for the individual cells (Levenspiel, 1972):

$$\sigma^2 = \sum_{j=1}^{n} \sigma_j^2 \tag{B.51}$$

where
$\sigma_j^2$ = variance change in the *jth* compartment, $d^2$

This may be related to the detention time and number of TIS for each compartment. From Equations B.22 and B.24,

$$\sigma_j^2 = \frac{\tau_j^2}{N_j} \tag{B.52}$$

where then the system is represented by:
$N_j$ = TIS for the *jth* compartment

$$\frac{\tau^2}{N} = \sum_{j=1}^{n} \frac{\tau_j^2}{N_j} \tag{B.53}$$

or

$$\frac{1}{N} = \sum_{j=1}^{n} \left[ \frac{\tau_j^2}{\tau^2} \right] \frac{1}{N_j} \tag{B.54}$$

In other words, the reciprocal *N*TIS values are additive in proportion to the square of the detention time fractions. If the compartments are all of equal size, then the *N*TIS values are simply additive, but not otherwise. For example, if 90% of the wetland is a compartment that behaves as 4 TIS, and the remaining 10% is a compartment that behaves as 10 TIS, then the system will act like 4.9 TIS.

It may easily be shown that pollutant removal is improved by compartmentalization because it moves the system closer to plug flow. However, for a fixed footprint, the wetland area is decreased because of the interior divider berms, and therefore multiple compartmentalization is not necessarily advantageous.

At the present time, it is necessary to rely on simulation results because there are not side-by-side tracer tests of compartmentalized and noncompartmentalized systems.

## TRACER TESTING PROTOCOLS

### Tracer Selection

Many different tracers have been used for hydraulic analysis of treatment wetlands. Desirable properties are that it is soluble in water, does not react with the pollutants or wetland constituents, occurs at low background levels within the wetland, may be easily analyzed, has low toxicity, and does not influence the flow pattern in a significant way (Headley and Kadlec, 2007). The three most common choices for wetland tracers have been fluorescent dyes and lithium or bromide salts. In FWS wetlands, both dyes and salts have been successfully used. Studies in HSSF and VF wetlands are generally performed using salt tracers.

Radioactive tracers, such as tritium, have very good tracer properties and have been used in constructed wetlands (Crohn *et al*., 2005; Xu *et al*., 2005; Kjellin *et al*., 2006). However, the use of radioactive substances in wetlands is often precluded by regulatory requirements and specific analytical requirements.

### Dye Tracers

Dyes have advantages of low detection limits, zero natural background, and low relative cost. However, they are susceptible to both photodegradation and biodegradation (Dierberg and DeBusk, 2005). This can complicate the analysis of tracer data, as discussed above.

Rhodamine WT is the most commonly used dye, mainly because of availability. Dissolved solids have no effect below about 600 mg/L, and pH has no effect above pH = 6, although the level of fluorescence is temperature sensitive, changing about 2% per degree Celsius (Smart and Laidlaw, 1977). Rhodamine WT is susceptible to biodegradation, photolysis, and adsorption onto organic solids, detritus, and some plastics (Smart and Laidlaw, 1977; Lin *et al*., 2003a; Dierberg and DeBusk, 2005). Due to the above characteristics, rhodamine WT should only be used in short-term tests ($\tau_n$ less than about three days) and within environments that are not highly organic.

Rhodamine WT is typically measured using fluorescence spectrophotometry at wavelength 558 nm and an emission wavelength of 580 nm (Smart and Laidlaw, 1977; Simi and Mitchell, 1999). Other dyes that have been used with varying degrees of success include eriochrome acid red (Bowmer, 1987), and uranine and eosine (Netter and Bischofsberger, 1990; Netter, 1994).

At high concentrations, fluorescent dyes are visible in FWS wetlands. For instance, just a cupful of RWT can easily be tracked through a 1-ha system. It is also feasible to use RWT for visible studies on large wetlands, such as the 147-ha cell 4 of the ENRP (see Figure B.8) (Dierberg *et al*., 2005). Visible studies are useful for establishing blatant shortcircuits, and cross-levee leakage.

### Salt Tracers

Bromide and lithium are the most extensively used ionic tracers, mainly due to their perceived noninteractive character

and ease of analysis. They are added as solutions of sodium or potassium bromide, or lithium chloride, and have yielded reliable results in numerous wetland studies (Bowmer, 1987; Netter, 1994; King *et al*., 1997; Rash and Liehr, 1999; Drizo *et al*., 2000; Grismer *et al*., 2001; Keller and Bays, 2001; Tanner *et al*., 2002a; Lin *et al*., 2003; García *et al*., 2004b; Smith *et al*., 2005). Lithium and bromide are not susceptible to degradation but are capable of being taken up by wetland plants and other organisms to a limited extent (Kung, 1990; Whitmer *et al*., 2000; Xu *et al*., 2004; Parsons *et al*., 2004). Perhaps more serious is the loss of any tracer, inert or not, caused by the movement of water from the water column to the rhizosphere due to the transpiration flux. Tracer is drawn into the root zone, where it is effectively lost during the relatively brief duration of a tracer experiment.

Background concentrations of lithium are typically very low; for instance 30 ± 14 µg/L (mean ± s.d.; range 4–50 for 20 FWS systems). Bromide may be present in natural waters at concentrations well above detection; for instance 420 ± 760 µg/L (mean ± s.d.; range 5–3,500 for 20 FWS systems). Bromide is typically analyzed via ion chromatography, although specific ion electrodes are available. Lithium can be measured using atomic absorption spectrometry (AAS) or inductively coupled plasma–optical emission spectrometry (ICP-OES).

Chazarenc *et al*. (2003) used high concentrations (67,000 mg/L) of sodium chloride solution as a tracer in a HSSF and measured conductivity in order to derive DTDs. They reported tracer recovery rates exceeding 78% from eight individual tracer studies. Sodium chloride can represent a relatively inexpensive option that can be easily monitored and logged in the field using electrical conductivity probes. However, high salt concentrations may have a negative effect on wetland biota and possibly treatment. Wörman and Kronnäs (2005) used potassium iodide as the tracer at the Alhagen, Sweden, wetland.

## Amount of Tracer

The mass of tracer in the impulse addition is based on the expected dilution, the method detection limit of the analytical techniques, and the background concentration of the tracer in the wetland system after dilution. During the introduction of the tracer impulse into the influent stream, the concentration should be considerably higher than both the analytical method detection limit and background concentration of tracer in the wetland. A target for the peak effluent concentration in the response might therefore be at least 20–50 times the background concentration, and at least 50 times the detection limit.

It is perhaps easier to plan in terms of the average concentration desired in the response curve. The peak-to-mean ratio (ratio of the peak tracer concentration to the mean tracer concentration over a period of three detention times) is typically 2–3 for FWS wetlands, and 4–5 for HSSF wetlands. The benchmark concentration can be defined as the mass of tracer added divided by the nominal volume of water in the wetland:

$$C_{\text{bench}} = \frac{M}{V_{\text{n}}} \tag{B.55}$$

where

$C_{\text{bench}}$ = benchmark concentration, g/m$^3$ = mg/L
$M$ = mass of tracer added, g
$V_{\text{n}}$ = nominal wetland water volume, m$^3$

The reader is reminded that the nominal wetland water volume for subsurface flow wetlands must take into account the porosity of the granular medium in the wetland bed. This benchmark concentration will be approximately 30–70% of the peak concentration. Keller and Bays (2001) suggest that the quantity of tracer added, if assumed to mix uniformly throughout the volume of the wetland, should achieve a benchmark concentration at least 10 to 20 times the background concentration.

## Density Stratification Problems with Salt Tracers

Tracer materials are most often available as either solids (e.g., NaBr, LiCl) or as concentrated solutions. These as-received materials are usually dissolved or diluted to form the tracer solution to be added, which is here designated to have concentration $C_{\text{dose}}$. Care should be exercised in preparing a solution to be dosed into the wetland because there can be large heat-of-solution effects upon dissolution. Most tests are conducted as impulse tests, which implies that the tracer should be dumped into the wetland inlet structure all at once. However, at high $C_{\text{dose}}$ concentrations, the density of the dosing solution may be substantially higher than that of the ambient water in the wetland to which it is added, causing the tracer pulse to sink to the bottom of the wetland.

In FWS wetlands, this situation is exacerbated by the presence of an inlet deep zone that serves as a repository for the dense slug of tracer. This effect is worsened by the transpiration flux in a FWS wetland, which draws water selectively from the wetland bottom and consequently may "pull" the dense tracer from the bottom of the water column into the soil matrix. Under such circumstances, tracer recovery will be poor. Although the typical interpretation of FWS wetland water flow is vertically averaged, water moves more slowly across the wetland bottom due to drag forces. This can cause the flow of the tracer through the wetland to be retarded as it slowly creeps along the bottom and stagnates in depressions. Consequently, density stratification can lead to a significant distortion in the DTD (Schmid *et al*., 2004a; 2004b).

To avoid the density stratification issue, the tracer concentration should not be so high as to result in a significant difference in density between the ambient wetland water and the tracer impulse when it is introduced into the wetland. For typical tracers salts, at 25°C, density equations are as follows (Söhnel and Novotny, 1985); all $R^2 \geq 0.9995$:

Lithium chloride $$\rho = 1.0000 + (5.0327 \times 10^{-7}) C_{\text{dose}} \tag{B.56}$$

Sodium bromide $$\rho = 1.0000 + (7.2869 \times 10^{-7}) C_{dose} \quad \text{(B.57)}$$

Potassium bromide $$\rho = 1.0132 + (6.9267 \times 10^{-7}) C_{dose} \quad \text{(B.58)}$$

Sodium chloride $$\rho = 0.9986 + (2.6123 \times 10^{-7}) C_{dose} \quad \text{(B.59)}$$

where

$C_{dose}$ = concentration of tracer dose solution, $g/m^3$ = mg/L

$\rho$ = density of tracer dose solution, $g/cm^3$

It is known that, in lakes, a density difference of about 1% is enough to maintain stratification. In their teaching lab experiment to demonstrate this effect, Wetzel and Likens (1991) use a density difference of 1.5%. It is therefore not surprising that Chazarenc *et al*. (2003) observed tracer stratification in full-scale HSSF systems at a density difference of 3.4%.

There is also a body of anecdotal evidence that implicates density effects in anomalous tracer tests. For example, several LiCl tests were run by the South Florida Water Management District on test cell wetlands with instantaneous dosing with 78,000 mg/L lithium chloride. The density difference would have been on the order of 3.9%. Recoveries were quite variable, with some as low as 23%. Rousseau *et al*. (2006) reported "losing" a dose of high-concentration lithium in an SSF wetland pilot but finding it residing on the wetland bottom. The studies of Whitmer *et al*. (2000) displayed very low recoveries of sodium bromide, impulse-dosed into deep zones at about 200,000 mg/L. The estimated density difference would have been approximately 14.6%. Although the loss was attributed to plant uptake, it seems highly probable that the dense bromide accumulated in the inlet deep zones and stayed there. Schmid *et al*. (2004a; 2004b) performed detailed experiments using salt tracers in shallow-water flumes, intended to emulate FWS wetlands. The presence of plastic dowels in the water column (which were used to represent plants) assisted in the prevention of stratification. Nonetheless, stratification in these idealized laboratory channels was found to exist for concentrations on the order of 150 mg/L of sodium chloride. Drizo *et al*. (2000) dosed HSSF mesocosms with potassium bromide at 20,000 mg/L, which has a density 1.2% greater than water. The tracer was found on the bottom of all mesocosms, whether planted or unplanted.

Density stratification may be ameliorated by aeration of the wetland. An aerated HSSF wetland in Anamosa, Iowa, was dosed with 142,000 mg/L potassium bromide (11.2% more dense than water) (Nivala *et al*., 2004). The measured recovery of 85% and volumetric efficiency of 91% were indicative of lack of stratification (Nivala, 2005). Nonetheless, at 25% of the bed length, the concentration peak in the top layer (15 cm) was five times higher than that in the deep layer (45 cm).

Based on these findings, it is suggested that the density of the tracer impulse should be a great deal less than 1% of the density of the ambient wetland water in order to minimize the risk of density effects. Clearly, it is also useful to promote as much turbulence as possible at the point of water introduction so that the tracer is further diluted by the primary inlet water flow.

Fortunately, the density difference problem can also be alleviated by prolonging the period of tracer dose introduction. This effectively dilutes the dose concentration with incoming water prior to the wetland. In effect, the impulse is replaced by a "square wave" tracer input. The clock for the test is set to zero at the midpoint of the inlet tracer delivery time series. There will then be no error in the computation of the tracer detention time. The variance of the tracer outlet response is adjusted by subtracting the variance of the inlet pulse (Levenspiel, 1972). In this way, the dose concentration may be diluted by a very large factor.

### Sampling Frequency and Duration

A quantitative tracer test requires definition of the full response curve, from the pretest background through the rising and falling limbs of the distribution and back down to a posttest plateau. This requires sampling for a long-enough period and at a suitable frequency to adequately describe the tracer response curve. Thus, an estimate of the likely DTD of the wetland should be made based on nominal parameters to design a sampling regime. Important aspects of the DTD to be considered when determining sampling frequency are the steeply rising limb of the peak concentration profile and the long, declining tail. However, tracer responses often cannot be accurately forecast. It is therefore prudent to collect and store more samples than anticipated to be needed because lithium and bromide do not degrade during storage. These supplementary samples can then be analyzed retroactively if they are deemed to be necessary based on analysis of the primary sample set.

About 30–40 sample points are normally adequate to define the response curve spread over about three nominal detention times. A minimal sampling frequency of 24 points is illustrated in Figure B.23. These are more densely spaced in the early portion of the response to capture the rise in concentration. A lesser frequency is needed far out on the tail. Where the flow rate is somewhat variable (stormwater wetlands, for instance), flow-weighted sampling will generally be the best way to ensure that accurate sampling of the tracer response curve is achieved. In any case, it is necessary to record both the time of sampling and volume of water that has passed through the sample point, as these are required in interpreting the variable-flow tracer-response data. The use of automatic samplers is of great benefit. They can be configured to collect samples at regular time intervals, or alternatively to collect samples on a flow-weighted basis.

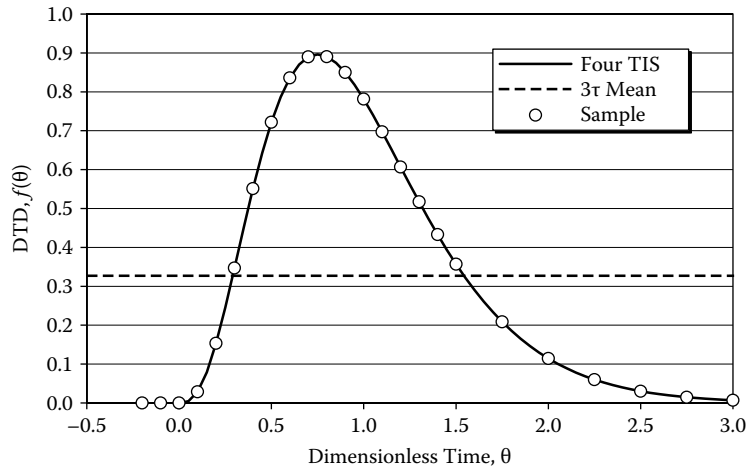

**FIGURE B.23** The concentration of the peak of a 4-TIS response is 2.74 times the mean concentration over three detention times.

Sampling should begin immediately prior to tracer injection to identify the background concentration at the time of the tracer study. The greatest sampling frequency is required at times when the concentration is changing most rapidly (that is, around the time of the peak in concentration). The rise typically begins at 10–30% of $\tau_n$. The peak will typically occur at 50–90% of $\tau_n$.

Following the expected peak in tracer concentration, the sampling frequency can be progressively decreased. To adequately capture the declining tail of the DTD sampling is typically required for an extended period. Examination of tracer responses from the numerous available experiments indicates that the impulse response is typically complete after four $\tau_n$. In general, care should be taken not to allow too much volume to exit without being sampled. Otherwise, a spike or dip in the concentration could be partially or even completely missed, particularly at high flow rates (Werner and Kadlec, 2000c).

## Hydrologic Measurements

To quantify the results of a tracer test, the complete hydrologic conditions must be known. The flow rates entering and exiting the wetland should be continuously logged over the duration of the tracer study. Rainfall can be important, and should be measured at the site. Evapotranspiration and seepage may be estimated. These combine to give the wetland water budget. In the context of a tracer test, the flows are necessary to compute the tracer mass balance and the recovery of tracer in the outflow. Effects of rain and *ET* are usually small, but not always (Chazarenc *et al*., 2004).

It is important to know the wetland water volume because it is required to compute the nominal detention time ($\tau_n$). In turn, $\tau_n$ is used to calculate the volumetric efficiency of the wetland $e_V = \tau/\tau_n$. For FWS wetlands, the bathymetry is used to obtain the water volume. As noted in Chapter 2, these measurements are somewhat ambiguous because, typically, the wetland bottom is not well defined. For FWS wetlands, the water volume requires knowledge of the upper water surface and the porosity of the media. That porosity may be accurately known for the bare media, but the extent of pore blockage by roots, biofilms, and accreted solids is typically not accurately known.

## Internal Sampling

In addition to inflow/outflow points, the tracer response at interior wetland points can be of some use in assessing the spatial characteristics of the wetland. There are two distinct cases to be considered: the individual cells in a multicompartment wetland, and points interior to an individual cell. The difference is considerable because, in the former case, the water volumetric flow rate past the measurement is known, whereas in the latter case it is not. Thus, it is possible to get a flow-weighted concentration at a cell outlet, whereas it is not possible at an interior point.

For cell networks with single inlets and outlets, there is no ambiguity, and efficient cells may be distinguished from inefficient cells. If there are multiple inlets and outlets, then averaging assumptions must be made, but analysis is still unambiguous. Perhaps the most involved cellwise tracer testing was performed at the Orlando Easterly treatment wetland, where the first 15 of 17 cells were tracer tested (Martinez and Wise, 2001) (see Figure B.24). These cells varied widely in their hydraulic behavior (see Table B.1). Results of the testing confirmed the need to re-establish the bathymetry of several cells (Sees, 2005).

Another multicell wetland tracer study was conducted at Lakeland, Florida (CH2M Hill, 1999; Keller and Bays, 2001). Four cells in series, of 81, 77, 166, and 30 ha, were tested separately, with recoveries of 67–106% and volumetric efficiencies of 0.04–0.45. Cell 2 had $\tau = 0.7$ d, and a $\tau_n = 19.1$ d, indicating very serious shortcircuiting. In such cell studies, it is feasible to measure the individual structure flows, and test protocols are the same as for single-cell wetlands. However, if a single pulse is to be followed through multiple cells in series, analysis must recognize that detention times (first moments) and variances (second moments) are additive (Levenspiel, 1972).

Both FWS and HSSF wetlands may also be sampled for tracer response at internal points, along and across the flow

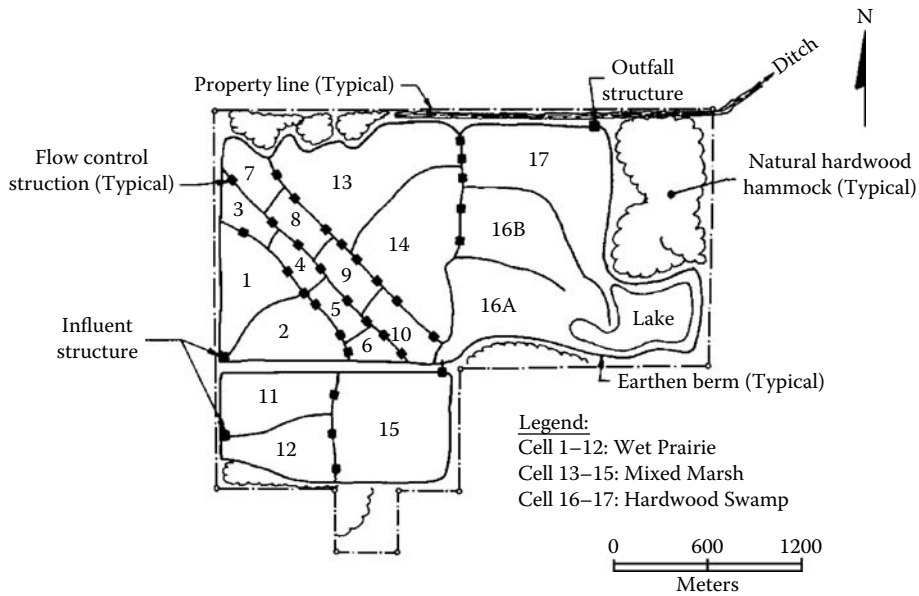

**FIGURE B.24** The layout of the Orlando Easterly treatment wetlands. The first 15 cells were tracer tested. (From Martinez and Wise (2003b) *Journal of Environmental Engineering* (*ASCE*) 129(6): 553–560. Reprinted with permission.)

direction, and at varying depths. In contrast to cell studies, the flow fraction passing such internal points is unknown.

Internal tracer studies on FWS have been reported by Kadlec (2001a), Jawitz and White (2002), Crohn *et al*. (2005), Dierberg *et al*. (2005), and Harvey *et al*. (2005). These studies confirm some intuitively obvious phenomena. The Des Plaines River wetlands studies showed that the shallow and backwater areas of irregular FWS systems saw relatively less tracer than the main flow path (Kadlec, 2001a). Jawitz and White (2002) found that vegetated barrier strips perpendicular to flow produced only small variations in tracer arrival times across the flow direction, regardless of high (aspect ratio = 45) or low (aspect ratio = 5) length-to-width ratio. Crohn *et al*. (2005) also saw only small variation in arrival times in a sequence of cross-deep zones at the Hemet, Californiia, wetland. However, remnant ditches and roads in cell 4 of the ENRP caused short-circuiting that was visible via rhodamine (see Figure B.8) but also quantified by quantitative analysis of the dye (Dierberg *et al*., 2005). Harvey *et al*. (2005) measured water velocities and conducted tracer studies to obtain the volume average water velocity. They found that the average velocity was only about two thirds of the spatial average due to the preferential velocity measurements being in open water zones.

Internal tracer sampling for HSSF systems was done in the researches of Spangler *et al*. (1976b), Fisher (1990), Pilgrim *et al*. (1992), Marsteiner *et al*. (1996; 1997), Drizo *et al*. (2000), García *et al*. (2003a; 2003b; 2004b), Melton (2005), and Nivala (2005). These studies provide a general picture of tracer preferentially moving through the bottom layers of gravel, regardless of whether it arrived there due to density or distribution (Figure B.25). When the bed floods, tracer testing indicates that almost all the flow is overland across the top of the gravel (Spangler *et al*., 1976b).

Flow in HSSF beds is typically nonuniform from side to side, as seen in Figure B.2. Time-series sampling at multiple points across the flow path often shows this imbalance in the form of quite dissimilar tracer responses (for instance, see Chapter 6, Figure 6.17). Studies by Pilgrim *et al*. (1992), Marsteiner (1997), Melton (2005), and Nivala (2005) show differing degrees of internal tracer response imbalance. However, internal patterns of tracer response are of no quantitative value in analyzing wetland behavior because of the lack of flow information to accompany them.

The old literature on tracer analysis describes internal average sampling (cross-transects) as "through the wall" sampling (Levenspiel, 1972). In the wetland context, this corresponds to arithmetic averaging of samples taken at a number of points perpendicular to the flow direction (Kadlec, 2000). Averages of tracer concentrations taken across the flow direction are not the same as the flow-weighted concentration at that point in the overall travel path; in fact, they are often very much different (Levenspiel and Turner, 1970). As described in Chapter 2, different sampling points across the flow path led to very different internal tracer response curves at the Benton, Kentucky, HSSF wetland. The same result was found at a Texas on-site facility (Melton, 2005). Thus, spatially averaged internal cross-sampling is likely to be valid only if done in a deep zone that ensures complete mixing of the various flow elements (Crohn *et al*., 2005).

## Analyzing Tracer Data

The goal of tracer studies is to understand the volumetric and DTD efficiencies of a particular wetland. Although the methods of processing data are straightforward, there are some nuances of data utilization that require explanation.

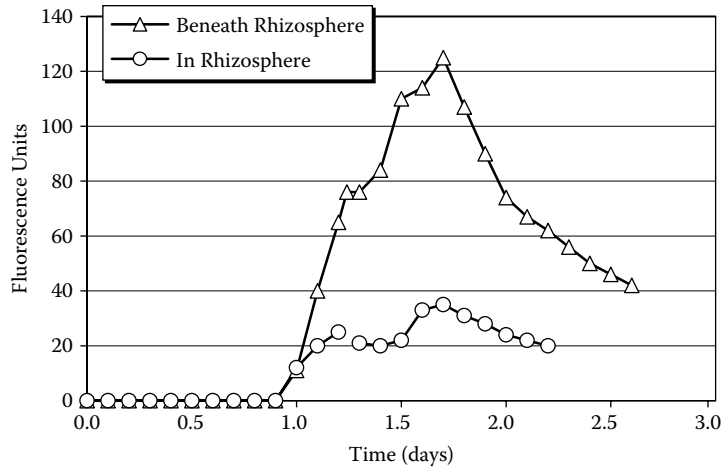

**FIGURE B.25** Tracer responses for locations in and beneath the rhizosphere in a HSSF wetland. (From Fisher (1990) In *Constructed Wetlands in Water Pollution Control*. Cooper and Findlater (Eds.), Pergamon Press, Oxford, United Kingdom. Reprinted with permission.)

## Baselines and Tails

In all cases, there will be a background concentration of the tracer in the wetland water. The value is not necessarily constant, but may vary during the test either due to random processes or to a (slight) time trend. Thus, the background concentration after the test may not be the same as before the test, either due to random effects or extremely slow bleed-back of some small fraction of the test material. In other words, the tail of the response may not come back down to the starting background concentration. An example is shown in Figure B.4 for Cell 2 of the ENRP in Florida. Over 2 tons of lithium chloride were added to this 167-ha FWS wetland, with care taken to prevent density effects. The initial lithium in the wetland outflow was about 8–9 μg/L. After the test, some 35 to 45 days later, the outflow lithium appeared to no longer have a trend, and was 12–13 μg/L. It is not known if the higher background is due to added tracer remaining after very long times, or due to other causes.

It is intuitive that the initial background should be subtracted from the measured concentrations to keep track of the added lithium. For the ENRP tracer study, the corrected recovery of tracer for this test was 98%. However, the fact that the response did not return to the original baseline has a fairly large effect on the computed tracer detention time. The small concentrations of tracer that occur at long times are disproportionately important in the numerical evaluation of this summation, as seen in Table B.2. In the ENRP example, the tracer detention time is 13 days, calculated over the entire 47 d of the test, and about 12% of that is due to the material leaving in the plateau at 35–47 days. This "tail error" has long been known to possibly seriously affect tracer test results (Curl and McMillan, 1966).

There are two procedures that have been used to de-emphasize the long-term plateau effect. First, the tail of the response ought to be exponential, according to the generally accepted modeling results (Vereecken *et al*., 1999). Therefore, the tail of the response maybe fitted with an exponential function, relying upon the higher concentrations prior to the tail to set the rate of decline. This procedure has been followed by some wetland researchers (Dal Cin and Persson, 2000; Wang, 2006). Often, the "tail" of the measured exit concentration distribution is poorly defined. Sometimes the sampling is terminated too soon; sometimes the final baseline does not return to the starting zero. Under these circumstances, the tail may be determined as an exponentially decreasing function, extrapolated from the data points past the second inflection of the response.

The alternative procedure is to perform a least-squares fit of the selected DTD to the data, which places equal emphasis on the errors across the entire test. The result of this procedure for the ENRP Cell 2 example is shown in Figure B.4.

## Tracer Mass Recovery

Closure of the tracer mass balance is a prerequisite to a good tracer test. Large losses or apparent gains of tracer, compared to the amount dosed, are a signal that something is awry with the water flows, or that the chosen tracer is undergoing extensive nonconservative behavior (Kadlec, 1994). The measure of the tracer test reliability is the recovery percentage. Outflow rates and tracer concentrations are combined and summed to compute the total mass in the exit tracer pulse:

$$M_o = \int_0^\infty Q_o C(t) dt = ? = M_i \qquad \text{(B.60)}$$

where

$C(t)$ = exit tracer concentration, g/m$^3$ = mg/L
$M_i$ = mass of tracer introduced with inflow, g
$M_o$ = mass of tracer exiting with outflow, g
$Q_o$ = average outflow rate, m$^3$/d

This permits a tracer mass balance and computation of the percentage tracer recovery. The concentrations used in this summation are first corrected for background. Secondly, if there are anomalies with the measured concentrations in the tail zone, or if the tail has been missed due to premature cessation of the test, then an exponential "patch" may be applied. Alternatively, a least-squares fit may be conducted. Typically, treatment wetland tracer recoveries in the range of 80–120% are considered acceptable.

## POLLUTANT REMOVAL EFFECTS

A primary reason for tracer analysis is to be able to account for hydraulic effects and thus reduce that part of the variability in pollutant reductions. First and foremost, it is desirable to know the real retention time, or equivalently the volumetric efficiency. Secondly, the distribution of detention times is important via the DTD efficiency.

The models discussed in this appendix are all concerned with correctly describing the behavior of an inert material as it passes through the wetland. However, the important target is correctly describing reactive materials. To understand the implications for DTD model selection, a hypothetical case is considered. Suppose that the wetland behaves like four well-mixed units in series, and suppose that the contaminant in question follows first-order kinetics and has a zero background concentration. For this illustration, the amount (concentration) of pollutant remaining at the outflow will be considered as the measure of performance.

The first questions are: Does it matter if there are four TIS? Isn't plug flow good enough? To answer those, a variety of rate coefficients and detention times may be considered for the two cases. It is the product $Da = k\tau/h$ that controls both cases. Figure B.26 shows that, for small $Da$, which corresponds to small removal of the contaminant, there is not much difference between models. If $Da < 1$, for which there is more than 40% of the material remaining, there is only a maximum of 10% difference. Either model could be effectively used if performance was to be in this low range.

However, if removals in excess of 90% are contemplated, then there are very big differences between the plug flow and 4 TIS forecasts. The ratio of fractions remaining grows from a factor of two at 90% 4 TIS conversion to a factor of twenty at 98% 4 TIS conversion. Therefore, if high removals are contemplated, it is very important to correctly characterize wetland internal hydraulics.

### The Tail of the DTD

The next issue is: How careful do we have to be in describing the details of the tracer response? Does it matter if the tail end of the DTD is accurately modeled? To answer these questions, we consider the origins of the unreacted material in the wetland outflow. If there are shortcircuits, they will carry the contaminant to the wetland outlet before they have had much time to react. If there are dead zones, water will remain there a long time and be fully reacted. These ideas may be quantified by considering the detention times for the unreacted materials. We therefore continue the illustration and calculate the fraction of the unreacted effluent material corresponding to different detention times. This is the same calculation as for degrading tracer that was considered earlier. Figure B.27 shows the travel time distribution of the unreacted material leaving for $Da = 2$. The material leaving primarily followed short detention paths: 98% of the leftovers came from detentions less than 1.5 times the average detention time, and 85% from detentions less than 1.0 times the average detention time. The tail is irrelevant to the determination of the amount of unreacted material.

The example chosen is representative of only one wetland hydraulics and one operating condition. However, exploration of the TIS model shows that the conclusion of tail irrelevancy is strengthened for lower numbers of TIS (TIS < 4), and

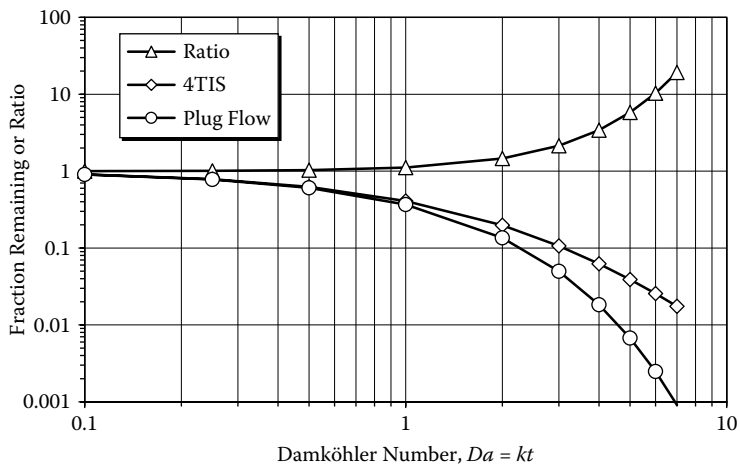

**FIGURE B.26** Variation of plug flow and 4 TIS model results for various rate constants.

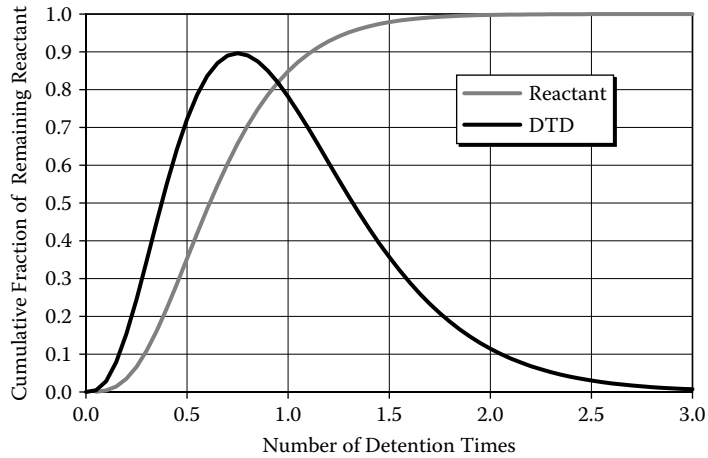

**FIGURE B.27** Origins of the unreacted material leaving a hypothetical 4-TIS wetland for $Da = 2$. The removal is 86.5% under these conditions, and the remaining reactant cumulative distribution refers to the remaining 13.5%. The DTD is scaled by a factor of ten.

also for non-TIS DTDs with longer and bigger tails. Higher Damköhler numbers, equivalent to higher removal percentages, shift the origin of unreacted material to even shorter detention times. For $Da = 1$, or 60% unreacted material, 99% of the leftovers come from detentions less than 2.0 times the average detention time, and 75% from detentions less than 1.0 times the average detention time.

## The Head of the DTD

The front end of the tracer response represents what is generically called *shortcircuiting*. In pathological situations, a large peak occurs far in advance of the nominal detention time. However, even in "normal" situations, it is often necessary to correctly account for the water and associated pollutants that leave the wetland early.

Given the insensitivity of pollutant removal to the tail of the DTD, it is logical to ask whether the head of the DTD is critical to pollutant removal. There is usually a delay of some magnitude before any tracer arrives at the wetland outlet, which is larger for HSSF wetlands than for FWS wetlands (see Figures B.5 and B.6). For 35 FWS wetland tracer tests, the first tracer breakthrough occurred at 23 ± 11% of the tracer detention time. For 32 HSSF wetland tracer tests, the first tracer breakthrough occurred at 37 ± 14% of the tracer detention time.

For some guidance, we return to the 4-TIS illustration. It is found that, for low rates of reaction, the early-departing material carries only a small fraction of the unreacted total. For FWS behavior, and for $Da = 1$, or 60% unreacted material, only 2% of the leftovers come from detentions less than 0.25 times the average detention time. For HSSF behavior, and for $Da = 5$, or 4% unreacted material, 48% of the leftovers come from detentions less than 0.4 times the average detention time. It is clear that care must be taken to provide a proper representation of the leading portion of the DTD if it is necessary to characterize high removals.

The two simplest choices for describing the breakthrough lag are the TIS model, and the TIS model modified to have a leading plug flow component (see Equation B.27).

In general, this three-parameter ($N$, $\tau$, $t_D$) fit of the DTD will give a better fit to data than the two-parameter TIS fit, especially if there is a substantial delay. However, it adds some complexity to pollutant removal modeling, and so it must be examined for necessity. As an illustration, the basis for comparison is taken to be a wetland that behaves like 4 TIS after a time delay. The "head effect" is known to be most important for high removal percentages, so the Damköhler number is selected to be $Da = 3$, corresponding to 95% removal in plug flow, or 5.0% remaining. For 4 TIS, the percent remaining is 10.65%. The TIS model appears to give a reasonable least-squares fit to the delayed tracer response (Figure B.28), but it does turn up a bit sooner than the delay. Because of the delay, the number of TIS grows with the delay, from $N = 4$ for no delay to $N = 17.9$ for a delay of 50% of the detention time.

The amounts of pollutant remaining also differ for the delayed "data" and the least-squares *N*TIS fit. The *N*TIS fit produces greater amounts remaining: 7% more for a delay of 23% of the detention time (FWS), and 10% more for a delay of 37% of the detention time (HSSF). Therefore, if the wetland is contemplated to remove less than 95% of a contaminant, it is probably acceptable to use the two-parameter *N*TIS fit rather than the three-parameter delayed *N*TIS fit of the tracer response.

It is also possible to use the moment method for fitting the *N*TIS model. Earlier it was seen that this method emphasized the tail of the DTD, but it also emphasizes the head of the DTD. Of course, that is exactly what is needed to better account for the delay.

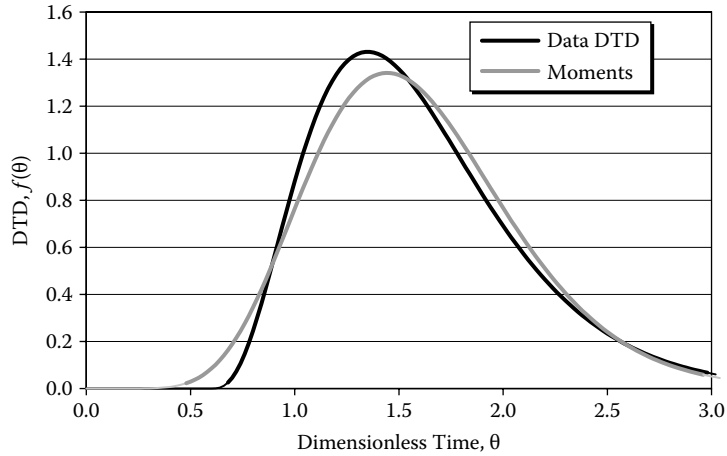

**FIGURE B.28** Tracer response with a delay. The points were generated from a delay of θ = 0.5 together with a 4-TIS response. The tracer detention time is θ = 1.5. A least-squares fit of the TIS model gives $N = 9.7$ for this case.

### Strategies for Data Fitting

The preceding model exploration exercises lead to suggestions regarding the strategy of fitting and using tracer data. These are

- The "tail" of the tracer DTD is not generally an important contributor to the amount of a pollutant that will pass through the wetland unreacted. It is probably not necessary to add parameters to tracer models to better account for long "tails."
- The "head" of the tracer DTD is important for situations where high contaminant removals are contemplated. The important feature is the existence of a delay before any tracer is observed in the wetland outflow. The presence of such a delay contributes to a better pattern of flow by virtue of adding a plug flow component to the response. Typically, for high removals, the contaminant residual is reduced 25% in FWS wetlands, and 35% in HSSF wetlands, compared to systems with no delay.

The delay may be accounted by adding a third parameter to the *N*TIS model. Alternatively, it is probably acceptable to use the *N*TIS model.

In the data processing in this book, we have used the simpler two-parameter approach.

### Reactions along Flow Paths for FWS Wetlands

In addition to distributions of detention times (across flow fractions), other factors exist that can influence overall Damköhler numbers. One class of possibilities arises from spatial distributions of wetland water depths and vegetation density. Distributions of Damköhler numbers across flow fractions may be created due to both $k$ and $t$ being related to vegetation density and depth.

Kadlec (2000) postulated that patterns of vegetation can strongly influence the perceived reaction rates in treatment wetlands, as well as affect the velocity and amount of water that passes through a given region of a FWS wetland. This presumption was explored in more detail by Carleton (2002).

As an example, consider a wetland with parallel flow paths of unequal vegetation density. High-velocity flow paths result from lack of vegetative resistance; low-velocity paths from large vegetative resistance (Hosokawa and Horie, 1992; Jenkins and Greenway, 2005). In addition, wetland data show that water velocity is strongly depth dependent (Kadlec and Knight, 1996). For laminar flow under a fixed water surface gradient,

$$u = \frac{a' h^b S^c}{X} = \frac{a h^b}{X} \tag{B.61}$$

$$t = \frac{L}{u} = \frac{LX}{a h^b} \tag{B.62}$$

where

$a, b, c$ = constants, $d^{-1}$
$h$ = water depth, m
$L$ = length of wetland cell, m
$X$ = submerged vegetation surface area density, $m^2/m^3$
$S$ = slope of the water surface, m/m
$t$ = time, d
$u$ = superficial water velocity, m/d

Different values of the exponent $b$ apply to different vegetation types. Here, for purposes of illustration, $b = 1$ is chosen. These relations state that, for a specified overall water slope, the water velocity is inversely proportional to the immersed vegetation surface area and directly proportional to the depth. Therefore, the detention time along any flow path is directly proportional to the vegetation density and inversely proportional to the depth. Consequently, cross-flow spatial distributions of $h$ and $X$ create a distribution of detention times, as detailed by Carleton (2002).

Depth and vegetation density effects on water velocity have been investigated, and an improved understanding is emerging (e.g., Hall and Freeman, 1994). Those same variables exert influence on pollutant-reduction rates, but the quantification of those

effects is still in early stages. There have been some definitive studies that establish the influence of water depth on volumetric rate coefficients; for instance, the data of Gearheart *et al.* (1989) that clearly demonstrated $k$ for BOD was inversely proportional to depth. In other cases, the relationship is less clear. Stem density has been found to be an important determinant of rate coefficients in some cases (Lakhsman, 1982) but not in others.

The wetland vegetation density influences many wetland pollutant removal processes. This may be due to the biofilms that coat submerged litter, roots, and stems, or to the biogeochemical cycling that creates net uptake to new sediments (Khatiwada and Polprasert, 1999a). Many removal processes are associated with surface area, such as mass transfer or microbial reactions. The active reaction zone may therefore be on the bottom, in the water column, or a combination. If the active zone is exclusively associated with immersed surfaces, the rate coefficient is presumptively proportional to $X$, as observed by Smith *et al.* (2000) for nitrate reduction. Conversely, many wetlands display constancy of areal rate, and thus the volumetric rate coefficients used in previous sections are inversely proportional to depth:

$$k = \frac{\beta X}{h} \tag{B.63}$$

There may be other influences on the rate coefficient, such as enhancement of mass transfer via increasing velocity. Here, such velocity dependence is assumed to be absent, as a limiting case.

The effect of parallel spatial patterns of vegetation density and water depth is to create spatial patterns of the removal rate constant. The effects of both types of distribution on pollutant removal are thus two-fold. Flows through low vegetation density regions are fast and ineffective, whereas flows through high vegetation density regions are slow and effective. Flows through high-depth regions are fast and ineffective, while flows through low-depth regions are slow and effective. Combination of Equations B.62 and B.63 for $b = 1$ gives

$$kt = \left(\frac{a\beta}{L}\right)t^2 = \gamma t^2 \tag{B.64}$$

where

$\gamma = (a\beta/L) =$ constant, $d^2$

This is the same result presented by Carleton (2002). The fraction remaining (for $C^* = 0$) along a parallel flow path of vegetation resistance $X$ and detention time $t$ is

$$\frac{C}{C_i} = e^{(-\gamma t^2)} \tag{B.65}$$

Under this potential scenario, the fraction of pollutant remaining along a given flow path decreases exponentially with the square of the detention time along that path. It is the result of a direct interrelation of $k$, $X$, $h$, and, $t$ and the corresponding wetland circumstance is termed the "*Xhkt*" condition. Note that there is a serious consequence of the *Xhkt* condition, in that travel time in a flow system is no longer equivalent to batch time in a non-flow-through system. Any batch experiment is necessarily done under conditions of constant $X$ and variable time, which is not possible in a flow system if travel time is dependent on $X$. This nonequivalence has been experimentally explored by Stein *et al.* (2003).

Vegetation density and depth distributions can produce a false impression of plug flow conditions. Poor treatment along fast flow paths produces a faster-than-average rate of pollutant removal at longer detention times, which precludes plateaus in concentration profiles. Kadlec (2000) points out that the interdependence of $k$ and detention time leads to an imputed PFR rate constant (from a PFR fit of the *Xhkt* data) that depends upon the hydraulic loading rate. Here, it is additionally noted that the *Xhkt* condition may yield the appearance of PFR performance for an *N*TIS wetland. To illustrate, the behavior of a 3-TIS wetland is examined under the *Xhkt* assumption for a zero-background concentration. The coefficient $\gamma = 0.25\ d^{-2}$ yields flow-weighted outflow concentrations that decrease with increasing mean detention time (Figure B.29). This hypothetical data may be fitted with a relaxed TIS model, where the variable $P$ represents the

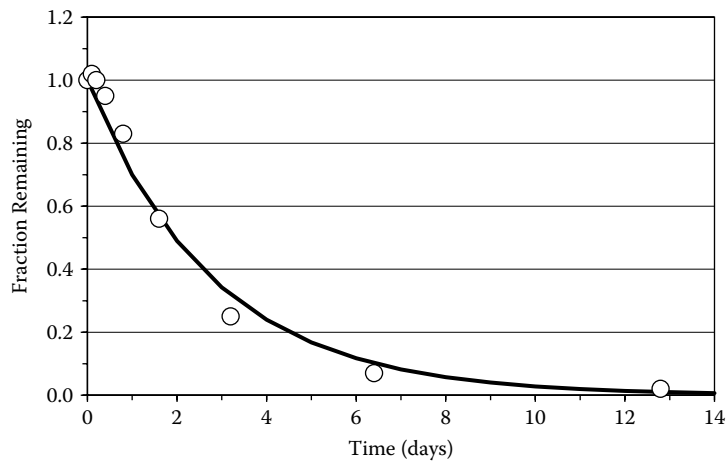

**FIGURE B.29** Fraction remaining for a single compound undergoing first-order degradation or removal in a wetland with variable vegetation density on parallel flow paths. The points are computed from Equation B.38, coupled to a 3-TIS DTD. The line represents the *N*TIS model, as well as the PFR model.

combined effect of the number of tanks, $N$, and weathering of the contaminant, as discussed in Chapter 6. The results for this model are $P = 1{,}834$, $k_{app} = 0.358\ d^{-1}$, and $R^2 = 0.982$. This high $P$-value corresponds to an apparent plug flow condition.

Thus, both increases and decreases in the apparent TIS number can result from internally distributed parameters. Interestingly, no combination of distribution effects has been found here that caused performance behavior to stray far from an envelope bracketed by apparent plug flow and apparent TIS.

## SUMMARY

Tracer testing offers a means of better understanding of the processes controlling the performance of treatment wetlands. Results are now available from hundreds of tracer tests of FWS and HSSF systems. Despite the appealing simplicity of the plug flow assumption that has repeatedly been made, and continues to be made, in the literature, it is abundantly clear that neither FWS nor HSSF systems behave as plug flow. Furthermore, many wetlands have significant fractions of the water column that are dead zones, which are not directly flushed by flowing water, as evidenced by volumetric efficiencies less than unity. The interpretation of wetland pollutant removal data, and the design for pollutant removal, are facilitated by a knowledge of the volumetric efficiency, as well as the DTD efficiency of the wetland.

The proper technique of conducting a tracer test has not always been adhered to, thus causing difficulties in interpretation. Density stratification, degradable and sorbable tracers, and lack of hydrologic control have obscured results in some cases. Nonetheless, a great deal of progress has been made in the last ten years toward better understanding of the features of treatment wetlands and how they affect hydraulic behavior. It has been possible to apply quite sophisticated models to represent tracer responses, but that level of detail is not always necessary for interpretation of contaminant removals. Importantly, this new understanding moves the science of wetland performance toward greater confidence levels. Although the old plug flow approach may have been sufficient for interpolating key process data in for design purposes, extrapolation beyond the existing data set was quite often disastrous. Tracer results enable a new generation of models that are better able to describe systems over wider ranges of operation conditions.

## I

Ice layers, 125–129
Implementation
FWS wetland
construction, 679–682
earthmoving and, 668–672
hydraulics, 666–668
physical design and, 655–666
stormwater, 678–679
vegetation establishment, 682–689
water control structures, 672–678
SSF wetland
cell configuration, 744–748
clogging dynamics and, 741–744
construction and, 757–764
flow distribution and management in, 753–757
hydraulics and, 748–753
layout and configuration, 738–739
liner systems, 757
number and type of wetlands in each flow path and, 739–741
siting, 735–737
Implied oxygen transfer, 584–585, 728, 732
Indirect capital costs, 805
present worth analyses, 811–817
Industrial byproducts as wetland aggregates, 390
Industrial stormwater wetlands, 539, 550–551
Industrial wastewater treatment, 10, 225
characterization, 602
fertilizer manufacture, 866–867
pulp and paper mills, 10, 225, 603, 662–663, 865–866
siting, 706–707
wood leachates, 864–865
Infiltration, 30–31, 598–599
FWS wetlands and, 834, 837–838
SSF wetlands and, 839–840
wetland design and, 612, *613*
Inflows and outflows, 26, 28
background concentrations, 82–83
control structures, 672–678
FWS wetlands, 34–35
infiltration and, 598–599
stormwater wetlands, 648–649
water depth, 41–42
Influents
dilution of, 828
piping, 762
Inlets
high-sediment waters and, 833
HSSF wetlands, 230, *231–232*
mass loading rates, 170
Insects, 784–786. *See also* Animals
Insulation of HSSF wetlands, 129–131
Integrated natural systems, 831–832
FWS and infiltration, 834, 837–838
ponds and wetlands, 832–834, *835–837*
Interception of particulates, 209–210, 227, 234
Interconnected pollutants, 630, 721–722
Intermittent downflow, 52, 53–55, 232–234
Internal cell arrangement, FWS wetland, 658–659
Internal cycling of total suspended solids, 216–218
Intersystem performance, event-driven wetlands, 554–555
Invertebrates, 695–697
Iron
additions to FWS wetlands, 823–824
boron adsorption, 474
coal mine drainage wetlands, 428–429
clogging in HSSF wetlands, *622*
deficiency, 410
in event-driven wetlands, 565, 567–568
flocs, 212
landfill leachate wetlands, 429, 862–863
phosphorus sorption and, 389
plant uptake, 427
reduction, 240
removal
models, 430–431
performance, 427–430
in soils and sediments, 426–427
wetland storage and processing of, 426–427
zinc precipitation with, 462, 464

## K

Kesterson effect, 480
Krebs Cycle, 61
*k*-value distribution (*k*VD), 243, 244, 305, 330
loading effect on, 248, 256–257
microbially dominated wetlands, 311–313

## L

Lagoons, 598, 599–600, 601, 675, 834, 837
Laminar flow, 43–44
Land costs, 794
Landfill leachates, 10–11, 200, 268, 429, 602–603, 857–858
ammonia removal and, 861
design considerations, 602–603, 859
iron and, 429, 862–863
receiving waters, 863–864
scale-up and, 864
trace metals and, 863
trace toxicants and, 861–862
types of treatment wetlands for, 858–859
volatile hydrocarbons and, 861
water budget considerations, 859–860
wetland vegetation, 860–861
Langmuir constants, 275, 357, 358–359, 389, 407, 420, 464
Layer cake model, 425–426, 455
Layout and configuration
FWS wetlands, 657–658
SSF wetlands, 738–739
Lead
chemical precipitation, 452
compounds, 447, 449
in event-driven wetlands, 565, 567
particulate settling, 452
partitioning, 452
plant uptake, *448,* 449
removal
performance, 452
processes, 452–453
solubility, 447
sorption, 452
toxicity, 449
wetland processing and storage of, 449–452
Leaves
leaf area index, 37, 38, 111
phosphorus content, 352
Length-to-width ratio of wetland cells, 745–746
Level control structures, 675–677, 756–757
Life expectancy, wetland, 812
Limiting reactants, 187–188
Linear alkylbenzene sulfonate (LAS), 530–531

Liners and rooting media, 670–671, 757, 758–759
  costs, 796–797
  placement, 681
Lithium tracer test, 177, 178
Litterfall, plant, 70, 76–77
  accretion, 81–82, 360–361, 365
  belowground decomposition, 79
  combined effects of successive cohorts, 79
  decomposition, 77
  mineral constituents of, 80–81
  patterns of weight loss, 77–79
  phosphorus in, 360–361
  sediment production, 213
Livestock Wastewater Treatment Database (LWDB), 10
Loading
  agronomic wetlands, 305–307, 313, 327–328
  BLI, 240, 244, 248, 256–257, 264–265
  charts, 715–718
  effect on *k*-value, 248, 256–257, 265–266
  hydraulic, 25–26, 55, 629, 751–753
  maximum and minimum criteria, 633–634
  nutrient, 777–778
  organic nitrogen, 296–299
  oxidized nitrogen, 335–338
  phosphorus, 375–377
  resting and, 739
  sizing and, 575–576, 584, 586–589, 715–717, 731–732
  total nitrogen (TN), 308–309
Long-term prospects for wetlands, 788–790
Lumping effects, 242–243

## M

Macroinvertebrates, 695–697
Macrophytes
  adaptations to flooded conditions, 66–67
  adaptations to wastewater stresses, 66–67, 68
  biochemical production of oxygen and, 135
  classification of, 64–66, 691–692
  functions
    in FWS wetlands, 97
    in SSF wetlands, 97–99
  gas transport in, *68*, 69–70
  hydropattern, 67–69
  mining, 365
  phosphorus processing, 363, 365
  photosynthesis, 135
  weeds, 99
Magnesium, *409*, 410
Maintenance, wetland. *See* Management, operations, and maintenance
Malaria, 784
Mammals, 699–702
Managed peat systems, 424–425
Management, operations, and maintenance
  assistance to operators, 791–792
  control of nuisance animals, 778–786
  costs, 809–811
    present worth analyses, 811–817
  long-term prospects, 788–790
  in modified and combined systems, 826–831
  monitoring, 770–774
  start-up, 767–770
  of structures, 788
  vegetation, 777–778, 786–787
  water level and flow, 753–757, 774–778
Manganese, 434–438
  zinc precipitation with, 462, 464
Mangroves, 91
Man-made aggregates, 390
Manning's coefficients, 34, 36, 40–41
Marine sediments, 390
Mass balances, 169–172
  ammonia nitrogen processes and, 286–287
  chemical, 170–172
  internal cycling and, 217–218
  nitrogen, 290–296
  phosphorus processing, 362–363
  pollutant, 628–630, 720–721
  sampling and analyses in support of, 771–773
  total suspended solids, 216–217
  water, 26, 197–198
Mass removal, 170
Mass transfer zone length, 396
Mats, floating, 87–90, 528
Mean water depth, 22
Meat processing, 854–855
Media, rooting, 670–671
  chemical addition reactants via, 822–826
  costs, 797–799
Melaleuca, 91
Mercury
  background (total), 467–468
  methylation, 466
  plant uptake, 467
  removal
    performance, 468–470
    process, 466–467
  sediment content, 467–468
  wetland processing and storage of, 466–468
Mesocosm, FWS, 288–289, 436
Metabolism, microbial, 61
Metalloids
  arsenic, 470–473
  boron, 473–475
  selenium, 475–480
Metals
  heavy
    cadmium, 453–457
    chromium, 457–462
    copper, 438–444
    lead, 447–453
    mercury, 466–470
    nickel, 444–447
    zinc, 462–466
  trace
    abiotic metal partitioning, 419–420
    accretion, 423
    design equations for removal of, 421–423
    equilibrium chemistry calculations, 421
    in event-driven wetlands, 565–568
    in FWS wetlands, 424, 425–426
    landfill leachates, 863
    layer assumption, 425–426
    managed peat systems, 424–425
    sediment storage concentrations, 423–426
    sorption relations, 420–421
    storage in plants, 423
    toxic effects in water and sediments, 419
    well-mixed surficial zone, 423–424
Methane emission, 147, 150
Methanogenesis, 240–241
Methylation, mercury, 466–467, 468–470
Microbes, 61
  ammonia rate constants, 325
  ammonification of organic nitrogen, 277–279
  biological solids production and, 228
  enhancement modifications, 820
  event-driven wetlands, 552
  pollutant removal processes using, 172–174
  total nitrogen rate constants, 311–313
Microbial phosphorus, 359–360
Milk products processing, 853–854
Mineral aggregates in HSSF wetlands, 390

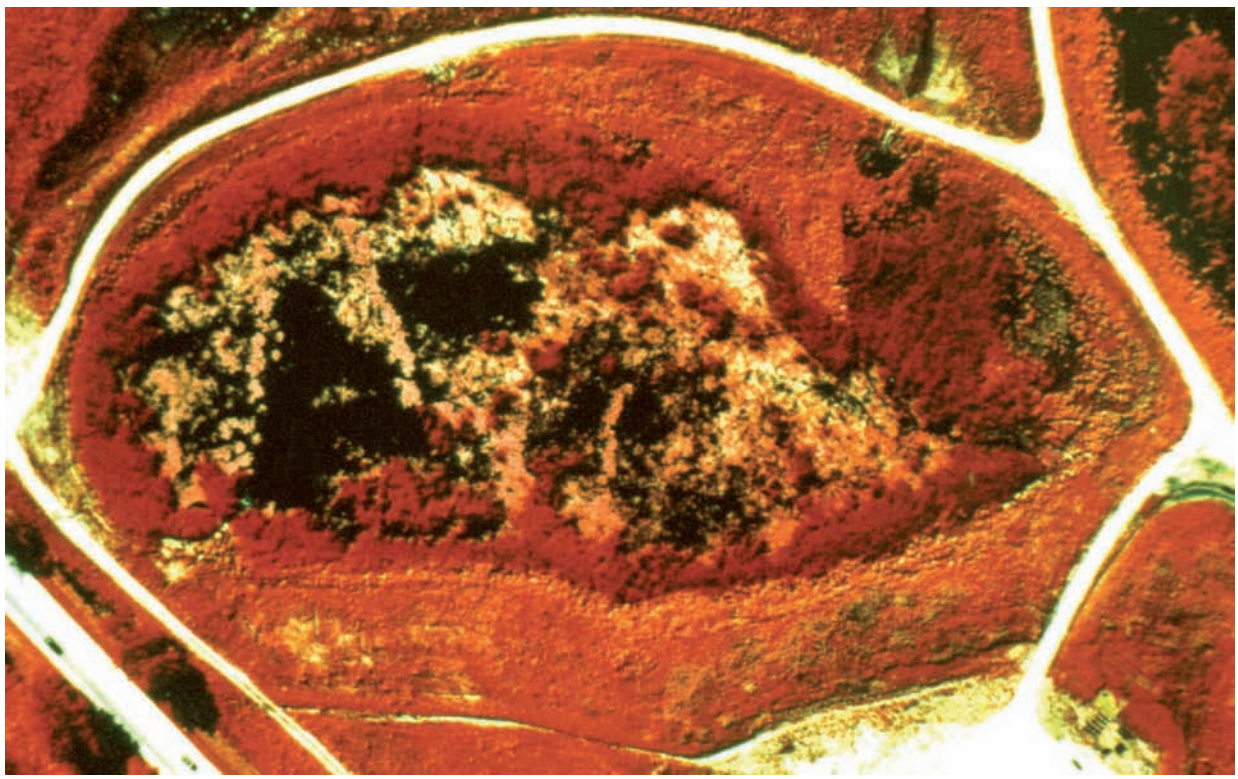
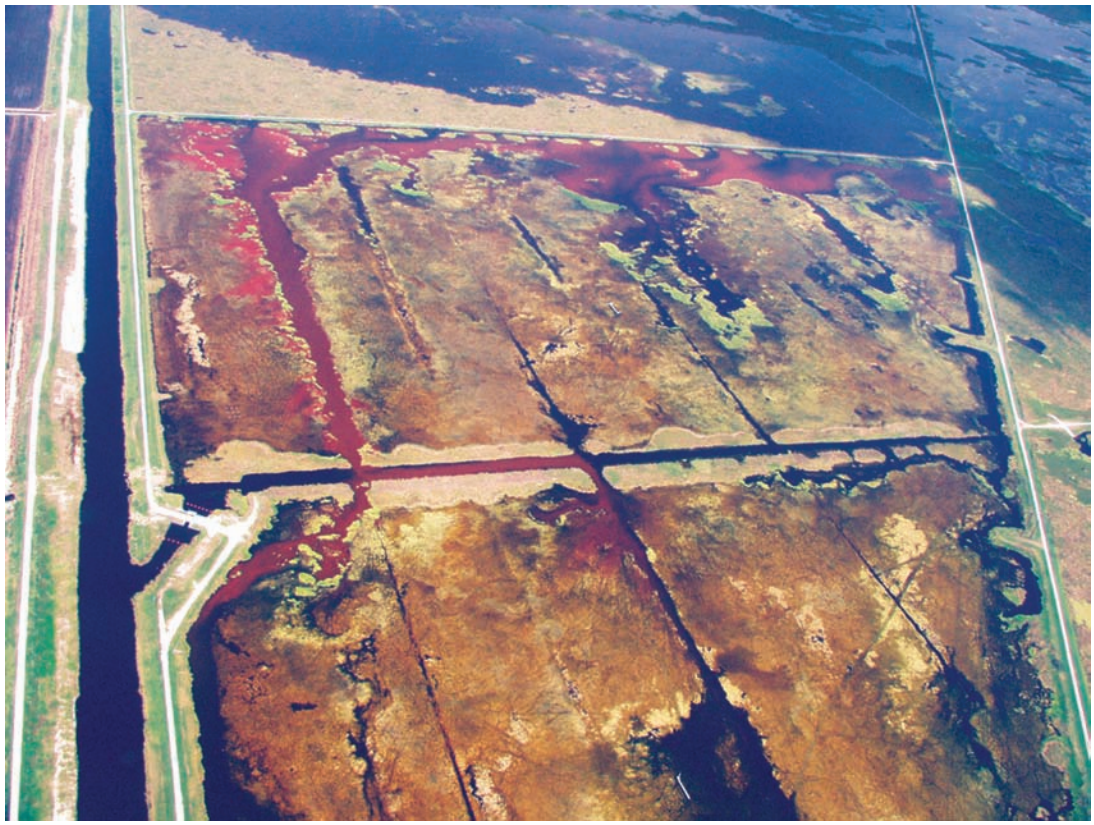
**COLOR FIGURE 1.13** Single-home HSSF wetland in Comfort Lake, Minnesota.

**COLOR FIGURE 3.33** Trees growing in the Vermontville, Michigan, constructed treatment wetland after 15 years of operation.



**COLOR FIGURE 7.10** Venting groundwater at this Wellsville, New York, site contains iron, which oxidizes upon contact with air.



**COLOR FIGURE 11.6** This HSSF wetland outlet structure at Tamarack, Minnesota, has become coated with elemental sulfur.

**COLOR FIGURE 14.7** An urban stormwater wetland in the city of Blue Mountains, Australia.

**COLOR FIGURE 22.7** Wetland EW3 at the Des Plaines River site near Wadsworth, Illinois. The fringe zone is vegetated by cattails and bulrushes, whereas the interior has submerged aquatic vegetation and floating-leaved plants. Open water shows as dark areas on this false color infrared photo.

**COLOR FIGURE B.8** Progress of Rhodamine WT dye tracer through a FWS wetland, cell 4 of the ENRP in Florida. The dye was introduced along the upper boundary, and flow proceeds from the top to the bottom. Note the short-circuit along the left-hand side, which is partially redistributed by the central cross canal. (Photo courtesy of T. DeBusk.)

**COLOR FIGURE B.22** Rhodamine dye dispersing through an inlet deep zone, with a spikerush band providing resistance to shortcircuiting. (From CH2M Hill (2003a) *PSTA Research and Demonstration Project, Phases 1, 2, and 3 Summary Report*, Prepared for the South Florida Water Management District.)

# TREATMENT WETLANDS

## SECOND EDITION

*Treatment Wetlands, Second Edition* represents the most comprehensive and up-to-date resource for the design, construction, and operation of wetland treatment systems.

This new edition is completely revised and updated. *Treatment Wetlands, Second Edition* expands on many key design concepts that can be further understood based on the data that is now available. Performance data from over 950 treatment wetlands around the world serve as the foundation for the new design tools and data analysis provided in this edition.

New information presented in this book includes:

- The hydrology and hydraulics of free water surface, horizontal subsurface flow, and vertical flow wetland systems
- The role of plant biomass cycling, and how it impacts nitrogen, phosphorus, and metals in treatment wetlands
- Energy balance methods for calculation of evapotranspiration and wetland water temperatures
- The impact of non-ideal flow and pollutant weathering in treatment wetlands
- Seasonal and stochastic variability in treatment wetland performance
- Probability distributions for *k*-rates and temperature coefficients
- An inclusive and integrated design sizing procedure
- Implied oxygen transfer rates in treatment wetlands, based on new concepts of nitrogen processing, such as anaerobic ammonia oxidation
- Methods for conducting tracer tests in treatment wetlands
- Updated loading charts for free water surface, horizontal subsurface flow, and vertical flow wetland systems
- Greenhouse gas emissions from treatment wetlands
- The role of wetland treatment systems in treating agricultural, industrial, and municipal wastewaters, including new applications such as the use of treatment wetlands for landfill leachates and contaminated groundwaters
- The use of wetlands for treating stormwaters
- Economics of wetland treatment, including capital and operating costs
- Designing wetlands for ancillary benefits, such as wildlife habitat
- Experience-driven guidelines for building treatment wetlands
- An updated list of over 2,400 references
